The following conclusions are drawn: immediate recognition of the injury is essential; kidney function should be preserved whenever possible; all ureteral anastomoses should be done end to end over a ureteral catheter; bilateral ligation is best treated by bilateral nephrostomies; and ureterovaginal fistulas that do not close spontaneously should be repaired either by ureteral transplant to the bladder or bowel or by nephrectomy.

THE TIME FACTOR IN THE DEVELOPMENT OF COMPLICATIONS OF GALLSTONES*

CARL BEARSE, M.D.

BOSTON

IF GALLSTONES remain in the gall bladder, according to Cheever,¹ "sooner or later, if their host lives long enough, they will cause damage of a serious nature." With this statement there can be only general accord, but the phrase "sooner or later" is vague. The following statistical study was undertaken with the hope of establishing a more definite time relation between the original disease and the sequelae.

It is generally acknowledged that gallstones may exist for many years without giving rise to symptoms,² but once they have been demonstrated, one is obliged to assume that eventually such sequelae as acute cholecystitis, acute pancreatitis, common-duct stones and carcinoma of the gall bladder may develop. Acute cholecystitis and acute pancreatitis may occur when no stones are to be found in the gall bladder; stones may even occur in the common duct with no calculi present in the gall bladder. The complications and sequelae of cholelithiasis, however, cannot be anticipated if the existence of stones in the gall bladder has not been established. Accordingly, the time factor for the development of biliary complications must resolve itself into the

time lapse between the onset of primary symptoms or demonstration of stones and the clinical onset of these complications.

A better understanding of this time factor would be of great assistance in treating today's civilians. Gallstones, which are estimated to effect approximately one third of the adult population,^{3,4} occur most frequently in persons over forty years old, and these are the people so essential on the home front. The older the age group, the higher is the incidence of gallstones. Lee has stated⁵: "Gallstones . . . increase in frequency with advancing birthdays, and it is likely that if people lived to be one hundred and twenty they all would have gallstones. Certainly, autopsies performed on people of eighty or over show almost uniformly the presence of gallstones." Moreover, as I⁶ pointed out in a previous paper, operation for gallstones may have to be deferred during the war because of the shortage of nursing and professional services, hospital accommodations and domestic help to care for children, as well as the desire of workers to remain constantly on their jobs.

A study has therefore been made of 260 private records of operation for gallstones. The average

*Presented at the Section of Surgery, American Medical Association, June 15, 1944

duration of symptoms was 5.1 years. As shown by Table 1, 157 patients (60 per cent) presented

at operation no biliary disease other than gallstones. Their histories reveal that symptoms were present for as long as thirty-nine years, with the average period 4.6 years. It is significant that 34 per cent of the patients had symptoms for more than five years and 15 per cent for more than ten years.

One hundred and three patients (40 per cent) had one or more complications at operation, including acute cholecystitis, acute pancreatitis, cholecholelithiasis and carcinoma of the gall bladder (Table 2); of these, 6 had more than one complica-

tion and are therefore listed twice. Whereas the average duration in the cases without complications was 4.6 years, it was 6.7 years in the cases with complications. Generally speaking, the longer the duration of symptoms of gallstones, the greater was the probability of complications. The interesting fact is that of this series 33 per cent had symptoms for less than one year before operation and 47 per cent for less than three years. Sixty-nine patients (27 per cent) had acute cholecystitis, including empyema, gangrene and acute free perforation of the gall bladder (Table 3). The

toms for five or more years, 33 per cent had had symptoms for less than one year. Six had no symptoms before the acute attack precipitating operation. These figures correspond with those in an analysis by Glenn,⁷ according to which 7 per cent of a series of patients had complications at the time of the initial symptoms and approximately 40 per cent had had symptoms for less than one year. It is thus apparent that acute cholecystitis may develop either early or late during the course of gallstones.

Although there is no general agreement concerning the pathogenesis of acute pancreatitis, a significant and fairly constant finding is its association with gallstones.⁸ Calculi have been reported in 70 to 81 per cent of cases of acute pancreatitis,⁹ which is therefore usually considered a complication of gallstones. In the present series 10 patients (4 per cent) had acute pancreatitis (Table 4). These cases,

according to Abell's¹⁰ classification, included acute pancreatic edema, acute pancreatic necrosis and acute pancreatic necrosis with hemorrhage. Five patients in this group had symptoms for less than one year before operation, 2 having acute pancreatitis with their first attack of biliary distress; 3 had symptoms for two years and 2 for thirteen and seventeen years, respectively. The average duration was 3.9 years. Acute pancreatitis was often an early complication than a late sequela of gallstones. Thirty-two patients (12 per cent) had stones in the common duct (Table 5). The average duration

of symptoms was 5.6 years, which with the exception of the cases of carcinoma of the gall bladder was the longest for those with complications. The duration period varied from less than one year to twenty years, except for 1 case with symptoms for forty years. Ten patients (31 per cent) were operated on before the end of twelve months, in fact, 3 were found to have stones in the common duct at operation following the first attack of colic. Fifty

patients were operated on after having had symptoms for 35 per cent of the cases with complications. Although 35 per cent of the average duration of symptoms was 4.9 years, which is practically the same interval as in the cases without complications.

seven per cent, however, had had symptoms for three or more years. The incidence of stones in the common duct relative to the duration of symptoms seems to be a subject of disagreement among authors. Heyd¹¹ reports the frequency of such stones as ranging from 1.9 per cent of patients with symptoms for less than two years to 16 per cent of those with symptoms from ten to thirty-five years, whereas Lahey and Swinton¹² report that 46 per cent of patients with common-duct stones have had symptoms for less than one year.

It is generally accepted that gallstones predispose to malignant change in the biliary tract.^{13,14} They are found in most cases of carcinoma of the gall bladder,¹⁵ and considerable evidence has been presented that stones precede biliary carcinoma.¹⁶ On the other hand, the usual incidence of carcinoma of the gall bladder in cholelithiasis is only 0.5 to 1.5 per cent,¹⁷ although it has been pointed out that its frequency is probably low because many patients undergo early cholecystectomy.^{11,13,14} Of 3 patients (1 per cent) in the present series with carcinoma of the gall bladder, 2 also had choledocholithiasis. Symptoms had been present for six, twenty-seven and forty years respectively, — an average of twenty-four years. Although carcinoma has been reported when symptoms were of short duration,¹⁸ most reports state that they were present for ten or more years.^{13,16,19} Its rarity as a complication of gallstones¹⁴ discounts it as a real risk in the temporary postponement of cholecystectomy.

In cases of long-standing gallstones, scarring, thickening and deformity of the liver edge are considered by some investigators as evidence of localized hepatitis,²⁰ whereas others think that the gross appearance of the liver is of little prognostic value.²¹ Livers that look damaged, it is stated, frequently show no appreciable evidence of parenchymal change. The liver has been shown to have a tremendous reserve power,²² and many hepatic functions are maintained even when only 20 per cent of the total liver tissue is normal.²³ Risk of operation because of liver damage can usually be combated and minimized by adequate preoperative management, and the optimum time of operation can be determined by appropriate liver-function tests.

Whether gallstones are a factor in diabetes or whether there is a metabolic process common to both is unsettled. Gallstones do appear to develop more frequently in patients with diabetes than in any population at large,¹⁴ and complications of gall bladder seem to be more frequent in diabetic duct with or without diabetes in addition to gallstones. The complication of symptoms before operation, however, cannot be said to be more frequent in stones in the gall bladder has not been reported. Accordingly, the time factor for the development of biliary complications must resolve itself in the presence of diabetes.

At the George F. Baker Clinic in Boston, it has been found that diabetic patients require as much insulin after cholecystectomy as before.²⁴

CONCLUSIONS

It is evident from this study that the sequelae of cholelithiasis do not appear at any well-defined time interval after the presence of stones is first determined. Biliary complications may be present with the initial attack or appear shortly after calculi are first demonstrated. On the other hand, complications may not develop for many years after cholelithiasis has been diagnosed or may never occur in spite of recurring attacks of biliary colic over many years. Yet in general it can be accepted that the longer symptoms continue in cholelithiasis, the greater is the possibility of biliary complications. The likelihood of the development of complications in any person known to harbor gallstones must be constantly borne in mind.

Biliary calculi should be removed, if practicable, as soon as possible after their presence is known. Today, however, because of wartime exigencies and the shortage of medical and hospital personnel, any elective operation such as cholecystectomy for gallstones without complications may have to be deferred. Until operation can be arranged, every effort should be made to reduce the dangers inherent in delay. Patients who cannot be operated on promptly should be put on a strict regimen of diet and hygiene in an effort to lengthen the period between attacks. They should be warned of the dangers of biliary complications and the necessity of seeking prompt medical advice. Should patients develop acute biliary emergencies, — and perforation of the gall bladder may occur within twenty-four hours of the onset of acute cholecystitis, — hospital beds should be promptly available, even if it means that hospitals postpone the admission of patients scheduled for elective operations. If these safeguards are observed, it should be possible for the duration of the war to minimize the risks involved in the postponement of operation for gallstones.

early surgery. It is equally the responsibility of the medical profession to bend every effort toward the provision of prompt hospital facilities. Acute cases should not be refused admission even if such admission requires the taking over of ward beds and the release of beds earmarked for elective treatment. In this age, when so much progress is being made in medicine and surgery, every effort should be made by surgeons in the furtherance and encouragement of such a program despite the economic situation as it exists. The economic plea for delay means complications involving not only a greater mortality rate but also greater morbidity and economic loss. Dr. John Fallon, Worcester: No paper could be more timely than this. When lifeboats are crowded and we have the law of the sea. Now hospitals are crowded and we have another law: "The sickest first." The elevator-hour patient, if compellingly sick, must come before him who has borne the aggravations of the waiting list. Otherwise hospitals are only hotels and we are hazarding a life to keep a promise. One of the operations we can usually delay is cholecystectomy. But when and for how long? Cholecystitis without concern, the end of the next war. On the other hand, jaundice or a suspicion of peritoneal inflammation demands hospitalization. Between these two extremes where do we stand? The man with attack increasing in strength, frequency or length is lucky. He has a stone lodged in the pelvis or cystic duct, and empyema, perforation or progress into the common duct are in the offing. Still, he is lucky because he has been warned. He can beat the storm. The others, those with colics every rainy Tuesday, can wait a little. The law of averages is with them, although Dr. Bearse shows that a considerable minority have serious complications within a year of diagnosis, and I remember at least two deaths in the first attack. In other words, the law of averages says we can wait a little, but we have no data concerning how long "a little" is. If we cannot say how long to delay, we can say how much harm delay does. Of a group of 1000 Fallon Clinic patients whose chief lesion was nonmalignant disease of the gall bladder or ducts, 41 died. Note that we are considering not the risk of operation but the risk of the disease. The series, to be fair, includes the 76 patients whom we tried to tide over without operation or until a more hopeful time for operation. Seven of these 41 deaths may be called accidents. These were the overwhelming attacks coming, without reasonable warning, in the old and decrepit and the emboli and coronary occlusions. Fifteen deaths were the fault of a doctor, oftenest myself,—shock, pneumonia (which is decreasing since the use of spinal anesthesia) or plain bad surgery done by someone before us or by one of us. But the majority, 19, were due to delay, despite adequate warning, until there were touch-and-go complications. It will be said that some of these deaths might have been saved by better judgment or better technique. True, but if there had been no delay, miracles would not have been needed. And the argument is academic when the mortality of operation for uncomplicated disease is a small fraction of 1 per cent. Fundamentally, delay killed these 19 patients just as it continued toward the deaths of several others and, among living and dead, added up a sum of misery not reducible to figures. How long can we delay? Certainly long enough to give priority to the acute patient but not to a patient with a hernia that can be controlled by truss. Who knows where the fuse is set on a time bomb? If that bomb is hurried under your own liver, delay takes courage. I should have to wait longer nowadays, but when I found out several years ago that I had gallstones, I delayed just one day, and only because the day was Christmas. When I tell my patients that story they say, "Ah, but you went to a good surgeon."

Dr. I. S. Otis, Meriden, Connecticut: The pathologic state of the gall bladder cannot always be safely estimated by any physical or laboratory test, hence the danger of delay. Not infrequently the problem arises of persuading a patient to have surgery when he or she seems to have recovered. Such patients are courted in trouble, and the necessity for operation should be insisted on at the first evidence of suggested symptoms. Here the attending physician is invaluable in leading the patient to such a decision. According to Ellason and Stevens, there is liable to be serious biliary damage because of the long period of the disease existing before the acute attack precipitating the operation. Often pancreatitis and hepatitis, together with cardiac and renal diseases, result in operative and postoperative deaths. It is odd that although surgeons are almost universally agreed that acute appendicitis should be treated surgically as an emergency,—within hours, not days,—in acute cholecystitis, in which it is generally agreed that one cannot foretell the severity of the pathologic condition, they sometimes wait an indefinite time before instituting surgery. This position seems doubly untenable when some writers report perforations as having occurred within twenty-four hours. Heuer, in an analysis of 35,000 cases, shows that 20 per cent progressed to perforation, with a mortality of 10 per cent. Others give frequencies of perforation up to 45 per cent. MacDonald in 1941 pointed out that gall-bladder disease in its early stages is often viewed with "alarming nonchalance". It is this very attitude that may be responsible for the frequently disappointing results following delayed operation. Graham illustrates the danger of procrastination by citing the mortality rates for cholecystectomy. After two attacks it is 2 to 3 per cent, after three or more attacks 8 to 9 per cent, in the presence of jaundice 10 to 12 per cent, and with pancreatitis 50 per cent. In Dr. Bearse's series, it is to be noted that 103 patients (40 per cent) had one or more complications at operation, with an average duration only two years greater than that in the cases without complications. Add to this fact that 35 per cent had symptoms for less than one year and 47 per cent for less than three years, and one sees that the principle of exercising the best surgical judgment should remain firm. Despite the pleas of patients concerning the lack of domestic help to care for children, as well as the desire of workers to remain constantly on their jobs, they should not be permitted to alter the surgeons' primary desire to reduce mortality and morbidity. The latter should continue to advise

LOW-BACK PAIN AS THE PRESENTING SYMPTOM OF MALIGNANT BREAST TUMORS

MAJOR THEODORE D. COHN, M.C., AND CAPTAIN HAROLD COHN, M.C.

PRIMARY malignant tumors of the female breast that have metastasized to the vertebral column and bony pelvis are not infrequently overlooked. These patients are at times erroneously treated for the numerous other causes of backache, such as "lumbago," "sciatica," sacroiliac strain and retroversion of the uterus. The frequency of diffuse skeletal metastases from relatively small malignant nodules in the breast is a well-recognized clinical fact, but the subject has not been extensively discussed or become crystallized in the literature.

Lamarque¹ in his discussion of skeletal metastases from breast cancer makes the point that many of his patients complained of vague bone pains or suffered from pathologic fracture before a small tumor, until then unrecognized, was discovered in the breast. Ducuing² maintains that the invasion of the skeleton may present the first symptoms of a breast cancer, which are frequently ignored. This can be manifested by a bony tumor, pains in the bones or spontaneous fracture. The initial cancer may pass unnoticed either because of its small size or because of large breasts that mask the tumor, the breast tumor then revealing itself late. Warren and Witham³ state that the first symptoms noted in malignant tumors of the breast are at times due to metastases, such as pathologic fracture or evidence of intracranial pressure. The prime purpose of this paper is not only to reiterate and emphasize that spinal metastases from an unrecognized breast tumor may be the cause of chronic low-back pain and may cause the presenting symptoms, but also to discuss the significance of such metastatic patterns in the light of new knowledge.

CASE REPORTS

CASE 1. A 52-year-old woman complained of low-back pain of 3 months' duration. She had been treated for a sacroiliac strain and myofibrositis of the lumbar muscles, with diathermy and local heat.

Physical examination revealed a well-nourished, middle-aged woman with negative physical findings except for a nodule in the middle of the right border of the right breast. The breasts were somewhat large and pendulous. A lymph node in the axilla was palpable. Biopsy revealed a scirrhous carcinoma of the breast. X-ray examination of the spine showed involvement of the 4th and 5th lumbar vertebrae and some infiltration in the body of the ilium.

The diagnosis was carcinoma of the breast with metastases to the spine.

CASE 2. A 50-year-old woman had been treated for low-back pain with diathermy and local heat for 1 month prior to her present illness. She was wearing a sacroiliac belt. A nodule the size of a walnut was found above the nipple in the right breast. Biopsy proved this to be a scirrhous carcinoma, and roentgenologic study of the spine revealed the lesions of bony metastases involving the sacroiliac joint and the lower lumbar vertebrae.

CASE 3. A 31-year-old woman underwent a ventral uterine suspension for low-back pain 3 years prior to her present illness. One year after the operation a nodule was found in the left breast; it was pronounced clinically non-malignant and a diagnosis of cystic mastitis was made. She became pregnant and delivered a normal child. Three months post partum, while bending down to pick up her baby she felt a sudden "crack" in the back and could not stand up.

A physician made a diagnosis of sacroiliac strain and strapped the back. The condition grew steadily worse, and the pain developed a left sciatic distribution. X-ray examination of the spine was negative. The patient was treated with short-wave therapy, strapping and a sacroiliac belt, obtaining only transient relief. Two months later, it was found that there was some degree of anesthesia over the left anal fold, as well as loss of the left Achilles reflex. A tentative diagnosis of cauda-equina tumor or herniation of a nucleus pulposus was made. Lipiodol studies of the spine were negative.

Throughout this period no attention was paid to the breast. The pain became severer and a back brace was ordered, with little relief. Subsequent examination revealed the breast mass to be the size of a hen's egg; it was hard and adherent to the skin. An enlarged node was found in the axilla. A diagnosis of carcinoma of the breast with bone metastases was made. Re-examination by x-ray, 4 months after the original films were taken, showed generalized spinal and pelvic metastases and some metastatic nodules in the skull.

The patient eventually died, and autopsy proved the lesion to be an adenocarcinoma of the breast with generalized spinal and skull metastases. The original x-ray films were reviewed but no demonstrable lesions were observed.

CASE 4. A 55-year-old woman complained of pain in the back of 5 months' duration. She had been treated for sacroiliac disease and low-back pain.

Physical examination showed tenderness over the left sacroiliac joint and pain in the left sciatic notch, with radiation down the left leg and over the right hip joint. A mass the size of a large hazel nut, adherent to the skin and non-tender, was palpated in the right upper quadrant of the right breast. A few lymph nodes were palpated in the right axilla.

The diagnosis was carcinoma of the breast with spinal and pelvic metastases. This was confirmed by punch biopsy. X-ray study of the spine and pelvis showed metastatic involvement of the lumbar vertebrae, left sacroiliac joint, left ischium and right hip.

DISCUSSION

It may seem elementary to suggest examination of the breasts in women suffering from back pain, but the 4 cases presented illustrate the importance of this procedure in all patients with complaints referable to the skeletal system. Such examination should be routine even if the patient is completely unaware of any mammary nodule or ulceration. As illustrated by Case 3, bone lesions may not become apparent roentgenologically until considerable bone tissue has been destroyed. Negative x-ray findings in the presence of bone pain and a nodule in the breast should not rule out bone metastases, at least early in the disease, and the patient should be followed by subsequent bone x-ray studies. Case 3 also illustrates the time-consuming, uncomfortable and extensive procedures that are often performed

before the true nature of the primary disease is recognized. This patient had lipiodol studies of the spinal canal, orthopodic appliances had been prescribed, and she had even been accused of hysteria.

* * *

Batson's⁴ has described the probable route of metastases from the breast. According to this concept there is a vast intercommunicating system of veins between the epidural and vertebral veins and the veins of the thoracic-abdominal cavity. This system of veins has no valves and the venous pressure is extremely low. With every increase of intra-abdominal and intrathoracic pressure, the intratunical pressure is raised to sufficient heights to permit the blood to flow into this vertebral system of veins. Thus there is a reversal of blood flow that bypasses the cardiopulmonary circuit. Since this system has no valves, a flow of blood occurs up and down the spine and into the skull. It does not involve the heart and lungs, and has many connections with the thoracic-abdominal system of veins. According to Batson, this provides a ready vehicle for the explanation of aberrant metastatic patterns and removes the stumbling block of the absence of lung involvement. The course through a patent foramen ovale, he states, is no longer necessary to explain this lung paradox. This system of vertebral veins is also called the meningothoracic system. By means of injections of radio-opaque dyes and subsequent roentgenography, as well as post-mortem intravenous injection of the mammary veins, Batson has demonstrated the role of these veins in spinal metastases from malignant tumors of the breast. He has shown that this vast vertebral plexus is constantly the site of a physiologic reversal of blood flow and communicates with the veins of the spinal column as well as those of the breast. Thus the spine may be the site of metastases from breast tumors long before the original lesion has been recognized. Batson writes:

According to this concept, in every act of straining, coughing or lifting with the upper extremity, blood is not only prevented from entering the thoracic-abdominal cavity; it is actually squeezed out of the cavity. Tumors and abscesses of the thoracic-abdominal wall, including the breast, tumors of the lung, pelvic tumors and abscesses, lesions of the shoulder and pelvic girdles and occasionally tumors and abscesses of other organs have connections with this vein system and may therefore have metastases distributed anywhere along the system without involving the portal, pulmonary or caval systems. Batson experimentally demonstrated the spread of flow from the caval system into the vertebral system by increasing the intra-abdominal pressure

SUMMARY

Four cases of carcinoma of the breast are presented in which pain from metastatic foci to the spine and bony pelvis was the first evidence of neoplastic disease. Negative bone x-ray films early in the disease, in the presence of bone pain and a mass in the breast that has proved malignant, should not rule out bone metastases. X-ray studies should follow. The probable route of metastasis by way of the vertebral veins, as described and suggested by Batson, is discussed. Metastatic foci to the lower back and pelvis from a primary breast tumor should be considered as a not uncommon cause of low-back pain. Breasts of all patients, especially women, should be examined routinely for tumors, particularly in the presence of low-back or pelvic pain.

MEDICAL PROGRESS

INSECT VECTORS OF DISEASE (Continued)

VLADO A. GETTING, M.D., DR.P.H.*

CONENOSE BUGS

The conenose bugs belong to the order Hemiptera, family Reduviidae.⁹¹ They are commonly called "assassin bugs," "kissing bugs," "corsairs," "black corsairs," "wheel bugs" and "bedbug hunters." Predatory in nature, several species protect themselves by biting, whereas others have developed a distinct habit of sucking mammalian blood. Two genera, *Triatoma* and *Rhodnius*, contain conenose bugs of medical interest. Although a few species are worldwide in distribution, the majority are found in the Western Hemisphere, particularly in the high cold regions of the Andes.

Most conenose bugs are active runners and good fliers. Since white man's invasion of South America, these bugs have become domesticated and now can be found in the straw huts of Indians in Brazil. They live in the cracks of the more permanent structures, and live on man and domestic animals. Adults of both sexes bite; the larvae and nymphs are wingless and therefore restrict their activity to the house. Nocturnal in habit, they quickly run for shelter when suddenly exposed to light. The bite is usually painless,⁹² so that a person bitten in his sleep is not awakened. The blood meal, lasting from a few minutes to half an hour, is followed by defecation of liquid feces. All the conenose bugs that bite man or animal infected with *Trypanosoma cruzi* become infected and retain the infection until death.⁹³ Although adult trypanosomes occur sparingly in the blood of patients with Chagas disease, nevertheless, when taken up by conenose-bug nymphs or adults, they lose their flagella and are transformed into "leishmania forms." In this stage, the trypanosomes multiply rapidly and develop into "crithidia," which in turn develop in the hindgut of the bug into the infective trypanosome forms. These infective forms then enter a new host (man or other vertebrate) through the medium of the infected feces deposited on the mucous membrane of the mouth or nose or on the conjunctiva of the eye or through the puncture wound created by the bug bite, an abrasion or an excoriation of the skin. Brumpt⁹⁴ proposed a method of diagnosis that calls for an insect vector (xenos) being fed on a suspected case, the bug being examined eight days later for the developmental stages of the trypanosomes.

Tryp. cruzi occurs naturally in armadillos, opossums, squirrels, certain monkeys, bats, cats, dogs and a California wood rat. *Triatoma gerstakeri*

naturally infected with *Tryp. cruzi* were studied by Packchianian^{95, 96} in southern Texas. Naturally infected triatoma have also been found in Arizona by Wood⁹⁷ and in California and Texas by Davis.⁹⁸ The nymphs of *Tr. gerstakeri* often occur in the nests of wood rats. *Tr. megista* is the most important vector of Chagas disease in the greater part of Brazil, and *Rhodnius prolixus*, primarily a human parasite, is the chief vector in northern South America.

The conenose bug is also incriminated as a mechanical vector of Western equine encephalomyelitis and of yellow fever.

The destruction of reduviid bugs is difficult as fumigation or insecticide spraying in tropical huts is impractical. Mosquito nets at night and adequate screening of houses offer protection against the adult bugs; however, the small nymphs are difficult to eliminate. Burning of infected huts may have to be performed as a last resort.

LICE

The order Anoplura, family Pediculidae, includes the sucking lice that subsist on blood. They attack man and other vertebrates and are vectors of typhus fever,⁹⁹ trench fever,⁶⁵ European relapsing fever and, less frequently, plague. Urticaria and melanoderma (Vagabond's disease) may follow from the bite. Because of irritation produced by the bite, scratching may result in cutaneous pyogenic lesions. The head louse may transmit typhus fever, and is also accused of transmitting favus and impetigo. So far as is known, the pubic or crab louse is not a vector. The body louse is by far the most important vector. Man and his clothing are the chief disseminators of body lice. Whenever the temperature of the environment approaches that of the body, the louse leaves the vicinity of the body and wanders about in search of other hosts. Hence, under crowded conditions, where several human beings are huddled either in search of heat or shelter from enemy action, the louse is afforded ample opportunity for new infestations. Typically, lousiness and louse-borne diseases are cold-weather affairs. A temperature of 86 to 90°F.—that which exists between the skin and clothing—is ideal for lice. Eggs are attached to the fibers of clothing, especially woolens. Cotton and silk are less likely to harbor lice, owing to the lack of fiber. The eggs of the head louse are attached to the hairs covering the head, whereas the nits of the crab louse can be found on the pubic hair or on the hair of the eyebrows and the beard.

*Commissioner, Massachusetts Department of Public Health, and lecturer in public-health practice, Harvard School of Public Health.

fever and Rift Valley fever. Ticks are also an important cause of anemia in domestic animals, a female tick ingesting a hundred times her weight in blood. Moreover, certain species cause tick paralysis through venom contained in the salivary secretions of the mature female at a particular time of her life before she drops from the host on whom she is feeding.¹⁰⁹ This paralysis is ascending in type and may cause death. In northwestern United States and British Columbia the common wood tick *Dermacentor andersoni* and in Australia *Ixodes holocyclus* have, in several cases, been reported as causing paralysis, respectively, of man and also of animals, calves, sheep and dogs.

The soft ticks are less parasitic than the hard ticks. The nymphs and adults are rapid feeders and tend to remain in the habitat of their hosts. There are two medically important genera, *Argas* and *Ornithodoros*.¹¹⁰ *Argas persica* (the fowl tick, miteana bug, blue bug or abode tick) is worldwide in distribution and an important poultry parasite whose habits are similar to that of the bedbug. It has a long life-span, — over four years if unfed, — and is a vector of fowl spirochetosis. Of the Ornithodoros ticks, there are some thirty species feeding on birds, mammals and reptiles,¹¹¹ and one species has experimentally transmitted rickettsial infections. Living in nests and burrows or the homes of man, they feed rapidly and intermittently. Their bite is painful, leaving an itching wheal. Of the six known species in the United States, *Ornithodoros coriaceus*, known as *pavlovii* in the southwestern states and *lexico*, is most venomous and feeds on cattle and deer. *O. talys* is found in Minnesota, Wisconsin, New York, the southwestern states and Central America; it is a vector of relapsing fever and lives in the dust, cracks and crevices of walls of rest-houses and huts. It feeds on birds and mammals including man.

The hard ticks are shorter lived than the soft. Their eggs are usually deposited on the ground; the larvae climb grass stalks to await small rodents and other suitable hosts. Nymphs and adults similarly await larger hosts, including man. *Dermacentor andersoni*, the western wood tick, is the most important vector of Rocky Mountain spotted fever and tularemia and also is capable of transmitting equine encephalomyelitis. A three-host tick, the field mice and squirrels, the adults on larger animals, such as horses, cattle, sheep, wolves and rabbits. Alan is an accidental host. *D. variabilis*, the common dog tick, is frequent in the eastern United States as far north as Cape Cod; it is a vector of tularemia and Rocky Mountain spotted fever,¹¹² and it has been used experimentally to transmit of Ixodidae have been experimentally proved to be capable of transmitting these diseases. *Hama-phyalis leporis palustris*, a widely distributed rabbit

The order Siphonaptera contains the wingless, hard-bodied, small, brown, parasitic fleas, which are provided with powerful legs adapted for jumping.⁶⁵ Adults of both sexes bite and suck blood; they are active and may jump upward 20 cm. or horizontally for almost twice that distance. Fleas leave the body of a dead host as soon as it begins to cool, seeking a new host. Often showing a preference for certain parts of the body, the adults are normally body parasites. The nests or dens, however, of animal and birds are normal breeding places. Fleas feed at frequent intervals, usually at least once a day, but occasionally much oftener since they are easily disturbed while feeding and seldom complete a meal. Even with a filled digestive tract, a flea may pass unaltered blood in the feces and still be feeding.

Fleas are important vectors of plague¹⁰¹ and endemic typhus fever and mechanically transmit yellow fever. The ordinary rat flea *Xenopsylla cheopis*, after feeding on an infected animal, may have its digestive tract full or even possibly blocked by solid growths of plague bacillus. Such fleas may regurgitate blood containing the plague bacillus into the wound, or may pass the organism into the feces, which in turn may be introduced into the skin either through the puncture or as a result of an abrasion. Probably the smallest known flea is the jigger, sand flea or chigoe¹⁰² (the chigger is not a flea but a larval mite¹⁰³). This flea is an especially annoying pest in the tropics and subtropics, where it may occur in extremely large numbers, especially in burrows into the skin, particularly beneath the toes, under toenails and in tender parts of the feet to lay eggs, and receives nourishment from the blood. The abdomen of the female flea begins to swell to the size of a pea, the posterior end barely reaches beyond the swelling of the host's skin and forms a plug for the hole. The eggs mature and are expelled through the tip of the abdomen, the female then shrivel and drops out or is expelled by ulceration. Treatment of this flea is difficult and consists of aseptically removing the entire flea and consequent disinfection.

TICKS

Ticks are not true insects and belong to the class Arachnida, order Acarina.¹⁰⁴ The family Argasidae is comprised of soft ticks, while the family Ixodidae consists of hard ticks. Of the order Acarina, they are now known to be vectors of relapsing fever (*Borrelia duttoni* type), Rocky Mountain spotted fever,¹⁰⁵ *fièvre boutonneuse*, African tick fever, Sao Paulo fever, tularemia, Chagas disease, louping ill, Western equine encephalomyelitis,¹⁰⁶ and American Q fever,^{107, 108} and they occasionally transmit yellow

tick, transmits naturally both Rocky Mountain spotted fever and tularemia.¹¹⁴

All tick vectors transmit disease from adult to eggs, to larvae and hence to nymphs and adults of the next generation. This hereditary transmission of disease complicates the control of tick-borne diseases. Soft ticks are controlled by methods used against bedbugs. Hard ticks, especially *D. andersoni* and *D. variabilis*, are extremely difficult to control. Tick-proof clothing, examination of oneself and one's clothing after passing through tick-infested areas, avoidance of underbrush and of herding sheep through an infested field, picking off ticks with tweezers and burning over underbrush, with the elimination of small rodents, are some control measures that have proved of value. Immunization against Rocky Mountain spotted fever in persons who are likely to be exposed is available by a vaccine prepared by the United States Public Health Service.¹¹⁵

A tick infected with Rocky Mountain spotted fever is not infectious until some time after attachment to the new host. The rickettsias are reactivated after a period of one and three-fourths hours to two or more days. Similarly, tick bites early in the spring are not likely to result in infection whereas tick bites in the fall are much more dangerous.

TRANSMISSION OF DISEASE BY INSECT VECTOR

Infection of Vector

The vector of a disease is primarily infected by biting a person or animal that is a blood carrier of the disease in question, whereby the insect ingests the blood containing the infecting organisms. In certain of the insect-borne diseases, such as Rocky Mountain spotted fever,¹¹⁶ the infective agent is transmitted by the primary insect host through the egg stage to succeeding generations. Occasionally the infective agent is passed from one insect to another during copulation. One or more of these methods may prevail in the case of certain diseases. Usually, when the infective agent is passed from one generation to another in the vector, the disease is persistent or long lived. The infective agent is not fatal to the vector, and there is evidence that this interrelation of the infective agent and the primary insect-host is sufficient to propagate the disease without the intervention of another host. This apparent symbiosis or survival of the infective agent in the insect host, with its transmission to subsequent generations, indicates that the disease is an old or usual one of that insect and that the infection of man is accidental, the latter being a true secondary host and unnecessary for the continued existence of the disease. These conditions are illustrated by the tick *D. andersoni* and the rickettsias of Rocky Mountain spotted fever.¹¹⁷

Infection of Host

The infective agent is transmitted usually to man or some other animal as a result of biting or attempted biting by the infected insect host. In some diseases the infected insect injects the organisms into the tissues of man in the act of biting; this is true in malaria; when the mosquito injects saliva into the tissue to maintain the blood fluid, malaria plasmodia are introduced into the victim. The regurgitation of stomach contents is occasionally the manner of infecting the bitten person; it is in this manner that fleas spread the bacteria of plague. In other instances, the surface of the skin is contaminated by the feces or glandular secretions of the infected insect, or by the infective material of an insect that is crushed on the skin as it bites. This infective material reaches the blood of the bitten person by being inoculated into the bite wound or through abrasions made by scratching or rubbing the bitten area. The infective agents of some of the insect-borne diseases, notably the bacteria of plague and the spirochetes of relapsing fever, can pass directly through the unbroken skin.

Biologic Transmission

Some of the organisms that cause insect-borne disease in men must undergo a stage of development in the body of the insect host before they can be transmitted to the human host. In such a disease both the insect host and man are necessary for the survival of the disease, and the absence of either results in the control or disappearance of the disease from the affected area. Control of this type of insect-borne disease is more feasible than that of the type in which the infective agent is passed through eggs from one generation of the insect host to the next.

Malaria and filariasis are examples of diseases that undergo this type of biologic development. The time required for the development of the parasite in the insect host constitutes the extrinsic period of incubation. The length of this extrinsic incubation varies for different organisms but is fairly constant for each organism, although influenced by temperature changes; colder weather lengthens the extrinsic period of incubation.

The life cycle of certain of the infective agents that undergo biological development includes a sexual and an asexual phase. The host in which the sexual phase occurs is called the "definitive host," whereas the one in which the asexual phase is passed is known as the "intermediate host." The insect vector or the human host may serve as a definitive or an intermediate host. In malaria, the sexual phase of the plasmodium occurs in the mosquito, which is the definitive host, and man is the intermediate host.¹¹⁸ In filariasis, on the other hand, of which the infective agent is *Wuchereria bancrofti*,

It is evident that most of the important diseases of man with which epidemiologists are concerned fall into the group of diseases with biologic transmission. Those that undergo cyclopropagative and propagative transmission are of chief concern, since in these diseases the parasite undergoes multiplication and hence the survival of the parasite in the arthropod host is more certain and the infection of man is statistically likelier.

PREVALENCE OF INSECT-BORNE DISEASES

Within certain limits, the geographic distribution of an arthropod-borne disease is governed by the distribution and prevalence of the insect host. Consequently, an insect-borne disease can prevail only in districts where the insect hosts are indigenous and where environmental conditions are favorable for their continued existence. For example, yellow fever, which is spread by the *Aedes aegypti* mosquito, is a disease of the tropics, where that mosquito is indigenous. In the days of clipper ships, however, yellow fever outbreaks occurred in Boston. They usually started in the middle of summer and always disappeared with the first frost. The disease began near the wharves and spread in the direction of prevailing winds. Apparently what took place was that *A. aegypti* mosquitoes were brought north from the tropics by the clipper ships and then bred in the open barrels of water that were conveniently placed on the wharves as protection against fire. The mosquito continued to survive so long as environmental conditions were favorable, and the disease spread throughout the summer; but with the first frost the mosquito was killed and the outbreak subsided. Subsequent outbreaks were due to reimportation of infected mosquitoes.

Because the tropics and subtropics supply favorable conditions for mosquitoes, mosquito-borne diseases are prevalent in these regions. Conversely, louse-borne diseases occur most frequently in cold and temperate regions, since the conditions produced by cold, namely, the wearing of heavy clothing, crowding in houses for heat and inadequate personal hygiene, favor the propagation and dissemination of lice. This has been well illustrated by the occurrence of typhus fever in the concentration camps in Poland and in the armies on the Russian front.

Since no insect or arthropod is worldwide in distribution, no insect-borne disease is worldwide in distribution. Moreover, even if the insect vector is present, the insect-borne disease spread by that vector need not be prevalent. A classic example of this is the absence of yellow fever in Asia. For an insect-borne disease to prevail, the following conditions must exist: the vector must be indigenous or be able

man is the definitive host, and the mosquito the intermediate host.

An essential consideration in respect to biologic transmission is the appreciation that in some instances the infective agent undergoes a cyclic morphologic change in the body of the arthropod, whereas in others the parasite undergoes simple multiplication; in still others there is both a cyclic change and a multiplication. It is worth while to examine the different arthropods regarding these two characteristics. Epidemiologists are greatly concerned with these two factors because they affect so much the behavior and the geographic distribution of the disease concerned.¹⁹ Both the interpretation of the observed epidemiologic phenomena and the institution of the indicated control measures are related to these characteristics.

The most complicated mechanism involved in biologic transmission of the infective agent is known as the cyclopropagative cycle. In this, the parasite undergoes a developmental cycle, with morphologic changes, and at the same time multiplies in the body of the insect host; both are entirely apart from any developmental process or multiplication taking place in man. The classic example of this cyclopropagative development is malaria. The sexual cycle, with multiplication, takes place in the mosquito, the definitive host²⁰; and in man, the intermediate host, the plasmodium undergoes an asexual cycle. There are thus an extrinsic incubation period, during which the parasite undergoes change and increases in number in the mosquito, and an intrinsic incubation period, during which the asexual cycle takes place in man.

A second and less complete form of biologic transmission is the cyclodevelopmental cycle, in which the micro-organisms undergo a cyclic change in the arthropod host but do not multiply there. Here, the best example is filariasis, in which the worms undergo morphologic changes in the mosquito but do not increase in number. This disease, filariasis, was the first to be proved to be insect-borne, when Patrick Manson made his fundamental discovery in 1878.

The third type of biologic transmission is termed the propagative cycle, since the etiologic agent undergoes simple multiplication without morphologic changes. A typical example of this type of transmission is that of the rickettsias of typhus fever in lice.

Mechanical Transmission

When it is not necessary for the infective agent to undergo a period of development or multiplication in the arthropod host, biting vectors may transmit the disease mechanically. Usually, the infective agent spread by this means of transmission is a bacterium. The spread of bubonic plague or of typhoid fever is a good example of mechanical transmission.

x — usual method of transmission.
m — mechanical transmission.
! — survival of organisms.

Of the rickettsial diseases, epidemic typhus fever is spread by lice and the endemic form by either lice, fleas or mites. Trench fever is also carried by lice. Rocky Mountain spotted fever, *fièvre boutonneuse*, African tick typhus and Sao Paulo fever are transmitted by ticks, and Tsutsugamushi disease or scrub typhus is spread by harvest mites. Of the insect-borne virus diseases, yellow fever, dengue, ¹²⁹equine encephalomyelitis¹³⁰ and possibly Japanese encephalitis¹³¹ are transmitted by mosquitoes. Louping ill and equine encephalomyelitis are transmitted by ticks, ¹³²but the latter is known to have been transmitted by the consensu or assassin bugs.

to become indigenous, the vector must propagate under favorable environmental conditions; the vector must be present in sufficient numbers to spread and maintain an indigenous level of the disease (if the number of vectors is reduced to below this critical level, the disease cannot survive in epidemic proportions); susceptibles must be present and exposed to the vector; an infected person must be bitten by the vector, which must have access to the human host; environmental conditions must permit the vector to bite the infected host and then the to-be-infected host; and, finally, the vector must survive long enough to permit the parasite to undergo the extrinsic incubation period and then bite a new susceptible host. If any one of these conditions is unfavorable, the disease ceases to be epidemic and the cycle is broken, and if the cycle is broken often or long enough, the disease tends to disappear gradually from the area. If, on the other hand, one of the factors that was missing is replaced, the disease can be reintroduced or may assume epidemic proportions in an area where it was formerly endemic.

When the cycle of transmission includes an animal host of the parasite, the prevalence of the disease concerned is modified or entirely governed by the accessibility of the animal host. It is important to note that the survival of the disease and any plan to control it must take into consideration this additional factor. It is this type of disease, namely, animal-arthropod-man, that presents some of the most complicated and fascinating problems of epidemiology.

CLASSIFICATION OF INSECT-BORNE DISEASE

Arthropods transmit not only diseases of man and other animals¹²¹ but also diseases of insects and plants,¹²² such as the diseases of the cabbage butterfly¹²³ and the various mosaic diseases of tobacco and tomatoes. So far as man is concerned, seven types of etiologic agents are transmitted by arthropods (Table I). These are as follows: helminths (round worms), protozoa; bacteria; bartonellas, spirochetes; rickettsias; and viruses.

The helminths are transmitted only by Diptera — filariasis by mosquitoes, gnats and gadflies¹²⁴ and onchocerciasis by Buffalo gnats.

Among the protozoal diseases are malaria, spread by mosquitoes and the most devastating insect-borne disease in the world, Texas cattle fever, spread by ticks, African sleeping sickness, spread by tsetse flies, and Chagas's disease, spread by ticks and assassin bugs.

The most important insect-borne bacterial diseases are plague,^{125, 126} spread by fleas, and tularemia, spread by ticks and gadflies.

Oroya fever, caused by a bartonella, is transmitted by sand flies.

The spirochetes of relapsing fever¹²⁷ are transmitted by ticks.

intestinal symptoms. Peristalsis was referred to as high-pitched and hyperactive which is suggestive of obstruction, but without a more elaborate description it does not really establish the diagnosis. Obstruction is often associated with tinkling, hollow, peristaltic sounds whose occurrence is synchronous with crampy pain.

The patient had normal-colored feces, and no guaiac test is recorded. The white-cell count was normal, which suggests that infection or necrosis

I have recently seen a patient who had a sigmoidoscopy, and we have already noted the lack of evidence of inflammatory reaction or bowel necrosis, the presence of which would lead one to conclude that, if she had an intussusception, it was not affecting the blood supply of the bowel.

So the problem becomes one of trying to discover why this patient had an intussusception at the age of sixty and, secondarily, why this intussusception did not do her any more harm than it did.

I have recently seen a patient who had a sig-

FIGURE 1. Roentgenogram after Barium Enema Showing Tumor Mass Advanced into Transverse Colon Pulling the Cecum after It.

of the bowel was not a part of the picture. "This impression is borne out by other vital signs. Now we come to the x-ray films, and I am sure that they will either make or break the diagnosis. Unfortunately no roentgenologist is present, so we shall have to rely on our own interpretation of the films.

There is a sausage-shaped mass in the right-hand portion of the transverse colon, which apparently advances at times over toward the splenic flexure. When it is in that position, the cecum is shortened and the terminal ileum is no longer visible. I do not see how one can avoid the diagnosis of intussusception in the presence of such findings. Only one of the many spot films, however, shows the characteristic dimple in the advancing end of the in-

moidal intussusception presenting at the anus in which the blood supply of the intussuscepted bowel was still intact. The leading point of this intussusception was a large carcinoma, and there was considerable bleeding. From that patient one might conclude that it is at least possible for adults to have chronic intussusception that does not produce bowel necrosis, and such must be the case with the patient under discussion.

Another question to be answered is, What was the leading point of the intussusception? I have already mentioned that the x-ray films show a sausage-shaped mass without the characteristic dimple in the leading portion. This suggests that this portion is not the bowel wall itself but a fairly large mucosal or intramural tumor. If this were the case, it would

CASE 31121

PRESENTATION OF CASE

A sixty-year-old married woman was admitted to the hospital complaining of abdominal pain, nausea and vomiting.

Seven years before admission, three months after repair of a cystocele, the patient first noticed a localized burning sensation in the back and pain under both costal margins, with morning nausea, vomiting and occasional diarrhea. This pain came in episodes that were intermittent until five years before admission, when the pain became persistent. A Graham test one year later revealed failure of filling and the presence of a gallstone in the gall-bladder area. Three years before admission she had an acute attack of pain in the right upper quadrant, with nausea and vomiting. Since that time she had had frequent morning headaches and mild upper abdominal pain, which were relieved by vomiting. During the previous two years she had also had mild lower abdominal pains that were relieved by episodes of diarrhea. About a month before admission a barium enema in the Out Patient Department showed a transient delay in filling at the hepatic flexure, and a smooth, round, filling defect was seen projecting into the lumen of the transverse colon (Fig. 1). Barium later passed around this defect to the cecum and it was possible to outline a smooth ovoid mass, measuring about 9 by 5 cm. On palpation or contraction of the bowel the mass moved distally, and on a post-evacuation film it reached

the midtransverse colon. With this movement of the mass the ascending colon became shortened. These findings were confirmed by a second barium enema.

Physical examination revealed an obese, well-developed woman. Examination of the heart and lungs was negative. The abdomen was moderately tender in the suprapubic area; there was no spasm. The liver and spleen were not felt, and no masses were palpated. Peristalsis was high pitched and hyperactive. A pelvic examination was not remarkable. A rectal examination revealed brown feces.

The temperature, pulse and respirations were normal. The blood pressure was 190 systolic, 120 diastolic.

The serum nonprotein nitrogen, protein and chloride were normal. Examination of the urine was negative. The white-cell count was 4100, and the hemoglobin 80 per cent. An oral Graham test was positive.

On the sixth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS D. MOORE: At the age of fifty-three this patient began to have gastrointestinal symptoms that were compatible with, although not typical of, gall-bladder disease. One year later a gallstone was shown to be present, and this was undoubtedly regarded as the cause of her symptoms. At the age of fifty-eight, two years before she came to the hospital, a new set of symptoms arose, which evidently had to do with the other end of the gastrointestinal tract, since the pain was in the lower abdomen and associated with diarrhea. It is true that she had had some diarrhea with her supposed gall-bladder attacks, but it apparently was not prominent. The new symptoms, however, were often relieved by the diarrhea, a train of events that strongly suggests an intermittently obstructing lesion.

Physical examination does not give us many clues but it does mention that the patient was obese and well developed, findings that one would not expect if she had had any sort of malignant tumor for either the two-year period or the seven-year period, accompanied respectively by the upper and lower gastro-

*On leave of absence.

On cholecystectomy and again after the operation. In both the ascending and transverse colon. When it was in the transverse colon, the cecum was elevated as though the advancing tumor had pulled the cecum after it—an intussusception, with the tumor itself leading. This, as Dr. Moore has stated, accounts for the fact that the usual dimple in the intussusceptum was not seen. This dimple is more frequently seen in children, for then a tumor is seldom present, the leading part being the bowel itself; in adults, an absence of the dimple is almost the rule. That the tumor was soft and compressible is shown on the film of the contracted bowel, the tumor being much longer and narrower than the stated measurements. The appendix lay in the right upper quadrant below the liver, where it presumably had been drawn upward with the cecum when the tumor was advanced by peristalsis.

PRESENTATION OF CASE

CASE 31122

First admission. A sixty-four-year-old Polish freight handler was admitted to the hospital with

jaundice.

The patient was in good health until three weeks

prior to admission, when he suddenly became

nauseated and vomited some whitish material. The

feeling of nausea lasted several hours, after which

he felt better. A few days later the nausea recurred,

accompanied by a "heavy feeling" in the epig-

astrium but no pain. He vomited several times,

and his appetite became poor. Two weeks before

entry, he noticed that his skin was becoming yellow.

At the same time his stools became light colored and

his urine dark. He stopped work and rested but

did not improve. The heavy feeling in his epig-

astrium persisted as the jaundice increased, and

he had two more attacks of vomiting. There was

no itching, chills, fever or change in bowel habit.

He lost about 8 pounds over a period of two weeks.

During this same period he noted slight ankle

edema, disappearing overnight.

The patient had had an attack of "double pneu-

monia" fifteen years prior to admission, following

which he continued to have a chronic cough, which

was worse in the morning and evening and pro-

ductive of about 30 cc. of white sputum each day.

He had never noted blood streaking or chest pain.

About twelve years before entry, following severe

trauma to the genitalia, the right scrotal sac had

remained enlarged, without alteration in

size.

Physical examination on admission revealed a

well-developed and well-nourished, deeply icteric

man in no distress. The fingers were clubbed. There

was bilateral marked arcus senilis, and the fundi showed moderate arteriovenous nicking. The chest resonance to percussion and diminished breath sounds and fremitus. Diffuse dry squeaks and rhonchi were heard, with sticky rales at the bases posteriorly. The heart sounds were distant. The liver was palpable three fingerbreadths below the costal margin, and the edge was smooth, sharp and nontender. The gall bladder could not be felt. The right scrotum contained a firm, 6-cm., nontender mass that failed to transmit light. A portion of the testis could be felt attached to the mass posteriorly. The temperature was 99°F., the pulse 70, and the respirations 20. The blood pressure was 120 systolic, 70 diastolic.

Examination of the blood revealed a red-cell count

of 3,650,000, with 12 gm. of hemoglobin, and a

white-cell count of 8000, with 78 per cent neutro-

phils. The smear revealed a hypochromic micro-

cytic anemia with many target cells. The urine had

a specific gravity of 1.020, with a ++ test for al-

bumin and a +++ test for bile and with a posi-

tive test for urobilinogen in a dilution of 1:2. The

sediment contained 10 to 15 white cells and an

occasional coarsely granular cast per high-power

field. The stools were clay-colored, soft and occa-

sionally guaiac positive. The serum protein was

5.7 gm. per 100 cc. with an albumin-globulin ratio

of 1:3. The van den Bergh was 15.2 mg. per 100

cc. direct and 26.2 mg. indirect. The prothrombin

time was normal, and the cephalin flocculation test

negative. A bromsulphalein test showed 100 per cent

retention. A galactose tolerance test, employing

the injection of 50 cc. of a 50 per cent solution of

galactose intravenously, revealed a blood level of

12.4 mg. per 100 cc. after 60 minutes, and one of

8.1 mg. after 75 minutes. The serum nonprotein

nitrogen was normal, and the chloride was 95

milliequiv. per liter. Agglutination tests with the

patient's serum against *Proteus vulgaris* X19, XK

and X2 and *Leptospira icterohaemorrhagiae* and

L. canicola were negative. The Hinton test was

negative.

A roentgenogram of the chest showed no

evidence of active disease in the lungs. The right

costophrenic sinus was obliterated, owing to old

adhesions. The heart showed no definite enlarge-

ment. A gastrointestinal series was negative.

Duodenal drainage was productive of 20 cc. of

whitish, translucent fluid in an hour. Half an hour

after the injection of 40 cc. of a saturated solution

of magnesium sulfate, another 20 cc. of similar fluid

was obtained. A smear of the sediment revealed no

sodium bilirubinates or cholesterol crystals, nor were

any bile-stained leukocytes seen. Culture revealed

abundant colonies of colon bacilli.

The patient was placed on a high-carbohydrate,

high-protein, high-vitamin, low-fat diet and given

bile salts (0.1 gm. Degaolol, three times a day). An

account for the lack of x-ray dimple and it might also suggest that, although the leading point was in the midtransverse colon, the actual amount of intussuscepted bowel was only a matter of a few centimeters above the ileocecal valve. The latter would make us feel more comfortable about the lack of evidence of bowel necrosis.

Such a smooth tumor could be a lipoma, fibroma, neurofibroma or lymphoma of the bowel wall. It would have to be in the terminal ileum or right at the ileocecal valve, because there is no evidence that the colon itself was being intussuscepted without pre-existing ileocecal intussusception.

Of these tumors, lymphoma is probably the most frequent, but lymphoma in the gastrointestinal tract tends to be multiple; even though occasional cases are recorded in which resection was curative, such cases are the exception. Furthermore, if this were lymphoma, I should expect that the patient would have had some bleeding from the region of the tumor itself.

I am therefore going to select a lipoma as the likeliest leading point for this intussusception. My diagnosis is intramural lipoma of the terminal ileum, with chronic ileocecal intussusception.

Possibly I am overlooking something in not trying to relate this lesion to the patient's antecedent gall-bladder disease. Although it is true that a gall-stone might have ulcerated through into the colon, I can see no reason why it should not have passed down to the rectum; furthermore, one would not expect that its attempted passage down the bowel would have produced retraction and shortening of the cecum. This latter chain of events, it seems to me, can be produced by intussusception or attempted passage of a long pedunculated submucosal tumor and by nothing else.

CLINICAL DIAGNOSES

Polypoid tumor of the right colon, with intussusception.
Cholelithiasis.

DR. MOORE'S DIAGNOSES

Submucosal pedunculated lipoma of the terminal ileum, with ileocecal intussusception.
Cholelithiasis.

ANATOMICAL DIAGNOSIS

Submucosal lipoma of ascending colon.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: At operation Dr. Allen carefully palpated the entire right colon and was unable to demonstrate the polyp that he had hoped to find. The bowel, however, had not been too well prepared. The bowel was not opened, and no resection was performed. There were dense inflammatory adhesions in the region of the gall bladder and the duodenum, and the hepatic flexure was

slightly adherent to this region. A shriveled, chronically inflamed gall bladder, within which was a 1.5-cm. stone, was removed. The common duct was not explored.

The patient left the hospital on the seventh post-operative day. Most of her symptoms were relieved for several months, but she still had occasional crampy abdominal pain to the right of the umbilicus.

FIGURE 2.

Another barium enema still disclosed the polypoid lesion in the colon, and it was decided to operate again.

Once more Dr. Allen was unable to palpate a tumor in the ascending and transverse portions of the colon. Using a needle, air was carefully aspirated from the large bowel and the needle hole was then closed. When the right colon was mobilized, an extremely soft tumor could be felt in the ascending colon. About 18 cm. of the terminal ileum and the right colon was resected, and an ileotransverse colostomy was performed.

The tumor proved to be, as Dr. Moore predicted, a submucosal lipoma measuring 9 by 6 by 4 cm.; it was attached by a mucosal stalk 3.5 cm. in diameter at a point 10 cm. distal to the ileocecal valve (Fig. 2). The tumor was soft, malleable and easily compressible, which accounts for the great difficulty the surgeons had in palpating it through the serosal surface.

Will you comment on the x-ray films, Dr. Schulz?

DR. MILFORD D. SCHULZ: This patient was examined on several occasions — twice prior to the

that we have seen positive Hinton tests in the presence of liver damage. I say that because two or three years ago I became interested in the subject and have a collection of 5 cases in which this was so, with no other evidence of syphilis to go with it.

We have excluded the first and second groups under the retention type of jaundice. I do not believe that it was a Hanot's type of cirrhosis because the appearance of the liver would have told us whether or not it was a hypertrophic biliary type. At the first exploration we are told that there was no obstruction. Yet I cannot escape the final conclusion that there was obstruction, that they found some sort of process that obstructed the biliary system and that a great deal of liver-cell necrosis was also present.

If I have to make a choice in the correct order I hardly know what to say. I believe that he had malignant disease, and my first choice is carcinoma. Where are we going to put it? He might have had metastases in the liver and in the spine causing peripheral nerve changes; it might have been primary in the testicle injured years before, or it might have been a primary tumor of the colon with metastases to the liver and somewhere along the common duct that caused obstruction. That is my first choice. My second choice is that he had that rare thing causing a positive guaiac test in the stools, a carcinoma localized in the duodenum around the ampulla of Vater. It could still be carcinoma of the pancreas, part of it involving the ampulla of Vater and head of the pancreas, and I am still supported in this by the positive guaiac test, and that is why I may reverse the order and put it down as my first choice. My third choice is a regurgitation-type necrosis of the liver, a severe form of the toxic group.

DR. CASTLEMAN: Your first choice is carcinoma involving the head of the pancreas?

DR. CHAPMAN: Yes, and the ampulla of Vater.

DR. CASTLEMAN: How do you explain the normal common duct at operation?

DR. CHAPMAN: One other thing I meant to bring out was the matter of the common-duct drainage. The first time it is described the sediment revealed no sodium bilirubinate, cholesterol crystals or bile-stained leukocytes. I think it was Bockus' who found that most patients with silent stone in the common duct show evidence by drainage of either bilirubin crystals or bile-stained crystals. In the last drainage, no bile was seen but there were a few bile casts and bilirubin crystals. Possibly, a silent stone jammed down toward the ampulla should be my fourth choice.

DR. CASTLEMAN: You still have to assume that the common bile duct was distended.

DR. CHAPMAN: But the patient did not have complete obstruction. Obviously he had intermittent

blood bilirubin. The first is the anoxic group — pernicious anemia, transfusion reaction, hemolytic jaundice, paroxysmal hemoglobinemia, phenylhydrazine poisoning and other types of blood disease that produce hemolysis. The second group comprises febrile diseases, and the attending physicians thought of this because they looked for positive agglutination tests with *Leptospira icterohemorrhagiae*, *L. canicola* and various strains of *Proteus vulgaris*. The third group is Hanot's cirrhosis of unknown cause.

Then we come to the regurgitation type. Here, the plasma gives a direct van den Bergh reaction because it contains bile that has backed up secondary to obstruction of the biliary tract, possibly with injury to the bile canaliculi. This may be due to three causes — necrosis of the liver cells, frank obstruction in the biliary system and catarrhal jaundice, cause undetermined. The necrosis of liver cells from toxic agents may cause jaundice of either kind or of both types together.

The patient was a Polish freight handler, and although he may have been a heavy drinker, there is no history of alcoholism, so we have no cause to think of alcoholic hepatitis with liver-cell necrosis. Now let us go back and look at the laboratory evidence and fit it into this classification. The laboratory tests do not favor the retention type as well as the regurgitation type. In favor of the retention type are the target-cell anemia, the urobilinogen, the negative duodenal drainage and the high indirect van den Bergh. In favor of regurgitation jaundice are the bile in the urine in consideration jaundice, the high phosphatase, which goes with liver damage and especially necrosis of liver cells, and the final duodenal drainage before operation, because the record clearly describes cholesterol crystals and bile casts but no bile. Obviously these laboratory data do not give us the answer.

What are the clinical facts, divorced from the laboratory data, that help us arrive at a diagnosis? He was a sixty-three-year-old man who had had a tumor of the testis, who was jaundiced and who had a big spleen and liver. He undoubtedly had necrosis of the liver cells, because we know that he improved after exploration. Then came pain over the liver, more jaundice, weight loss and the appearance of general weakening and certain reflex changes in the leg. He developed a positive Hinton test, and above all he had guaiac-positive stools. I am so glad to get complete data on that because it is an important observation and outweighs all the laboratory evidence that was presented. This man had blood in his stools. Where was that blood coming from? From the gastrointestinal tract? Or is it possible for the necrosis of the liver cells in the regurgitation type to be severe enough to cause a positive guaiac test in the stools? As for the positive Hinton test, I am going to dismiss syphilis. I know

exploratory laparotomy was performed on the ninth hospital day. The liver presented an unusual granular mottling and seemed edematous, suggesting some form of hepatitis rather than cirrhosis. The gall bladder was normal, readily compressible and no stones were present. The head of the pancreas was soft. The common bile duct was of normal size and appearance. No biopsy specimen was taken.

Following the operation the patient seemed to improve. The van den Bergh gradually fell to 5.8 mg. direct and 8.8 mg. indirect, the stools became light brown, but no urobilinogen was present in the urine. He was discharged on the forty-third hospital day, to be followed in the Out Patient Department.

Second admission (ten weeks later). Following discharge, the patient continued to improve for about a month. The jaundice became less noticeable but never disappeared, and he gained a few pounds. About six weeks prior to admission he began to feel weak, with attacks of pain in the right upper quadrant and epigastrium, which were often stabbing in character, and occasional nausea. His stools again became light colored. He developed some unsteadiness of gait. At about that time, the van den Bergh was 15.8 mg. direct, and the serum protein 6.31 gm. per 100 cc., with an albumin-globulin ratio of 0.83. The cephalin flocculation test was negative, and the urine contained no urobilinogen.

On readmission the patient appeared cachectic and still deeply icteric. The liver was four finger-breadths below the costal margin and slightly tender. There was evidence of a small amount of fluid in the abdomen, and minimal pitting edema of the ankles was present. The deep tendon reflexes were hypoactive in the upper and absent in the lower extremities. There was a questionable extensor plantar response on the left.

A roentgenogram of the chest revealed no definite change from the previous examination. A gastrointestinal series showed considerable curling of the esophagus but no definite varices. The liver was enlarged, and the spleen slightly enlarged. The stomach was slightly compressed by the liver and spleen and showed rather marked thickening of the mucosal folds.

The serum protein was 5.76 gm. per 100 cc., with an albumin-globulin ratio of 0.73. The van den Bergh was 12.4 mg. direct and 13.6 mg. indirect. The cephalin flocculation test on one occasion was \pm after twenty-four and $++$ after forty-eight hours, and on another occasion negative. The alkaline phosphatase was 34.8 units per 100 cc. The prothrombin time, serum nonprotein nitrogen and chloride were normal. The cholesterol ranged from 147 to 250 mg. per 100 cc. The blood Hinton and Wassermann tests were positive. Urine examination revealed a $++++$ test for bile and numerous tyrosine crystals. Urine urobilinogen varied from

negative to positive in a dilution of 1:16. Duodenal drainage revealed a few bile casts and bilirubin crystals but no bile. The stools were light brown and occasionally guaiac positive.

On the thirty-first hospital day a laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. EARLE M. CHAPMAN: "The stools were clay colored, soft and occasionally guaiac positive." I should like to know how many stools were guaiac positive.

DR. BENJAMIN CASTLEMAN: The first stool examination was guaiac negative; the second, positive; the third, $++$; the fourth, $+$; and the fifth, negative.

DR. CHAPMAN: That is an important contribution.

It is interesting that this man had disease in the chest. The x-ray does not reveal it. Physical examination says that rales were present, and I think that rales are a sign of disease. This case I believe is the epitome of the diagnostic problem, because one is presented with laboratory evidence which at one and the same time indicates an obstructive process and a nonobstructive type of jaundice. Obviously the attending physicians were puzzled as to which it was, for the first time they made a great effort to prove that it was obstructive and later on that it was nonobstructive. On the first admission, they must have been convinced that it was obstructive because the evidence leans more on that side and the patient was explored. But still the surgeon failed to give them a diagnosis. I want to pause and say that a biopsy of the liver at the first exploration would have been helpful.

The next thing I want to point out is that the head of the pancreas was described as soft. It has always been my opinion that the head of the pancreas is hard and firm and that at operation the surgeon sometimes has difficulty distinguishing the normal head of the pancreas from carcinoma.

Following exploration the patient improved. That is revealing and throws the diagnosis over into the nonobstructive field. I am sure that was the thought when he left the hospital. He finally returned and seemed to go back into the obstructive category, because he was again explored.

In going through the steps of making a diagnosis, it is helpful to use Rich's¹ classification of jaundice. He distinguishes two major types, retention jaundice and regurgitation jaundice, the latter being the obstructive and the former the nonobstructive, based on the fundamental pathology of the process. In retention jaundice the bilirubin is increased in the plasma, and since all of it is not removed by the liver cells an indirect van den Bergh reaction results. With this increase in blood bilirubin the kidneys excrete an increased amount of urobilin. What causes this? Three groups of disorders increase

involve the hepatic ducts, the extrahepatic ducts, the cystic duct and the ampulla of the gall bladder. DR. CASTREJAN: The patient died following the operation, and at autopsy we found a tumor involving both hepatic ducts. It had apparently begun in one of the hepatic ducts and had extended out into the hilus for a few centimeters so that Dr. Wallace could feel it, but it had also involved the cystic duct. Beyond the tumor there was 6 cm. of perfectly normal uninvolved common bile duct. The tumor, which proved to be an adenocarcinoma, had spread through the lymphatics to involve the surface of the body and tail of the pancreas, but the head of the pancreas was perfectly normal. This patient also had bronchiectasis and a cyst in the tail of the pancreas. There was no evidence

Peritoneoscopy showed severe bile stasis, biliary cirrhosis and marked dilatation of the bile ducts. We found a bile duct measuring 2 or 3 mm. in diameter in the biopsy specimen, which must have been taken from the periphery of the liver, so that this patient really had a hydrophepatosis. There was definite bile-duct proliferation (Fig. 1). Following this procedure, Dr. Wallace operated. He might tell us what he found. DR. RICHARD H. WALLACE: I explored this patient on both occasions. I was much interested the first time because two days before I had operated on a woman with painless jaundice and removed a common-duct stone. This is especially noteworthy because of the relative infrequency of painless jaundice with common-duct stone. In the series

FIGURE 1. Photomicrograph of Liver.

of the diffuse cystic disease of the pancreas that is occasionally seen in children and that may be associated with bronchiectasis. In both lower lobes the bronchi were distended to the very periphery of the lobes and contained large quantities of viscid yellowish-green material.

DR. WALLACE: This man, who had an obstructive jaundice, had no chills or fever either at the first admission or at the second, nor did he give a history of any in between times. I wonder if that would have been helpful if that had been brought out. DR. JOYES: I do not know. It is surprising that he did not have elevation of the temperature, because in patients with metastatic or primary involvement of the liver with new growth, fever is frequently an essential part of the picture.

DR. CHAPMAN: As a teacher of physical diagnosis I should like to emphasize, and I am sorry that Dr. Merrill Sosman is not here, that here we have still

that Dr. Allen and I reviewed less than 2 per cent of the patients with common-duct stones were without pain. At the first exploration, I found a normal gall bladder, a normal common duct and a normal pancreas, and except for the abnormal liver findings, the exploration was entirely negative. Following the biopsy of the liver by Dr. Benedict it was brought out that possibly there was a common-duct stone without a dilated common duct, which I had never seen. We rather hoped that we might find this at the second exploration. At that time, the gall bladder was still collapsed and on aspiration perfectly clear white mucoid material was obtained. The common duct was normal, the liver was smooth, there was a hard nodular mass that was not present at the first exploration. During the six-month interval between explorations it had grown down to

obstruction because he was well after the first operation. Manipulation and pressure may have forced drainage around it.

DR. WILLIAM W. BECKMAN: I was impressed at the time of admission, before the laboratory work was done, by the fact that he stated that one day he was completely well and the next day he was sick and started to vomit. After a week he noticed jaundice. This seemed to me to be in favor of hepatitis of some sort. The laboratory data did not seem to support that diagnosis. Finally, an exploration was performed and I was delighted that my original idea was supported. I thought that he certainly had hepatitis but could not understand why he did not get better after two months. He was readmitted and there was a great deal of controversy, but we finally decided to re-explore.

DR. JACOB LERMAN: There are always differences of opinion about some clinical points. I saw this man in the Out Patient Department. A routine follow-up note said that he was better. I was quite sure that he was not, because the jaundice was just as severe, although the color of the skin had changed. It turned brown rather than green. I thought that his jaundice was complete and persistent and had not changed much since his stay in the hospital. The stools were noted as occasionally clay colored but usually brown. We checked that by doing bile determination on the brown stools and found that they did not contain any bile. Consequently the chances are that they were always equivalent to clay-colored stools.

DR. CHAPMAN: How did you know they were brown?

DR. LERMAN: They looked brown to the examiner and to the patient.

DR. CHESTER M. JONES: I saw the patient toward the end of his stay on the first admission and later on in the second admission. My feeling was much like that of Dr. Beckman, — that he had an acute episode of damage to the liver which might well have been on an infectious basis, — and I thought he ought to be treated for liver failure rather than anything else.

I remember seeing the first specimen of duodenal contents, and there is little reason to believe that the interpretation of the sediment was incorrect. There was no evidence of bile pigment, bile casts or crystals. In other words, no bile was obtained. I do not know about the second drainage. When I first saw this man I thought the picture was that of infection and I did say that there might be an intrahepatic block due to the type of infection that goes with infection of the common duct — cholangitis. Dr. Wallace's description at the time of the first operation was entirely consistent with a biliary type of obstruction that had not arrived at cirrhosis but presented a smooth, finely granular liver, with mottled discoloration.

The second time I saw him I still thought he had primary intrahepatic disease and that such was going to be found. If the biopsy at that time showed a biliary type of involvement, one had a right to explore the common duct again to see if there was any local tumor or other obstruction, such as a gallstone.

About the positive guaiac in the stool, the presence of occult blood can be found in any type of jaundice, regardless of its nature. It is found commonly if the jaundice is severe and of long standing. I think that it is not of diagnostic significance. In a group of seriously jaundiced patients there was a positive guaiac test in at least 40 or 50 per cent. This finding of occult blood is probably due to the fact that there is a tendency to spontaneous bleeding associated with a lack of prothrombin.

DR. FLETCHER H. COLBY: Did I understand that you seriously considered tumor of the testicle as the primary focus, with metastasis in the liver, as well as somewhere in the common duct and spine to explain the reflex changes? Would it not be unusual to have tumor for twelve years and not to have it metastasize before this? He was operated on and the surgeon found no demonstrable disease in the region of the gall bladder. We had one somewhat similar patient at the Huntington Hospital, who, nine years before, had been given heavy external radiation. The only symptom of recurrence that this man had was jaundice. He was operated on with a diagnosis of possible gall-bladder disease, and he had a huge mass pressing on the common duct, a metastasis from the testicular tumor.

DR. JONES: Infiltration of the liver would not cause this picture.

CLINICAL DIAGNOSIS

Carcinoma of hepatic ducts.

DR. CHAPMAN'S DIAGNOSIS

Malignant disease: (?) carcinoma of head of pancreas, involving ampulla of Vater, (?) carcinoma of colon, with metastases to spine, liver and about common duct, (?) carcinoma, metastatic, to liver and about common duct from testicular tumor.

Common-duct stone?

ANATOMICAL DIAGNOSES

Adenocarcinoma of hepatic ducts, with metastases to pancreas.

Cirrhosis of liver, obstructive type, with acute hepatitis.

Bronchiectasis.

Cyst of pancreas.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Dr. Wallace operated on this man after a peritoneoscopic biopsy had been done.

Peritoneoscopy showed severe bile stasis, biliary cirrhosis and marked dilatation of the bile ducts. We found a bile duct measuring 2 or 3 mm. in diameter in the biopsy specimen, which must have been taken from the periphery of the liver, so that this patient really had a hydrophepatosis. There was definite bile-duct proliferation (Fig. 1). Following this procedure, Dr. Wallace operated. He might tell us what he found.

Dr. RICHARD H. WALLACE: I explored this patient on both occasions. I was much interested the first time because two days before I had operated on a woman with painless jaundice and removed a common-duct stone. WHAT SHALL WE DO ABOUT CANCER?

Can we afford to wait for a miraculous cancer cure to appear? Ten million Americans now alive will die of cancer unless we discover methods of therapy that are more effective than those now available. Six million more will die unless our present knowledge is more effectively implemented and applied. Improvements in the therapy of cancer may come by chance, but earnest effort by competent, well-equipped workers will do much to increase such a chance. The limiting factor on cancer research is money, and the limiting factor on dissemination of knowledge about cancer is inertia. Both these bid fair to be removed.

When penicillin is given by mouth, it is largely inactivated in the gastrointestinal tract or remains unabsorbed so that only extremely low levels are attained in the circulating blood and only a small proportion of the ingested drug is excreted into the urine.¹ It has therefore seemed impracticable to use penicillin by the oral route. When given parenterally, penicillin is rapidly excreted into the urine, so that it must be given either by constant intravenous infusion or by frequent intramuscular injection. Each of these methods is objectionable. The constant intravenous drip requires careful regulation of the flow and, hence, constant supervision. It also necessitates the intravenous administration of moderate to large volumes of fluid, which may be undesirable in certain types of patients. Furthermore, thrombosis of the veins occurs quite regularly; this necessitates frequent changing to other veins and also carries with it a not inconsiderable danger from embolism. Thrombosis of the vein during therapy may also interrupt the flow of penicillin unless the condition is recognized

PROLONGING THE ACTION OF PENICILLIN

importance of the problem to be solved. must be supported and staffed in proportion to the out the country; furthermore, these institutions situations must be established at key points throughout this campaign succeed, but research in- and to provide service for cancer sufferers. Massachusetts, through its cancer-control program administered by the Department of Public Health and sponsored by the Massachusetts Medical Society, has gone a long way to see that knowledge about cancer is effectively utilized. Even this phase of the task, however, is far from completed.

early and the needle reinserted elsewhere. When the intramuscular route is used, absorption is prompt and the drug is rapidly eliminated into the urine so that effective concentrations are difficult to maintain for more than two or, at most, three hours. In severe cases of staphylococcal or *Streptococcus viridans* infections it is often necessary to give 20,000 or 25,000 units every two hours. This means the injection of a volume of 4 or 5 cc. each time, since the use of penicillin in greater concentrations than 5000 units per cubic centimeter often produces excessive local irritation. Furthermore, since it is necessary to repeat the injections throughout the day and night, the patient can have no continuous period of rest, and a physician or trained nurse must always be available to give the injections.

One of the major problems in the use of penicillin, therefore, has been concerned with methods that would simplify its administration both for the patient and for the attending physician and nurses. Several methods have been suggested. These have as their purpose either delaying excretion of the drug by the kidneys or prolonging its absorption from the local site. In either event the attempt is made to maintain an effective level for a longer period after injection or with a smaller amount of penicillin.

One of the methods that has been suggested for accomplishing the first of these purposes involves the principle of "excretory blockade." Rammelkamp and Bradley² showed that the excretion of penicillin in the urine was depressed by the simultaneous injection of Diodrast. Para-aminohippuric acid is rapidly excreted by the kidneys and, like Diodrast, has been used in tests of renal function. The former has been used by Beyer and his associates³ to produce the same result that Rammelkamp and Bradley demonstrated with Diodrast. By intravenous injection of this compound together with penicillin it was found possible to attain and to maintain materially higher concentrations of penicillin in the circulating plasma of animals than are practical without the use of excessive amounts of penicillin. Toxicologic studies indicated that the *p*-aminohippuric acid is nontoxic to mice, rabbits and dogs in the amounts necessary to produce this effect. Previous use of this compound in human beings

has been limited to short periods during renal-function tests; hence, the effects of continuous use, particularly in patients with severe infections, is not known, but clinical trials are in progress. No matter how the results of these trials turn out so far as indicating the feasibility of the method or the toxicity of the compound, this type of therapy is obviously not desirable or practical. Although it reduces the dosage of penicillin, it does not obviate the need for constant intravenous infusion. Indeed, careful regulation of the rate of injection of the two compounds simultaneously makes the proper use of this method even more difficult and requires even more constant supervision and control than does the injection of penicillin alone.

Another method involves the intramuscular injection of penicillin in a medium from which it is slowly absorbed. After trials with various oils and other substances, Romansky and Rittman,⁴ at the Walter Reed Hospital, have found mixtures of beeswax and peanut oil to be the most satisfactory for this purpose. Preparations of penicillin in this mixture were shown to be quite stable and did not deteriorate when kept at refrigerator, room or body temperature for a period of thirty to sixty-two days. In initial experiments in rabbits, it was found possible to maintain satisfactory levels for six to twelve hours with this mixture, whereas with the same amount of penicillin given in saline solution an effective level was maintained for only two hours. In human subjects, single injections of 41,500 and 66,400 Oxford units were given in 2.0 to 2.4 cc. of the beeswax-peanut oil mixture. Measurable levels were maintained in the blood for six to seven hours, and penicillin was excreted into the urine for twenty to thirty-two hours, indicating that some penicillin was retained in the blood throughout that period. In preliminary trials these workers obtained clinical and bacteriologic cures in 11 of 12 patients with acute gonorrhea by a single injection of penicillin in the beeswax-peanut oil mixture, whereas single injections of a similar amount of penicillin in saline solution were only rarely successful.

A third method that has been suggested involves the use of a continuous intramuscular infusion.⁵ Such a continuous drip requires a minimum daily volume of 1000 cc., since it is difficult to control

the rate of flow with smaller amounts of fluid. The flow may be regulated at 12 to 15 drops per minute or 50 cc. per hour and can be adjusted so that the total daily volume delivers 100,000 units of penicillin or any other desired amount. Apparently, the rate of delivery, and hence of the absorption, of penicillin by this method is even more difficult to regulate than with intravenous injections. It has therefore been suggested that the needle be left in situ and that the flow be interrupted at regular intervals. Even with this modification the method is not particularly desirable since it requires considerable manipulation and many adjustments, as well as resulting in local discomfort. Apparatus that permits the continuous daily injection of as little as 100 cc. of a solution has been devised by Scottish workers⁷ who claim that its use demands little attention.

A simple method of delaying absorption from the ordinary intramuscular injection has been suggested by Trumpeter and Hunter,⁸ of the National Naval Medical Center. These workers have made use of local chilling by means of an ice bag placed over the site of the intramuscular injection for a period of one or two hours before and for five to twelve hours after each injection. A harness is applied to keep the ice bag in place, and the ice is changed every three or four hours. With a single injection of 50,000 to 100,000 units given in this manner they have been able to maintain effective blood levels for five or six hours, as compared with two and a half hours when the same amounts are given intramuscularly without cold applications. By the use of this method cures of acute gonorrhea have been obtained quite regularly with a single injection of 50,000 units of penicillin. This method, however, is cumbersome and does not seem feasible for prolonged therapy.

It is possible that the addition of a vasoconstrictor drug to the penicillin given in a medium in which it is absorbed slowly will result in a further delay of absorption. Adrenalin and longer acting vasoconstrictor drugs, together with gelatin, have been shown to prolong the action of penicillin.⁹⁻¹⁰ None of the methods thus far proposed, however, have as yet received adequate clinical trial, particularly in severe infections that require the maintenance of significant blood levels over considerable periods.

MASSACHUSETTS MEDICAL SOCIETY
COMMITTEE ON LEGISLATION

The following copy of Judge Cabot's decision concerning a petition brought by the Trustees of Middlesex University seeking to revise and reverse the decision of the Approving Authority regarding Middlesex University School of Medicine will undoubtedly be of interest to many members of the Society.

William E. Browne, Chairman

COMMONWEALTH OF MASSACHUSETTS

SUFFOLK, SS:

SUPERIOR COURT
No. 393180

IN RE THE TRUSTEES OF MIDDLESEX UNIVERSITY

Findings, Rulings and Order for Decree

This is a petition brought by the Trustees of Middlesex University under the provisions of General Laws, Chapter 112, Section 2, as amended by Statute 1936, Chapter 247, seeking to "revise and reverse the decision of the Approving Authority" created by that statute. The petitioner is a corporation chartered by statute in 1937 and operates a medical school called the Middlesex University School of Medicine (hereinafter usually referred to as Middlesex). Although no party respondent is named in the petition, an order of notice was issued to Dr. H. Quimby Gallup, secretary of the Board of Registration in Medicine, and the Approving Authority, appeared by the Attorney General, and the proceeding was conducted as an adversary one against that body with full scope to each to cross examine witnesses, introduce evidence and in general to be heard as would opposing parties in a suit in equity.

In the first place, it is pertinent to examine briefly the statute above referred to so that the nature of the proceeding should be made clear. The act makes it a condition precedent to the right of any person to take the examination to become a licensed physician that he shall have received a degree of doctor of medicine from an "approved" medical school. Paragraph two of the act allows any medical school to request the Approving Authority to make an inspection of it whereupon it becomes the duty of that body to inspect and either approve the school or notify it what steps it must take in order to gain approval. It is to be noted that there is no provision under this paragraph for a final determination of disapproval. The next paragraph of the act gives a school the right to request approval from the Approving Authority, and it then becomes the duty of the latter, after holding a public hearing, to approve or disapprove. It is to be noted that there is no duty imposed upon the Approving Authority either to make an inspection or a decision as to approval unless so requested although, on the other hand, there is no prohibition to its granting approval without a request. Thus, a school may request inspection, in which case it may receive either approval or a direction as to what it must do to gain approval without incurring the risk of a final decision. Only after the school itself requests a final decision does it incur the risk of disapproval. Only after such final decision of disapproval or withholding approval does the school have the right to file a petition in the court to "revise and reverse the decision of the Approving Authority." The statute as finally extended became operative as to persons who entered a medical school on or after January 1, 1941.

Middlesex first requested an inspection in May, 1941. Pursuant to this request the Approving Authority made an inspection on May 28, 1941, and by letter dated August 1, 1941, notified Middlesex that in order to gain approval it would have to take the following steps:

- (1) Its Board of Trustees shall be reorganized so that the management and control of the medical school shall be vested in trustees who are unquestionably qualified to manage, control and administer such an important institution as a medical school.
- (2) The dean shall be one who is recognized as having had experience in the broad field of medical education and who possesses executive and administrative ability.
- (3) The medical school shall have financial resources adequate for providing medical education which meets generally accepted present-day standards.
- (4) There shall be a faculty of which a majority of the members thereof have attained such eminence in their profession that they are so recognized by their fellow workers in their specialties.
- (5) There shall be adequate clinical material available for teaching purposes for all branches of medicine, with special emphasis on medicine, surgery, pediatrics and obstetrics.
- (6) The facilities, both in space and equipment, for research shall be substantially increased.

Early in 1943, Middlesex again requested an inspection, which was made on April 2 and May 25, 1943, and by letters dated June 25 and July 23, 1943, the Approving Authority notified it that it was deficient in the following respects:

- (1) Although the administrative organization and personnel have undergone changes, they are still inadequate for accomplishing the objectives of the institution.
- (2) The medical school has not the financial resources to provide adequate medical education.
- (3) The faculty falls below acceptable standards in numbers and quality.
- (4) There are insufficient clinical facilities for the teaching of the various branches of medicine.
- (5) The facilities in the Library are inadequate in number and selection.

Again on June 20, 1944, the Approving Authority inspected the school pursuant to its request, and by letter dated July 13, 1944, notified it that the following steps were necessary in order to gain approval:

- (1) That the quality and number of the faculty should be improved.
- (2) That the amount of clinical material available for teaching purposes should be increased.
- (3) That the financial resources of the medical school are not sufficient to provide adequate education and that these resources should be greatly increased.
- (4) That the administrative organization and personnel is still inadequate for accomplishing the objectives of the institution.

At some time shortly before July 17, 1944, Middlesex filed, with the Approving Authority, a written request for approval. Thereupon a hearing was set for July 17, 1944, Middlesex was duly notified, and the hearing was held on that date in the Gardner Auditorium in the State House where all persons desiring to be heard were heard. Middlesex was represented by its attorney who presented such persons as he desired to present the case of the school for approval. Other persons gave their views, and although they were not cross examined by the attorney for Middlesex, there is nothing to indicate that he could not have done so had he desired. The hearing was more in the nature of those that are commonly held by the committees of the legislature than of the kind familiar in judicial proceedings. By letter dated July 20, 1944, the Approving Authority notified Middlesex that "the Middlesex University Medical School is not approved by the Approving Authority for the purposes of Section 2 of Chapter 112 of the General Laws as amended." It is this decision that this petition filed in this court on August 16, 1944, seeks to "revise and reverse."

The statute provides that "the court shall hear the case and finally determine whether or not such approval shall be granted or revised." Inasmuch as there can be a petition in this court only if approval is denied by the Approving Authority it is difficult, if not impossible, to understand how "such approval" can be "revised" even if that word is construed as "review" as it was in a different statute in Ott v. Board of Registration in Medicine, 276 Mass. 566. It is not so difficult to give effect to the word "revise" as it is used in that portion of the statute which gives an institution aggrieved by an adverse decision of the Approving Authority the right to file a petition "to revise or reverse the decision of the approving authority." Here a construction of the word "revise" as "review" would indicate that the jurisdiction of this court is limited to a re-examination of proceedings already had before the Approving Authority rather than an entire retrial such as would arise on appeal. The point need not be decided, however; because from the outset of the trial before me the parties were fully heard both upon the aspect of a review of the proceedings already had and a trial of the merits of whether Middlesex should be approved or not and because my decision is the same whichever is the proper construction of the statute.

A review of the proceedings of the Approving Authority indicates no reason why its decision should be revised or reversed. A public hearing was held seasonably after the request for approval was filed by Middlesex, which was given due notice of it and was heard without restriction. Within twenty

available spends per year much more than the amount of the tuition, the lowest spent by any of the above three schools being something more than \$800 per year per student. Although on the other hand, for the year ended June 15, 1944, had a total income, all from tuition fees, of \$190,106.30 and spent \$180,919.10 including the sum of \$45,271.61 for administrative expense, which is an anomalously high compared, for example, with about \$15,000 administrative expense for Boston University. I am satisfied and so find that, unless there are some unusual circumstances not here present, it is necessary for a medical school to spend an amount in the neighborhood of \$800 per year per student in order to give a proper medical education.

The graduates of Middlesex have in the past year collected some \$50,000 for its use, but only \$5000 has so far been actually turned over to the school. They hope to raise \$50,000 per year hereafter, but so far that is a hope rather than a reality. A parents' association has raised some \$200,000, but this is to be turned over to the school only if it receives approval. Regardless of what the future may hold the present financial backing of the school is far below what is necessary to give an adequate medical education.

(2) The quantity of the faculty is not sufficient. The school has in recent years been able to obtain for its teaching staff a number of European refugees who are well qualified in their particular fields. By and large the qualifications of its teaching staff are satisfactory. It is in numbers that it is deficient. At present there are 45 teachers for a student body of about 340. This compares with Harvard having 87 teachers for 525 students, Tufts 43 for 404 students, and Boston University 190 for 255 students. The chief difficulty in obtaining more teachers is again financial. Middlesex uses too high a proportion of its available funds for administrative expenses and does not have sufficient funds to hire a sufficient number of teachers. Clearly 340 medical students cannot be adequately trained by a teaching staff of 45.

(3) The most serious deficiency of all is Middlesex's almost complete lack of clinical facilities for teaching. The modern method of teaching medical students is in great part the observation of sick patients under the guidance of a doctor who is not only a trained practitioner but a teacher as well. In order to do this a medical school must have a connection with one or more hospitals having a sufficient number of so-called "teaching beds." The typical curriculum of a medical school involves for the first year lectures, laboratory work and general demonstrations in hospitals; for the second year the same as the first with the addition of some clinical teaching in hospitals; for the third year almost entirely clinical teaching; and for the fourth year entirely clinical teaching. Frequently, indeed usually, the teacher appointed by the medical school and on its faculty also holds an appointment on the staff of the hospital. Thus he has a double duty — to care for patients in the hospital and to instruct groups of students who go with him as he sees these patients in rounds. A very large number of "teaching beds" is required both because the students have to be taught in small groups and because a small number of beds would not produce a sufficient variety of human ailments. Harvard, for example, for its 525 students has 1872 "teaching beds," and Tufts and Boston University on a comparable basis somewhat less. The only hospital with which Middlesex has a similar connection and where persons are paid by it to instruct students at the bedside is the Brockton Hospital, which has a total of 45 "teaching beds." Fourth-year students at Middlesex each have about two weeks' training at this hospital and they also have a short period as "clinical clerk" in a number of other small hospitals. A "clinical clerk" does certain clerical examinations at hospitals and generally assists practicing doctors and interns in those hospitals. Although these "clinical clerks" from Middlesex usually act under the supervision of "clinical preceptors" those persons are not employed by or on the teaching staff of the school and have no actual responsibility for the training of the students. Without doubt these "clinical clerkships" are of value to the student but they fall far short of the value received from organized teaching in hospitals. Middlesex has made strenuous efforts to improve its facilities for clinical teaching but has had little success due to various obstacles not the least of which being the fact that it is not an approved school. The fact remains, however, that at the present time its clinical facilities are grossly inadequate for proper medical education.

days after the hearing it made its decision in writing and notified Middlesex of such decision. The statute requires nothing more. On the other hand, it does not limit the Appointing Authority to a consideration of such matter as may be brought out in the public hearing. Obviously, it might, from its three previous inspections of Middlesex. From its inspections and study of other medical schools both within and without this commonwealth it had a basis for a comparison of the medical education given at those schools with that given at Middlesex. Two of the members of the Appointing Authority are themselves licensed practitioners of medicine and by the very nature of their official positions are presumed to be and in fact are well qualified to judge the kind of education necessary to produce an adequately trained doctor. The third member, although not a specialist in the field of medical education, is a specialist in the field of general education. Both he and the other members of the board are by training and experience far better qualified to pass on the merits of medical education than is this court. They acted fairly and conscientiously and with rigorous regard to the provisions of the statute under which they acted. If this be merely a proceeding to review the proceedings of the Appointing Authority its decision must stand.

If the jurisdiction of this court is not limited to a mere review of the proceedings of the Appointing Authority but includes an entire trial of the issue as to whether Middlesex be approved or not the decision must be the same. The statute lays down neither for the Appointing Authority nor for this court any guide by which approval should be granted or withheld. Obviously, however, it is designed to make sure that the people of this commonwealth get as good medical care as possible and the fundamental consideration must be that all persons who are licensed to practice medicine are adequately trained for that purpose. It is equally obvious that the purpose of the statute was not to allow as many medical schools to exist (and it is hard to see how one could exist for many years without approval) as there may be students who would like to attend unless such schools give an adequate medical education. The Legislature has recognized that the mere passing of an examination is not a sufficiently adequate basis on which to allow one to practice medicine and has therefore provided that a prerequisite to taking the examination must be a proper premedical and medical training. Whether the training which any particular school may give is adequate must in great part depend upon a comparison with the training that other schools give. It must be judged in the light of present-day standards of medical education having regard to the health of the residents of the Commonwealth. Not only the best school or schools are entitled to approval, but somewhere the line must be drawn between a school which is sufficiently adequate and one that is not. A school which years ago might have been the best in the country would not today, had it not kept reasonably abreast of general improvement, be entitled to approval. My decision is, therefore, primarily based upon a comparison with other medical schools concerning which evidence was produced. These were primarily the medical schools of Boston University, Harvard and Tufts.

It would serve no useful purpose to recount these very considerable number of aspects which might, standing by themselves, entitle Middlesex to approval, for there are three aspects in which it is fatally deficient. Nor would it be helpful or material to point out the difficulties Middlesex has had in overcoming these deficiencies in spite of a very genuine attempt in recent years to improve its standards. Nor is it material to consider what it might be in months or years hence even though it be recognized that the very fact of approval would remove some of the obstacles with which the school is faced in its attempt to improve itself. Middlesex, not the Appointing Authority or this court, chose the time at which it would seek approval and this court must view it as it now is and not as it has been or may become.

The fatal deficiencies are these:

(1) The school has not adequate financial backing. Substantially all of its income is derived from tuition fees paid by students. These are \$450 per year per student, which is not out of line with the tuition fees in other schools. Tufts being \$500, Boston University \$475 and Harvard \$400. But each of these other schools by reason of having other income

Although I have treated this petition as a matter sounding in equity, it is not clear whether it is a proceeding in equity or one at law. In order, therefore, to adequately protect the rights of the parties I pass upon their requests for rulings of law as follows:

The petitioner's requests numbered 1, 2, 3, 4, 5, 16 and 17 are denied and all others granted. The requests of the Approving Authority are all denied.

A decree may issue affirming the decision of the Approving Authority.

SUPPLEMENTAL FINDINGS OF FACT

In the document entitled "Findings, Rulings and Order for Decree" it is stated, "Middlesex, not the Approving Authority or this court, chose the time at which it would seek approval." Nothing in these supplemental findings is intended to modify that statement. It is, however, clear that Middlesex chose the summer of 1944 as the time to ask for approval in order that the students might be able to file applications to take the examination to become licensed physicians which was to be held in November of 1944.

The class graduating from Middlesex in July, 1944, embraced in major part the first students who had originally matriculated in the school after January 1, 1941. The graduation of these students would normally have taken place in June or July of 1945, but because the school had, in common with other medical schools by reason of war exigencies, accelerated its program, the course for these students was completed in July of 1944. Thus, the adoption by the school of the accelerated program deprived it of additional time which it would otherwise have had before asking for approval to enable those students who matriculated on or after January 1, 1941, to take the state examinations and thus it was also deprived of almost a year in which to continue to endeavor to improve the standards of the school.

COMMITTEE ON POSTWAR PLANNING

On March 7, a meeting of the Committee on Postwar Planning heard a report from the Subcommittee on Hospitals that comprised a consideration of the requirements for hospitals providing internships and residencies in the postwar era. It is recognized that many hospitals in the Commonwealth badly need interns and residents and wish to organize staff personnel to provide the proper educational experience for such men. The Committee on Postwar Planning is eager to receive questions and suggestions in this field and will gladly communicate with hospital representatives or appropriate committees of district societies.

HOWARD F. ROOT, *Chairman*
LEROY E. PARKINS, *Secretary*

NEW HAMPSHIRE MEDICAL SOCIETY

DEATHS

HAWKINS — Frederick L. Hawkins, M.D., of Meredith, died November 8. He was in his eighty-fourth year. Dr. Hawkins received his degree from Jefferson Medical College of Philadelphia in 1886. He was a member of the Belknap County Medical Society and the New Hampshire Medical Society.

His widow survives.

NORMANDIN — Armand Normandin, M.D., of Iaconia, died February 14. He was in his fifty-ninth year.

Dr. Normandin received his degree from the University of Montreal in 1911. He was a member of the Belknap County Medical Society, the New Hampshire Medical Society and the American Medical Association. He retired from active practice in 1944.

His widow, three sisters and three brothers survive.

OBER — Charles F. Ober, M.D., of Manchester, died January 29. He was in his ninety-seventh year.

Dr. Ober received his degree from New York University Medical College in 1879. He was a member of the New Hampshire Medical Society and the American Medical Association.

His brother survives.

NOTICES

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The general oral and pathological examinations (Part II) for all candidates will be conducted at Atlantic City, New Jersey, by the entire Board from Thursday, June 14, through Tuesday, June 19, 1945. The Hotel Shelburne will be the headquarters for the Board. Formal notice of the exact time of each candidate's examination will be sent him several weeks in advance of the examination dates. Hotel reservations may be made by writing direct to the hotel.

Candidates for re-examination in Part II must make written application to the secretary's office not later than April 15.

The Office of the Surgeon General of the United States Army has issued instructions that men in service, eligible for Board examinations, be encouraged to apply and that they may request orders to detached duty for the purpose of taking these examinations whenever possible. Candidates in military or naval service are requested to keep the secretary's office informed of any change in address.

Deferment without time penalty, under a waiver of the published regulations applying to civilian candidates, will be granted if a candidate in service finds it impossible to proceed with the examinations of the Board. Applications are now being received for the 1946 examinations. For further information and application blanks, address Dr. Paul Titus, Secretary, 1015 Highland Building, Pittsburgh 6.

TUFTS MEDICAL ALUMNI ASSOCIATION

The annual dinner meeting of the Tufts Medical Alumni Association will be held on Wednesday, April 11, at the Copley Plaza Hotel, Boston. The committee on arrangements consists of Dr. James W. Manary, chairman, Dr. Harry Blotner, secretary-treasurer, and Drs. Carl Bearse, William E. Browne, Hilary J. Connor, Roy J. Heffernan and Frank Ober.

The guest speaker will be Senator Claude Pepper, who will speak on the subject "The Findings and Recommendations of the Senate Subcommittee on Wartime Health and Education," of which he is chairman. Other speakers will include Dr. A. K. Paine, professor of obstetrics, Dr. Louis E. Phaneuf, professor of gynecology, Captain A. Warren Stearns, dean-on-leave, Dr. Dwight O'Hara, acting dean, Dr. Benedict F. Boland, clinical professor of gynecology, and Dr. Leonard Carmichael, president of Tufts College.

NEW ENGLAND DERMATOLOGICAL SOCIETY

The regular and annual meeting of the New England Dermatological Society will be held in the Skin Out-Patient Department of the Boston City Hospital on Wednesday, April 11, at 2 p.m.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, April 5, at 7:15 p.m. in the classroom of the Nurses' Residence. Dr. Bianca R. Lia will speak on the subject "Lipiodol Study of the Uterus and Tubes."

Number 13

THE YOUNG STETHOSCOPIST*

REGINALD FITZ, M.D.

BOSTON

WHEN I visited Cleveland a few months ago and looked at the Surgeon General's books

housed in the Allen Memorial Library, I happened to meet an old friend. It was a small and unobtrusive volume called *The Young Stethoscopist*, apparently as much at home in Cleveland as in Boston, and now proudly sporting, as if it were a military decoration, the bookplate of the Army Medical Library. I felt unaccountably pleased that Boston should be represented in such a magnificent collection, and found myself wondering how it happened that a Boston book printed nearly a hundred years ago and as obsolete as a Model T Ford should still be considered of sufficient distinction as to be so beautifully cared for in the Nation's most important medical library.

I found it necessary to go back a long time to discover a plausible answer, back to the days when Bostonians were a race of people dominated by a Brahmin caste, when the State House was the hub of the solar system and when medicine was held firmly in the hands of Harvard College through the unyielding influence of the Warrens, James Jackson and their friends.

The Harvard Medical School in the early nineteenth century had scarcely become established on its own feet, and there was still a good deal of informality in its way of doing things. Yet even when it opened in 1783, John Warren laid plans for the future, and by 1821, when the Massachusetts General Hospital received its first patient, the Warren dynasty was fairly well ensconced: John C. Warren in the chair of surgery, James Jackson in theory and practice, Walter Channing in midwifery, and Jacob Bigelow in materia medica—Brahmins, Harvard College graduates, a closed corporation and as cozy as peas in a pod. The wonder is that the school ever survived such inbreeding.

*Presented at a dinner of the Boston Dispensary, with no trace of self-consciousness, classified its patients racially, as Bostonians, Americans, Hibernico-Americans and Other People.

Medical Library, Washington, D. C., October 5, 1944.

A hundred years ago the Boston Dispensary, with no trace of self-consciousness, classified its patients racially, as Bostonians, Americans,

School go forward and equally eager for the youth-ful Massachusetts General Hospital to do things. He had been abroad and knew something of the organization of a modern teaching hospital, and no doubt hoped that some day the hospital might attain a high position. Therefore from the very beginning he attempted to make all that he did there as lively as possible, and among other innovations introduced, as promptly as he could, clinical teaching at the bedside.

The teaching at the hospital in those early days also appears to have been conducted on an informal basis. There was but one physician, and one surgeon, on the staff—Jackson and Warren—and also a resident apothecary and house surgeon who were medical students appointed by the Trustees on recommendation by the physician and surgeon. As can be surmised, the presence of medical students "to see the practice of the House" was encouraged so long as they "demeaned themselves correctly and orderly"; clearly a good hospital not only must take care of sick people but must also serve as a teaching center.

It was obvious that the physician and surgeon might be prevented from making ward rounds every day, so provisions were made for appointment of assistants who could carry on the work of their chiefs when necessary. Walter Channing was made assistant physician in 1821, and John B. Brown assistant surgeon in 1823. At first there were only 53 medical and 40 surgical beds in the institution, and during the opening year about 200 cases were followed with the gratifyingly large surgical experience of 40 operations.

In the spring of 1821, the *New England Journal of Medicine and Surgery* published a carefully written review of Laennec's recent book on physical diagnosis.¹ This was an article of more than fifty pages and appeared in the April and July numbers. It ended by stating:

We may be permitted to say that the analysis we have made of this work has cost us much labour. But it would be injustice to Laennec not to say that our review gives a very imperfect representation of the learning and original observations which his work displays. We have already given some opinion respecting the value of the stetho-

(Notices continued on page xvii)

Dr. Jackson, Sr., answered:

On the first I received yours of the 28th Oct. It is on the use of the stethoscope, its difficulties. I believe that I wrote you in the same month stating the difficulties on my part. I scarcely expect to overcome them, yet I expect you to do it. It is incomparably easier for you than for me, and you will have great opportunities abroad.

As everyone knows, James Jackson, Jr., died before he had any opportunity to bring to medicine more than great promise. It fell to his successors to accomplish his father's aims.

Henry Ingersoll Bowditch was properly bred to take a part in such a plan.⁴ His father was a distinguished scientist and a former Harvard overseer, his mother a Miss Ingersoll and his birthplace Salem. He went to Harvard College and the Harvard Medical School, he served in his student days for a year as house surgeon in the Massachusetts General Hospital, and finally, in 1832, he followed James Jackson, Jr., to Paris.

He stayed in Paris for two years, there coming under the influence of the teachings of Laennec through such masters as Chaumel, Andral and particularly Louis. He walked the wards with these men, listened to their lectures, copied their mannerisms and for Louis developed the highest admiration. From him he learned three lessons of fundamental importance to his later life: the art of physical diagnosis, the importance of clinicopathological correlation and, above all, the realization that the edifice of medicine reposes entirely on facts that are well and carefully observed.

In Paris, along with Jackson and Holmes, Dr. Bowditch had the honor of election to the Society of Medical Observation. This was a club formed by a group of students under the presidency of Louis. It was the aim of this club to make its members observers of disease. It required each one to go through a kind of initiation in the recording of medical observation, and it demanded that such observations as were made should be submitted to the criticism of the entire membership. Those who belonged were bright and ambitious youngsters. They met each week. They kept notes of what they heard, and each was prepared to pounce on even the most trivial omissions in what the speaker of the evening had to say. Louis summed up their results by criticizing the reader and his critics and by adding anything to the subject under discussion that he chose.

Dr. Bowditch's recollection of his own first performance before this club is still vivid. He recalls language at such a gathering, the disparaging attitude of his friends toward his paper and how Louis finally annihilated him by pointing out that his presentation was incomplete since he had discussed only half the subject. Yet experiences of this sort were invaluable and not in the least humiliating; on the contrary, they were inspiring, for although

they were arduous, they were never malicious, they represented honest endeavor, and they were controlled by the guiding hand of a great master. Dr. Bowditch came back to Boston in the fall of 1834. The organization of the Massachusetts General Hospital and the Harvard Medical School was such that no place could be found for him immediately, and so he occupied himself as sort of a voluntary teacher* until his innings were due. One of the first things that he did was to found the Boston Society of Medical Observation.[†] Its opening meeting was held on March 28, 1835, when Dr. Bowditch and four students organized themselves into "a society for the purpose of collecting and reading detailed observations of cases of diseases as they presented themselves at the Massachusetts General Hospital and elsewhere in Boston." Dr. Bowditch spoke about the parent society in Paris and its usefulness; the members pledged themselves to follow the Parisian model and to meet for two hours one evening each week. At once they elected Louis an honorary member, and before long they were an active club with an increasing list of distinguished members.

Dr. Bowditch took great pride in the society. The early records make interesting reading; it was here that trichinosis was first described in Boston; a curious epidemic of pulmonary disease among horses was studied; and the Massachusetts General Hospital was informed—to its everlasting benefit—that its records were of no particular value from the viewpoint of advancing clinical knowledge. It was here, more than fifty years before appendicitis was named, that a bizarre case was reported concerning a young woman who after breakfast one morning was suddenly seized with a violent colic complicated by chills and fever. As Dr. Bowditch said, the suddenness of the attack, the chills and fever and the colicky pain made the diagnosis difficult. The disorder did not appear to be strangulation of the intestine nor to originate from a diseased liver. What could be the significance of the fact that the region around the cecum was acutely sensitive? It was here that the clinical picture of diaphragmatic hernia was clearly drawn and that for hydrothorax was suggested; and it was here on one memorable occasion that Dr. Bowditch read a paper on hippophagy, defending the use of horse meat as an edible viand—perhaps accounting for the existing predilection of the Harvard Faculty Club to serve horse steak at dinner as a particular delicacy. Indeed, the Boston Society for Medical Observation played a part in making medical history.

In 1838, Dr. Bowditch received his first appointment at the hospital and was given a post that was

*In the catalogues of the Harvard Medical School of that era he is listed as "instructor," which was not a formal appointment. The early records of the Boston Society of Medical Observation are in the Boston Medical Library.

scope. The continued use of this instrument has satisfied us more and more of the benefits which may be attained by it; but we believe it must be used a long while before so much can be ascertained by others, as has been by the inventor. On this point it may be proper to add

THE
YOUNG STETHOSCOPIST,
OR THE
STUDENT'S AID
TO
AUSCULTATION.

BY HENRY I. BOWDITCH, M. D.

that much must depend on the perfection of the sense of hearing. A man with a nice ear for music would probably discover much more by this instrument than one who has not that organ so delicately constituted.

Obviously someone in Boston obtained a copy of Laennec's book shortly after its publication and started to work on physical diagnosis by his methods. The review* is unsigned, and the owner of the original copy that was the pioneer in Boston cannot be identified. It is known, however, that Dr. Jackson was much interested and that as soon as possible after this review was printed he began to teach auscultation and percussion in the Harvard Medical School. To prove this, in 1827 there appeared from his pen for the use of his students a textbook on the theory and practice of physic.³ He has some interesting things to say about these methods.

*There is a hint in it that Dr. Jackson wrote it, for he appears to have found auscultation a difficult art. In a letter dated March 5, 1833, he said, "My ears are old and were not trained early."

In the investigation of the causes of dyspnoea, as well as of other symptoms in thoracic diseases, much may be learnt by attending to the effects of position and motion; also by percussion and by auscultation, mediate or immediate. . . .

The practice of percussion is founded on the following circumstances. When the air is admitted fully into the lungs, the thorax resounds on percussion like a hollow cask, with the exception of certain regions. When the air is not permitted to enter any particular part of the lungs, a blow over that part will produce a flat sound. The extent, over which this flat sound is perceived, will determine the extent to which the air-vessels are compressed or obstructed; and if the compressing cause be moveable, such as a fluid in one of the cavities of the pleura, this may be discovered by attending to the effects of a change of position, as regards the parts affording the flat sound.

The use of the stethoscope is founded on the following circumstances. The motion of the air in the lungs, with all the obstacles to the regular passage of it, is productive of sounds, which may be heard by placing the ear on the chest. So also is the motions of the heart capable of being ascertained by the ear. But these sounds in the thorax may be ascertained most conveniently through a cylinder of wood or of other material; one end of the instrument being rested on the chest, and one end being applied to the ear. When such an instrument is used the auscultation is mediate; when the ear is applied to the thorax the auscultation is immediate. If the instrument be applied when the patient is speaking, a tremor is perceived over healthy lungs; but when the lungs are diseased, or compressed, the changes are manifested by certain peculiar changes in the sounds transmitted through the instrument.

It would certainly be very useful to distinguish during life, the different organic changes [in the heart]. . . . We can however with some degree of assurance, distinguish the following affections, viz: hypertrophia of the heart, dilatation of its cavities, and these two combined. In making these distinctions, much aid may be derived from the use of the stethoscope. We may also sometimes distinguish diseases of the valves and aneurism of the aorta. Dropsy of the pericardium is not easily distinguished.

For a teacher growing no younger year by year and with hearing becoming less acute, it was excessively hard to improve one's skill in physical diagnosis by the method of self-teaching. The obvious answer was to send to France to learn the new technic a procession of Bostonians from the right kind of families so that, as Dr. Jackson expressed it, these young men when they returned could put their ears in use at his hospital.

The leader of this procession was James Jackson, Jr., who left the medical school as an undergraduate in 1831; he was soon followed by Henry Ingersoll Bowditch, Oliver Wendell Holmes and Mason Warren. There is something appealing about young Jackson's first letter home and his father's reply to it.† From Paris, shortly after he arrived there, James Jackson, Jr., wrote:

I feel almost disposed to cover a sheet or two in enumerating the difficulties of auscultation. If Laennec has added an important aid to our insufficient means of exploring diseases of the chest, he has, at the same time, rendered the study of those diseases more difficult, more laborious I would say, to the learner. . . .

By the by, you would be much surprised, my dear father, to see how much more the immediate auscultation is used here, than the mediate. There is one other point, we are too apt to neglect at the M. G. H. It is the examination of the dorsal region. The French examine the back more than the front; we do the contrary; both err, but they the least.

†Many delightful letters between James Jackson, Jr., and his father can be found in Putnam's *A Memoir of Dr. James Jackson* (Boston and New York: Houghton, Mifflin and Company, 1906) and in Jackson's *A Memoir of James Jackson, Jr., M.D.* (Boston: I. R. Butts, 1835).

In these days when we have, besides the stethoscope, the x-ray, the cardiogram, a method for visualizing the heart sounds, new drugs, allergy, blood chemistry and metabolism tests, all combining to make diagnosis complicated and common sense obscure, the last verse of the "Stethoscope Song" is worth remembering.

Now use your ears, all you that can,
But don't forget to mind your eyes,
Or you may be cheated, like this young man,
By a couple of silly, abnormal flies.

DERMATITIS EXFOLIATIVA FOLLOWING ARSPHENAMINE THERAPY*

Observations on Fifty Cases

Maurice J. Costello, M.D.,† and Simon Landy, M.D.‡

NEW YORK CITY

The ages of the patients ranged between eighteen and sixty-nine years. There were 3 in the second decade, 9 in the third, 12 in the fourth, 16 in the fifth, 8 in the sixth and 2 in the seventh. The average age was 38.5 years. There were 26 women and 24 men. Twenty-six were Negroes, 22 were Whites, and 2 were Japanese. Nineteen occupations were represented. Housewives, restaurant workers and unemployed constituted over 60 per cent of the total number. The average hospital stay was forty-three days, the shortest four days and the longest one hundred and seventy-one days. The average duration of the arsenical dermatitis was sixty-nine days, the shortest ten days and the longest two hundred and forty days. Forty-eight patients were improved or cured, and 2 died.

When admitted to the hospital for treatment of the arsenical dermatitis, 1 patient was in the primary stage of syphilis, 34 were in the secondary stage, 3 had early latent syphilis, and 11 had late latent syphilis. None of the patients had manifestations of tertiary syphilis. One patient had a papulo-necrotic tuberculide.

Forty-two patients had received neoarsphenamine, 2 had received Mapharsen followed by neoarsphenamine because they developed a mild dermatitis from the former, and 2 had received acetylglycocoarsphenamine.

The tune that was used is lost, but the words remain. The story of the song is simple enough; it is about a young Boston doctor who procured a new stethoscope, with an ivory cap and a lovely polish. Unfortunately a couple of flies housed themselves in it so that whenever he used the instrument he heard noises that would have perplexed Laennec; and he made improbable diagnoses that were invariably wrong. At last six young maidens, who were growing pale and had taken to sighing or to eating such things as coal or chalk, consulted him. Naturally, because of his zeal in using the stethoscope, the young doctor was not interested in anything so commonplace as looking at them, but he heard such ominous buzzings in their chests when he listened that he felt sure they all must die. However, before this happened, six young men fell in love with the maidens and married them, and at once they grew well.

a little noise around Boston. To poke fun at it in the midst of a group of intimate friends would have amused Dr. Holmes, would have been timely and was the sort of thing he knew how to do so well and gracefully.

DURING the course of each year, a number of patients suffering from dermatitis exfoliativa caused by the arsenamines are treated in the dermatologic wards of Bellevue Hospital. Most of these patients have been treated for syphilis by private physicians, hospital clinics or public-health services in New York City. The 50 cases reported herein were observed at Bellevue Hospital between the years 1937 and 1942, showing that the dreaded postarsphenamine dermatitis is not rare even in the present period of antisyphilitic therapy. These patients were studied in the dermatologic wards from their admission until they were well enough to leave the hospital. Three of the patients had received their antisyphilitic treatment in this hospital.

The histories of these cases furnish convincing evidence that this complication of treatment could have been avoided in a number of cases, and that if it had been possible to obtain a proper history and if the warning signs had been recognized.

probably more to his taste than any other. The hospital had grown considerably since it opened and since that memorable day in 1825 when General Lafayette, accompanied by the governor and the lieutenant governor, had driven to the Bulfinch Front and after being properly received by the president and members of the Board of Trustees, flanked by the physicians and surgeons, inspected the building. Business was so brisk that an admitting physician had proved necessary, a doctor who would see the patients before entry, determine their condition, decide whether they were properly admissible, do whatever outpatient work was indicated and, more important still, be responsible for all pathological examinations of the institution. Dr. Bowditch felt pleased to receive this appointment, for it gave him an opportunity to put into practice some of his Parisian training. One of his students said that he now regularly spent an hour each morning examining patients, at the same time teaching physical diagnosis and giving his young assistants every opportunity to practice this art.* If an autopsy was to be performed, he would devote the entire afternoon to it, appointing a student assistant and making the medical house pupil take notes from dictation so that the record might be as complete as possible.

Apparently this method of teaching met with the approval of the president and fellows of Harvard College. For the catalogue of 1841-42 for the first time announced that the course in medicine embraced lectures given at the medical college on the general principles of pathology and treatment and clinical lectures given at the Massachusetts General Hospital. The latter were given twice a week and occupied two hours each. The catalogue states, "Students have an opportunity of visiting all the cases and of observing and learning the symptoms and treatment of each case and particularly of the exploration of the body for the physical signs of disease by *palpation, auscultation and percussion*." In this fashion the use of the stethoscope was finally made respectable in Boston and all students were taught how to use it.

Any teacher who has a hand in developing a new course at the Harvard Medical School is likely to wish to prepare his own textbook. It is not surprising, therefore, that in the summer of 1844, Dr. Bowditch wrote a friend: "I sit most of the time in the front parlor preparing my book on auscultation, which I believe I am fairly engaged in now," nor that in December, 1845, the *Boston Medical and Surgical Journal* prepared a welcome for *The Young Stethoscopist*. "We understand," it stated, "that Dr. Bowditch of this city, has in press a new work, under the above title, on the Physical Signs of Diseases of the Chest. It is intended as an aid to students, and to physicians resident in the coun-

try. About the middle of January it will, probably, be ready for the trade."

The Young Stethoscopist came out on time, a slim volume full of wisdom and practical hints on how to examine the chest properly. Henry J. Bigelow¹ reviewed it shortly after its birth and remarked of Bowditch and his work: "He has booked Laennec up to date and has compressed his genius, as the fisherman in the *Arabian Nights* did his, into a prodigiously small volume. We commend it to auscultors and to non-auscultors."

The Young Stethoscopist proved popular and went through two editions. It is one of the first books on auscultation and percussion by an American writer to be published in this country, and it has an interesting background, relating together Laennec, Louis, the Jacksons and through them all subsequent American auscultors. For these reasons it is more than a bibliographic curiosity and has well earned a place in the Army Medical Library. Besides this, there is reason to imagine that the book is unique: as a possible appendage, it has a humorous Back Bay postscript that forever makes its contents point a significant moral to young stethoscopists.

The Boston Society for Medical Improvement was established in 1828.⁶ It started simply — a gathering of colleagues who met regularly to talk shop. But from the beginning the society developed a delightful tradition that I am pleased to observe has been copied by the Honorary Consultants to the Army Medical Library — the tradition of an annual dinner. The dinner was an occasion of geniality where men talked and laughed, sang songs or even poetized if the spirit moved them. When Dr. Holmes was secretary he left a pleasant account of what went on:

At seven o'clock the Society disposed itself at table animated by the presence of the dinner, which, by its outward arrangement and intrinsic excellence, did honor to the taste and judgment of the provider. . . . No incident occurred to interrupt the festivities of the evening, with the exception that a couple of our most efficient members were interrupted for a short time by accidents too frequent on these occasions. An amiable indiscretion, dating undoubtedly from some bright May morning, was visited upon the heads of Drs. Ware and Adams, by a midnight call into the midst of a February snowstorm. The hilarity of the company was temporarily diminished, and the census of the city permanently increased during their absence.

As the years rolled by, the annual dinner came to be anticipated with increasing eagerness; one was sure of a good meal, an evening of relaxation, speeches that were neither too long nor too dull and a poem by Dr. Holmes.

It was at the dinner in February or March of 1846,[†] I suspect, that Dr. Holmes introduced the "Stethoscope Song." *The Young Stethoscopist* was then brand new but already old enough to have made

*Dr. Bowditch still had no formal appointment in the medical school so that his teaching must have been largely a voluntary effort.

[†]This date is a matter of guesswork. No student of Dr. Holmes has determined accurately when the "Stethoscope Song" was written or first sung. F. F. Currier, who knows as much as anyone about the matter, says that its first printed appearance, so far as he can ascertain, was in the 1849 edition of the doctor's poems, which appeared in November, 1848.

coalescence became plaque-like, hyperpigmented, lichenified and scaly. In the patients who developed this type of dermatitis for the first time, the lesions were macular and later maculopapular, in contradistinction to the vesiculobullous lesions occurring in the explosive types, especially in those who were sensitized by previous medication.

Concomitant symptoms of dermatitis exfoliativa varied with different patients. They included malaise, jaundice, hiccoughs, epileptiform convulsions, nervousness, toxemia and cough.

The indications of lowering of resistance to cutaneous bacterial infections in dermatitis exfoliativa due to arsenic are the frequent occurrence of furuncles of the axillae, purulent conjunctivitis, blepharitis, and deep-seated abscesses that have followed the intramuscular injection of crude liver extract. Bronchopneumonia as a result of similar bacteria was the cause of 1 death. Stokes and Cartwright believe that dormant foci of infection should not be disturbed in patients suffering from arthropod-borne dermatitis, because of the danger of septicaemia.

Of the mechanisms involved in the causation of the arsenical dermatitis, we agree with Allore that in severe eruptions the sensitization phenomenon is more important than either the angioneurotic reaction syndrome or the associated infection.

Complete blood-cell counts were performed on many of the patients, and in most cases they were within normal limits. In a few cases the red-cell count was as low as 2,500,000, and in several it averaged about 3,500,000. A number of patients had a low hemoglobin; in several cases it was between 50 and 60 per cent. One patient had thrombocytopenia, the blood platelet count being 60,000. Leukocytosis was more frequently encountered than leukopenia and ranged from 18,000 to 27,000. Eosinophilia was frequent, the percentage ranging from 10 to 56, but severe injury to the bone marrow resulting in agranulocytic angina and purpura was not observed.

Sodium thiosulfate was administered intravenously to 30 patients. The smallest number of injections was three, the highest ten and the average four. These patients also received 1 gm. of sodium thiosulfate by mouth three times a day for ten days. This drug was of no value, which agrees with the clinical experience of Allore and the experiments of Alur, who investigated the effect of sodium thiosulfate in the treatment of arsenical poisoning in rabbits. One gram of calcium gluconate was administered intravenously to 10 patients every other day for six doses. It was of questionable value.

Intravenous glucose solution was administered to 10 patients in daily amounts varying from 20 to 50 cc. of a 50 per cent solution to 1000 cc. of a 5 per cent solution, being continued for ten days. Glucose administered in this manner appears to be

Twenty-five of the patients had a temperature of over 100°F. The highest temperature was 101°F. in 9 cases, 102°F. in 4, 103°F. in 8 and 104°F. in 3. One patient had a temperature of 105.6°F. Even moderate fever was accompanied by malaise and prostration.

Clinical jaundice occurred in 2 patients. In a patient with latent syphilis, it preceded the eruption by three days. The patient had received four injections of neosphenamine. The icteric index was 9, the van den Bergh direct reaction was delayed, and the indirect reaction was slightly positive. The other patient had been treated several years before. The icteric index was 9, the van den Bergh direct reaction was delayed, and the indirect reaction was slightly positive.

Urinalyses did not show abnormal findings in the majority of the patients. Albumin, casts and white or red cells were occasionally found. A + test for sugar was noted in 1 patient. The urines of 10 patients were examined for arsenic. In 6 patients, the amounts per liter varied from 0.004 to 1.540 mg.; in 2, arsenic was said to be present; in 1, there were varying amounts; and in 1, a +++ test for arsenic was reported.

Twenty-seven patients had a positive blood Wassermann reaction and 23 a negative reaction. In the great majority of the cases studied, the eruption was generalized or universal. The regions of the body affected, in the order of frequency, were as follows: extremities, torso, axillae, groins, neck, face, chest, back, eyelids, hands, feet, ears, wrists, ankles, scalp, lips, oral mucous membrane and conjunctivas. Generalized adenopathy was present in most of the cases.

It is well known that the arsenical drugs are capable of causing many types of toxic cutaneous manifestations; of these, dermatitis exfoliativa is the most serious. Pruritus, burning and pain in varying degrees were common to all the eruptions. Erythema, scaling and severe exfoliation occurred in nearly all the patients. Edema, especially of the lower extremities, due to stasis, and angioneurotic edema of the eyelids, face, lips and mucous membranes were constant features of the early manifestations of the dermatitis. Denudation of the mucous membranes of the mouth and respiratory tract, causing severe bronchitis, was frequently encountered.

Feeling of the palms and soles, accompanied by pruritus and fever, were occasional forerunners of the severe generalized eruption. In many cases, if these signs had been heeded, the generalized dermatitis might have been prevented or its gravity lessened.

The eruption began with the appearance of flexural erythema and pruritus, followed by large coin-sized, dusky red, slightly elevated lesions on the torso, especially the back. These lesions often resembled those of erythema multiforme and by

mine. The type of arsenical administered to the remaining 2 patients was unknown.

The smallest number of injections administered prior to the development of dermatitis exfoliativa from neoarsphenamine was three and the largest sixteen, with an average of eight. The majority of the patients complained of pruritus or dermatitis soon after the fifth, sixth or seventh injection. In many cases either these warning signs were not observed or the patient was not questioned concerning them. Ignorance of the significance of mild itching and mild dermatitis in the course of arsenical therapy led to full-blown dermatitis exfoliativa.

One of the patients had pruritus after the third injection. This increased until it was accompanied by dermatitis after the seventh injection, and death followed soon after the tenth injection. Another patient, who developed a severe dermatitis exfoliativa after the first injection of neoarsphenamine, later gave a history of having had a similar eruption eleven years before that had required hospitalization for two months; the eruption followed the third injection of an arsenical preparation. It began as generalized urticaria and angioneurotic edema of the face and lips and was characteristic of the dermatitis that occurred in those who had previously been sensitized. This severe complication of arsenical therapy can usually be anticipated, but several of the histories show that in patients sensitized by previous injections of an arsenical preparation the eruption appeared after the first injection of the arsphenamine.

Another patient received one injection of neoarsphenamine and developed a severe dermatitis exfoliativa with numerous vesiculobullous lesions. She had received about seventy-five injections of neoarsphenamine in 1935 and 1936, which was three years prior to the eruption on admission.

A patient stated that he had received a course of neoarsphenamine followed by a course of mercury sixteen years previously, without untoward effect. After the second injection of neoarsphenamine in the series of treatment before entry, a mild dermatitis appeared. He did not report this until he had received six injections of neoarsphenamine, when a generalized pruritic exfoliating dermatitis was present.

Another patient tolerated well his first course of an arsphenamine and two courses of bismuth salicylate, but developed a moderately severe dermatitis following the first injection of the second course of neoarsphenamine.

One injection of neoarsphenamine was administered to a patient in 1920, and he received no further treatment until 1941, when he developed an eruption of a mild nature following the fifth injection of Mapharsen and a dermatitis of severe character after subsequently receiving two doses of neoarsphenamine—0.2 and 0.4 gm., respectively—at weekly intervals.

Robinson and Moore¹ have induced a second attack of dermatitis with a very small dose of arsphenamine—0.1 cc. of a 1:2000 solution—injected intradermally six years after the first eruption.

One patient developed an eruption after having received twelve injections of Mapharsen. The dermatitis was mild, and intravenous injections of neoarsphenamine were substituted for Mapharsen. After the fifth injection of the latter drug, the patient developed generalized pruritus, and after the sixth injection a lichen planuslike eruption on the wrists and ankles. Later the eruption became generalized, exudative and fissured and was accompanied by edema of the face and severe itching. It is probable that Mapharsen sensitizes such patients to the neoarsphenamine subsequently administered.

Mapharsen was the cause of an arsenical eruption in 2 patients, to whom it was the only arsphenamine administered. In one of them, the dermatitis appeared after the twenty-first injection; in the other, it appeared after the sixteenth injection. Mapharsen seldom causes an arsenical dermatitis. When it does, the eruption usually appears late, unless the patient has been previously sensitized.

Acetylglucoarsphenamine, administered by intramuscular injection, was given to a selected group of patients in the dermatologic wards of Bellevue Hospital. One patient after the sixth injection of this drug developed pruritus and a mild dermatitis, which became aggravated and more extensive after the seventh injection. Another received ten injections of acetylglucoarsphenamine before the eruption appeared.

Intramuscular injections of bismuth salicylate and intravenous injections of an arsphenamine were administered in alternating courses to 12 patients. In 10 cases these drugs were given concurrently, that is, the heavy metal was administered in the same week as the intravenous injection of the arsenical drug. Twenty-eight patients received only the arsenical drug without the heavy metal. It appeared to make little difference whether the arsphenamine was administered with a heavy metal in alternating courses, concurrently or alone. When it was administered in alternating courses with a heavy metal the eruption appeared, on the average, following the ninth injection; when it was given concurrently, after the eighth injection; and when administered alone, after the sixth injection. This leads one to believe that the extra load of heavy metal therapy is not a factor in the production of arsphenamine dermatitis exfoliativa.

All the patients who developed an eruption following the first or second dose of an arsenical preparation gave a history of having previously received an arsphenamine. Moore,² and Stokes,³ whom he quotes, state that they have seen patients who developed exfoliative dermatitis after the first dose of an arsenical preparation.

Space does not permit complete discussion of the control of various types of insect-borne diseases. There are, however, certain factors that apply to most of these diseases.

In the normal course of an epidemiologic investigation, collections are made of the insects suspected of transmitting the disease in question. The best method for collecting insects is to take advantage of their feeding habits. Adult mosquitoes may be collected either while biting man or while resting on walls and ceilings.¹ A large glass test tube, containing rubber bands saturated with carbon tetrachloride or chloroform at the bottom is placed over the specimen until the mosquito is anesthetized. Then it is slowly removed and the tube corked with the specimen inside the tube. After an interval of a few minutes the specimen is carefully placed between layers of cotton batting in a suitable container, such as a pillbox, and properly labeled. The following data should always be noted at the time the specimen is captured: place of capture — state, town, street and number of house or location of barn, description of surroundings and so forth; date, time of day, climatologic conditions and so forth; remarks regarding conditions when caught, such as biting man or horse, where resting and so forth; and name and address of collector. When mosquito larvae are collected, similar data should be noted,¹² particularly the type of body of a suction bulb and are put into test tubes containing 70 to 80 per cent ethyl alcohol or 10 per cent formalin. Each tube should be properly identified, preferably by placing a slip inside the tube. Bugs and ticks should be removed by forceps, as crushing the arthropod between the fingers may result in infection of the collector. Specimens

*Commissioner, Massachusetts Department of Public Health, and lecturer in public-health practice, Harvard School of Public Health.

should be immersed in 70 per cent ethyl alcohol containing 1 per cent formalin. Large specimens, after killing with chloroform or carbon tetrachloride, may be transfixed by pins and mounted in a box. Sucking lice are found only on their host. Mites are most easily collected from animals. Fleas may be collected both from animals and their nests. Specimens can be preserved in 70 per cent ethyl alcohol.

Two groups of arthropod-borne diseases, namely, those that are transmitted by mosquitoes, chiefly malaria, and the typhus fevers, which are transmitted by lice, mites and fleas, will be used to illustrate the methods of attack against these diseases.

Mosquito-Borne Diseases

The malignancy with which malaria can attack an area is illustrated by the spread of the disease in Brazil after the introduction of *Anopheles gambiae* from Africa by either ship or airplane.¹⁰ In 1937 and 1938 it caused an epidemic in one section that affected some 60,000 out of a total population of 70,000 and caused over 5000 deaths. Vast sums of money were expended by the Brazilian government and the Rockefeller Foundation in an attempt to exterminate *A. gambiae*,¹³ which threatened only to pauperize Brazil but to extend throughout South America and perhaps even farther. Until quite recently it was believed that this vector had been eliminated from Brazil, but it has again been found, probably being a reimportation.¹³

Briefly, the control of any mosquito-borne disease must be based on one or more of the following procedures: control of the mosquito vector; protection of man and animals from the bites of infected mosquitoes; immunization of susceptibles; removal of sources of infection of mosquito vectors; and, finally, prevention of entry of the mosquito into areas and possible sources of infection into areas unaffected by the disease. All these methods are not applicable to every mosquito-borne disease.

Mosquito control. Certain conditions are necessary before a mosquito-borne disease can become

of benefit in detoxifying the patient. Mu⁶ thinks that there is an association between liver damage and glucose metabolism. It was necessary to give blood transfusions to 3 patients because of severe secondary anemia.

Concentrated vitamin preparations, including ascorbic acid, 100 mg. three times a day, were administered. It was impossible to determine their value because they were not administered alone. Seven patients received intramuscular injections of crude liver extract. In several cases this form of therapy had to be abandoned because the patient developed deep abscesses that had to be widely incised and drained. Hence, patients suffering from exfoliative dermatitis should not be given crude liver extract intramuscularly because of the likelihood of abscess formation at the contaminated sites of injection.

It was necessary to administer sedatives to many of the patients because of the nervousness and loss of sleep occasioned by intolerable itching and burning. Patients were encouraged to drink copiously of fluids, especially fruit drinks.

Local treatment in general consisted of the following: potassium permanganate, starch and colloid baths; body inunctions with boric acid ointment; and wet compresses of a 1:10 Burow's solution. Other forms of local therapy were applied, depending on the indications that arose. Dalibour's solution (1:10) was applied as wet dressings and was also used in the bath. Wet boric acid compresses and wet dressings of silver nitrate solution (1:1000) were of value in treating areas of secondary infection. Aquaphor and lime-water ointment proved to be a good emollient. Ten per cent oil of cade in aquaphor relieved the pruritus in the dry stage of the eruption. Forty per cent sulfur ointment was of little value. A 1 per cent alcoholic solution of brilliant green proved efficacious on moist, oozing areas, such as the axillas and inguinocrural regions. Crude coal-tar paste was of value in the patchy dry areas that remained when the universal eruption was undergoing involution.

The application of Unna boots was helpful in patients who had uncontrollable itching and severe edema of the lower extremities. The application of subfractional doses of superficial roentgen rays had no appreciable effect on the pruritus or the dermatitis.

The following recommendations are based on the clinical findings in this series:

The patient should be asked at each visit whether he has itching, a rash, fever or headache.

When arsphenamine, neoarsphenamine or silver arsphenamine has been used, it is advisable to have the patient remove his clothes for a complete examination of the skin before the sixth, seventh and eighth injections. A similar examina-

tion should be performed before the twelfth to the fifteenth injection of Mapharsen.

If a patient develops an eruption that is not readily recognized as one caused by the arsphenamines, it is safer to withhold treatment until a dermatologist decides the question.

The patient should always be asked, regardless of the stage of the syphilitic infection, whether he has previously received intravenous or intramuscular injections. Information on this point may modify treatment and thus prevent the explosive reaction following the first dose of an arsphenamine drug in a sensitized person.

Further treatment with an arsenical preparation should never be given if the original dermatitis was vesiculobullous or exfoliative. Disregard of this warning may be fatal. Subsequent treatment with an arsphenamine is also dangerous if it produces a macular, maculopapular or lichenoid exfoliating eruption with pruritus. If treatment with an arsenical drug is imperative in this group, all vestiges of the dermatitis must have disappeared before an arsenical drug in small doses is again cautiously administered. Reappearance of the dermatitis following this procedure should forever contraindicate the administration of the arsphenamines.

It is advisable to examine the urine daily during the course of dermatitis exfoliativa and to conduct a complete examination of the blood frequently in the acute phase, because blood dyscrasias are at times associated with the former complication.

SUMMARY AND CONCLUSIONS

The observation and treatment of 50 patients with dermatitis exfoliativa caused by the arsphenamine drugs are discussed. Recommendations regarding therapy that are based on these observations are given.

Age, sex and race apparently played no part in the causation of arsenical dermatitis.

Freedom from reaction to arsphenamines at a previous time does not guarantee the same good fortune with future arsenical treatments.

Major arsenical dermatitides are extremely resistant to all forms of general and local treatment, including the application of superficial roentgen rays.

The major arsphenamine dermatitides have certain features in common: they are pruritic; they are generalized or universal; they are exfoliative, with constitutional symptoms and evidence of injury to the viscera, especially the liver; and they are made worse by the continuation of arsenical therapy.

140 East 54th Street

hour. Dimethyl phtalate is intermediate in lasting qualities. Repellents must be applied to all exposed surfaces except the mucous membranes. Certain species of Anopheles prefer animal blood to that of man. In areas where such mosquitoes are vectors, they may be diverted by the importation of animals. This zoophilic attraction to cattle has been used in the Balkans.

Immunization of susceptibles. Specific immunization has proved effective in yellow fever.¹⁴³ It is, however, not yet available to the public in all endemic areas. Although the vaccine is a live attenuated virus, no case of typical yellow fever has resulted from over two million vaccinations performed in Brazil.¹⁴⁴ Furthermore, it has been demonstrated that mosquitoes that bite vaccinated persons did not infect monkeys on subsequent biting. Unfortunately, immunity is temporary and annual revaccination is required.

In equine encephalomyelitis, a vaccine composed of formalized virus obtained after growth in chick embryos has proved effective in the protection of horses.¹⁴⁵ Except for laboratory workers, this vaccine has not been used in man, owing to the severe reactions that have been encountered. Moreover, the risk of exposure to the disease has been so small that community immunization has not been indicated. Vaccination of horses must be repeated annually, since the immunity is temporary. The decrease in the incidence of this disease since 1939 has been attributed in part to the vaccination of horses.

There is no specific immunization against the other mosquito-borne diseases. The suppressive use of quinine¹⁴⁶ and Atabrine¹⁴⁷ in malaria is an attempt to destroy the plasmodium as soon as it is introduced into the blood stream. Neither drug,¹⁴⁷ however, is effective in preventing the disease. The activity of the plasmodium is reduced while suppressive doses of the drug are being administered, but about two weeks after such doses are stopped, symptoms of clinical malaria are likely to make their appearance. There is some evidence that the prolonged use of suppressive doses of both quinine and Atabrine, which are about equally effective, tends to lessen the seriousness of malaria in subsequent attacks. Plasmodium is of no value as a suppressive drug in malaria.

There is no general cross immunity in malaria, nor are there any between types or even different strains of the same type. This was well illustrated by failure of the British attempt to forestall malaria in Malaya by using Indian troops who had previously had malaria.¹⁴⁸ Removal of sources of infection. This is effective only to a limited extent. Cases of the disease, with the infecting agent in the circulatory blood, may act as foci of infection for vectors. Theoretically, it is therefore good preventive medicine to isolate

these patients in mosquito-proof quarters. Except for malaria and filariasis, which are, respectively, due to a protozoan and a helminth, the mosquito-borne diseases are caused by a virus that remains in the blood stream for a relatively short time,¹⁴⁹ frequently disappearing soon after the disease manifests itself.¹⁵⁰

Malarial gametocyte carriers are the foci of outbreaks of the disease in new areas.¹⁵¹ Since filariasis is often symptomless,¹⁵² and since the worms may remain in the blood for prolonged periods, persons with mild forms of the disease and carriers may act as sources of vector infection. Malarial carriers may be eliminated by adequate treatment, but filarial carriers remain permanent, since there is no known effective drug therapy in this disease.

Prevention of entry into new areas. This method is applicable to all arthropod-borne diseases. The principles of isolation and quarantine¹⁵³ are utilized in every community. In the case of certain diseases, especially those with a wide host selectivity, the prevention of the spread of a disease is difficult. This feature is well illustrated by yellow fever. This disease was apparently controlled in Brazil by the use of the usual mosquito-control methods and isolation and quarantine on a community basis.^{154, 155} Suddenly, however, it became apparent that jungle yellow fever was due to the persistence of the disease in other hosts and vectors.¹⁵⁶ Equine encephalomyelitis has an even wider host selectivity. Its spread may be due to vectors or hosts. Since the hosts include animals and birds, the geographical limitation of this disease becomes a difficult problem. Malaria and filariasis are usually spread by hosts who are not known to be infected, and in these days of rapid transportation it is practically impossible to eliminate the travel of such persons.¹⁵⁷ Moreover, several instances are recorded in which disease vectors and other insects have been transported to areas where they had never been found.^{158, 159}

When control methods are dependent on control of man, only limited success may be expected, as some individuals are unco-operative. The most effective method in the control of mosquito-borne diseases has been a direct attack on the mosquito,¹⁰ which results in a reduction of vectors to a point below the critical level required to maintain the disease.

Typhus Fevers

The typhus fevers comprise a group of diseases entities each with its peculiar epidemiologic setting.¹⁶⁰ Classic European or epidemic typhus fever is louse transmitted,¹⁶⁰ and all measures that are employed to delouse achieve a measure of control of the disease. The older methods of delousing bodies and clothing¹⁶¹ are familiar to all veterans of World

epidemic or reach a high endemic index. One of these is the existence of a certain numerical relation between hosts, vectors and susceptibles. When this numerical relation is upset by a reduction of the number of vectors, the disease ceases to be epidemic and rapidly declines, either arithmetically or geometrically, depending on the interrelation of many related factors. It becomes apparent that a moderate reduction in the number of mosquitoes below the critical level will markedly reduce the prevalence of the disease in an area where there are many persons who are immune, but in a region with many who are susceptible, the reduction below the critical level must be much greater. This concept was developed many years ago by Ross, who applied it to malaria; Carter and Gorgas applied it to yellow fever.

The bionomics of mosquitoes are such that control measures must be designed to eliminate or control the larvae or the adults. The measures that are most effective in any area depend on local factors and on the genus and species of the mosquitoes concerned. It is impractical and uneconomical to attempt to control all mosquitoes. The control measures must be directed against that species which it is desired to reduce below the critical level. Therefore, in order to ensure effective control measures, it is important to understand the bionomics, breeding habits and seasonal and geographical distribution of the species that are concerned with the transmission of the disease. Since local circumstances vary, it is necessary that a mosquito survey^{51, 137} be made before control measures are introduced into any area for the purpose of controlling mosquito-borne disease. Even in controlling mosquitoes as a nuisance, it is necessary to determine their bionomics before an economical and efficient nuisance control can be expected.

Mosquito control has been effective in malaria and yellow fever. There has been considerable less experience in the effectiveness of this method in dengue fever, but since the principal vector of this disease is the same as that of yellow fever, there is every reason to believe that mosquito control will prove just as effective. In filariasis this method has also proved to be effective where it can be applied. To date, there has been no notable effort to control the vectors of equine encephalomyelitis. Theoretically, this method should be effective; but the natural vector of this disease has not yet been determined, and additional epidemiologic and entomologic investigations are needed before this method can be applied.

Mosquito control measures are of two types—temporary and permanent¹³⁸; to these may be added natural control, such as surface-feeding fish. Temporary measures consist of the application of larvicides, such as oils, Paris green, other dusts and, finally, D. D. T. (dichloro-diphenyl-trichloro-

ethane). Larvicides are used whenever permanent control is either not possible or not economical. The best larvicidal oil kills in less than thirty minutes and consists of No. 2 fuel oil. It kills by suffocating the larvae by blocking the respiratory tubes, the toxic action of the volatile oils and vapors, the toxic action of the water-soluble fraction and the change in surface tension whereby the larvae cannot remain attached to the water surface. The oil is applied by sprays, at a rate of about 15 gallons per acre at intervals of seven to ten days. Paris green is usually diluted with other dusts so that the final mixture contains 2.5 to 5 per cent Paris green by volume; it is applied by a rotary blower using $\frac{1}{2}$ to 1 pound of Paris green per acre at weekly intervals. It is especially active against anophelines, being an intestinal poison that floats on the surface and is easily available to the top-feeding larvae.

Permanent control measures may include drainage, channeling of streams and marshes, filling, shore-line cleaning and removal of vegetation, periodic water-level fluctuation, flooding, flushing and automatic syphoning, changing water salinity, shading or exposing to sunlight and introducing natural enemies. Their application depends on the terrain, the species to be controlled and the cost and effectiveness of the types of control measures available. Only an expert malariologist should attempt to decide on proper permanent control measures.

Protection from mosquitoes. Effective protection from the bites of mosquitoes can be accomplished only under extremely limited conditions. Screening, the use of nets and the avoidance of unnecessary exposure are the most effective methods. Spraying in houses, the application of mosquito repellents¹³⁹ and the killing of individual adults are adjuvants. For this method to be really effective, animals and man would have to remain behind screens at all times. Since this is a physical impossibility, protection against mosquito bites is only partial. It is about equally applicable in all mosquito diseases, the differences being dependent on the habits of the adults of the species concerned.

Military units moving into areas where mosquito-borne disease is prevalent can avoid unnecessary exposure by locating camp sites at distances from breeding places and native habitations that are greater than the flight range of the vector, due regard being taken of the direction of prevailing winds.^{140, 141}

Numerous substances have been used as repellents; they are at best transitory, and some are toxic if used liberally. At present there are three fairly good repellents—"612," Indalone and dimethyl phthalate.¹⁴² The first gives protection for about four hours, even when persons are sweating. Indalone lasts equally long except under sweating conditions, when it should be reapplied every half

- Mosquitoes*. D. D. T. as a 5 per cent emulsion in kerosene, light oil or water, when used as a mist or fog, is effective at a rate of 1 liter per acre against 90 to 99 per cent of the adult mosquitoes within an hour. If sufficiently large areas are treated, the centers of these can be kept free of mosquitoes for several days. Aerosol bombs containing about 500 gm. of aerosol (5 per cent D. D. T.) are about equally effective against adult mosquitoes for periods of several hours. Spraying the inside of a building will cause death of mosquitoes for days to come.
- Both *Culicinae* and *Anopheles* larvae are susceptible to D. D. T.'s. A 5 per cent emulsion in No. 2 fuel oil in amounts of 1 or 2 liters per acre of water surface is usually adequate for six to nine days. Prolonged effectiveness, up to three or four weeks, may be obtained with doses of 5 to 10 liters per acre. The oil should be applied as a fine spray and not as a drip or poured on the water. Concentrations of 1 part in 10,000,000 are lethal to fish. If dust is used, about 200 gm. of finely powdered D. D. T. should be mixed with 5 to 10 parts of fine road dust or other diluent and dusted over 1 acre.
- Fishes*. Oil or water emulsion sprays are fatal to flies in about thirty to forty-five minutes. The drug is also effective as a powder or dust; residual action is particularly important, rendering a building free of flies for about a month.
- Bedbugs*. Spraying about 250 cc. of a 5 per cent emulsion of D. D. T. in kerosene on a bed will keep it free of bedbugs for perhaps as long as four to six months.
- Lice*. A powder containing 10 per cent D. D. T. mixed with talc or pyrophyllite, when applied to the entire inner surface of clothing worn next to the skin, particular attention being paid to the seams, and on the skin, is efficient in keeping persons free if repeated at monthly intervals or after each change of clothing.¹⁷⁶⁻¹⁷⁸ Areas about the neck, armpits, waist and crotch should receive special attention. About 30 to 60 gm should be used for each treatment. Since the dry powder is not absorbed, it is harmless; it should not be used on animals, since they may ingest toxic doses by licking themselves.
- Clothing may be impregnated with a 10 per cent emulsion of D. D. T.; this is effective in killing lice even after six to eight weekly washings with soap and water. The amount of emulsion required is about 2 per cent of the weight of the clothing.
- Pubic lice may be killed by applying 10 per cent D. D. T. to the hairy portions of the body and repeating after eight to fourteen days; the drug does not kill the eggs.
- Fleas*. Both the powder and the emulsion are effective in killing fleas. The residual effect of emulsion is effective
- Roaches*. These pests, except for the German roach, which is light brown and about 0.5 cm. long

and "occurs in the southern United States, as easily controlled as are flies and fleas. The powder should be applied in the same way as other roach powders.

Miscellaneous. D. D. T. is not effective against mites, spiders, ticks and centipedes. It must be used with caution, since it is toxic to many beneficial insects, such as bees.

War I, since lousiness was characteristic of all troops. The present war, however, has brought about miraculous developments in delousing techniques,¹⁶¹ resulting in virtual elimination of epidemic typhus from the Army and its control among civilians in combat areas. Methyl bromide fumigant in cartridges is available for disinfecting clothing in barrack bags. More phenomenal in its success against the head and body lice (*Pediculus humanus capitis* and *P. humanus corporis*) has been the application of D. D. T. powder to both the body and clothing. These drugs are also effective against fleas but have no effect against mites.

Endemic or murine typhus is spread by fleas. About 90 per cent of the 4000 cases reported annually in the United States occur in Alabama, Texas and Georgia.¹⁶² In 1926, Maxcy¹⁶³ made important epidemiologic studies, which eliminated the possibility of louse transmission of typhus fever in southern United States. In 1931, Dyer and his associates¹⁶⁴ obtained murine typhus from the brains of rats captured in a prison in Mexico City. It has since been demonstrated that the infection is passed from rat to rat by both rat fleas (*Xenopsylla cheopis*) and rat lice (*Polyplax spinulosa*).

Scrub typhus or tsutsugamushi fever is transmitted by several species of Trombicula mites and does not occur in the United States.^{165, 166} It is prevalent in the South Pacific and Asia. Clothing impregnated with dimethyl phthalate is efficient in killing the mite vectors.¹⁶⁷ The burning over of areas used to bivouac troops is effective in ridding the area not only of fleas and mites but also rodents and other vermin that may act as vectors of disease.

These three types of typhus fever are immunologically distinct¹⁶⁸ and can be identified in the laboratory by Weil-Felix reaction and by complement-fixation tests.¹⁶⁹ Vaccines have been prepared by various methods,¹⁷⁰ employing chick embryos, lice and so forth, and have proved effective against the epidemic and endemic forms of the disease. The same vaccine, however, is not effective against scrub typhus.

Rodent control is, of course, of importance in the control of endemic typhus fever,¹⁷¹ but the control of rodents in other rickettsial diseases is only of value under limited circumstances. Nevertheless, wild rodents, from field mice to rabbits, may be hosts of the exoparasites that are infected with various types of rickettsia.¹⁷²

DICHLORO-DIPHENYL-TRICHLOROETHANE

D. D. T. was first synthesized by a German chemist in 1874,¹⁷³ but it was not used as an insecticide until 1939, when a Swiss firm sold it as a control for moths and plant lice. Since November, 1942, the United States Department of Agriculture has experimented with D. D. T., not only as a control for agriculture insect pests but as a control for arthropod vectors.

D. D. T. is a tasteless, fine, white powder, insoluble in water. It tends to form lumps, is not affected by exposure to the air and sunlight and does not vaporize. The residue on a sprayed surface retains its toxicity as a contact poison to insects for several weeks.⁶¹ It is easily dispersed in dust and forms an emulsion with oils.

A powerful poison to the insect nervous system, it is absorbed through the chemotactic sensory organs in the tips of tarsi. Soon after exposure, the insect drags its legs, loses co-ordination, develops tremors and dies in convulsions. It is not a repellent and does not kill instantaneously like pyrethrum; death usually takes from several minutes to several hours.

Although the dry powder is not absorbed through the skin, concentrated oily emulsions are absorbed and may prove toxic in large doses, causing hyperexcitability, tremors, chronic convulsions and liver damage.¹⁷⁴ Precautions must therefore be taken to avoid repeated and prolonged contact with oil emulsions. Inhalations of heavy concentrations of D. D. T. smokes have not proved toxic to either animals or man. When ingested, however, D. D. T. is toxic for both animals and man, 200 mg. per kilogram of body weight per day killing 90 per cent of the test animals. When applied to water in the amounts recommended for larvicidal purposes, it is not toxic to fish, animals or man. Cyclohexanone is frequently used as a solvent for D. D. T.; although it is less than one tenth as toxic as D. D. T., in heavy concentrations it causes a temporary, harmless irritation of the eyes, nose and lungs.

D. D. T. may be mixed with 9 parts of inert powder for use as an insecticide or with the same amount of talc or pyrophyllite for use against body lice. An emulsion containing 25 per cent D. D. T., 68 per cent xylene and 7 per cent Tritonx-100 may be diluted with 4 parts of water, making a 5 per cent emulsion; or the pure powder may be mixed with No. 2 fuel oil, No. 10 lubricating oil, kerosene or other oils to form a 5 per cent emulsion. Aerosol bombs containing 0.3 per cent pyrethrins and 3 per cent D. D. T. have been demonstrated to be effective as an all-purpose insecticide. Such bombs should prove of value in disinsectizing planes. Special nozzles for spraying or dusting equipment are required, depending on the use to which the drug is being put. A fog is most effective against adult insects; for larvicidal purposes a fine spray is best; and for a residual effect on solid surfaces a coarse or semi-fine spray is needed to moisten the surface. A residual of 0.1 to 0.2 gm. of D. D. T. per square foot is desired; thus 1 liter of a 5 per cent solution is adequate for 250 to 500 square feet. The drug continues to be effective for weeks or months, depending on climatologic conditions. The drug may be sprayed both indoors and out. Although D. D. T. tends to stick to surfaces, heavy rains wash off a considerable amount, which may be detectable in the runoff.

abundant colonies of *Staphylococcus aureus*. Re-
peated serum nonprotein nitrogen and carbon dioxide
determinations were normal. The sulfadiazine level
did not exceed 6 mg. per 100 cc. The white-cell
count and the differential were unchanged. The
patient was given 50,000 units of penicillin and was
placed in an oxygen tent. A surgical consultant
thought that the abdomen and the subphrenic region
were negative.
On the sixth day, the patient felt much better and
the rectal temperature had fallen to 100°F. At 3

On the second hospital day the chest was some-
what better aerated and the respiratory rate re-
turned to 20. The gall bladder was faintly visualized
in a Graham test.
On the fourth day a definite gallop rhythm was
heard at the apex. Fresh blood was seen in the
sputum. There was a definite but mild cellulitis of
the left forearm. Measurements above and below
the knees were symmetrical. The rectal temperature

FIGURE 1.

a.m. on the seventh day he became extremely rest-
less, began to moan and appeared to be in marked
distress. He promptly began to gasp and expired
shortly thereafter.

DIFFERENTIAL DIAGNOSIS

Dr. DERA KINSEY: Out of this long and com-
plicated story we have little definite knowledge.
We do know, however, that this sixty-four-year-old
patient had been chronically ailing for at least one
year. His chief complaints were chest pain, weight
loss, abdominal pain and urinary difficulties. The
final illness came on suddenly; it may have been a
part of the chronic illness or something new.

reached 103°F., and sulfadiazine was started. The
pulse fluctuated between 100 and 120, and the
respirations between 25 and 35. A thoracentesis
in the ninth interspace on the right posteriorly
yielded 60 cc. of grossly bloody fluid containing
6000 lymphocytes and monocytes per cubic milli-
meter. After the chest tap the respiratory rate was
elevated to 60. Localized edema was noted over
the painful area in the right chest posteriorly. There
was tenderness in the costovertebral angle. A
catheterized specimen of urine showed occasional
red cells and 75 white cells per high-power field,

CASE 31131

PRESENTATION OF CASE

A sixty-four-year-old man was admitted to the hospital because of hemoptysis and abdominal pain.

He had been in good health until approximately a year before admission, when he first noted a dull, aching, nonradiating, intermittent pain under the lowest rib in the right midaxillary line. Six weeks before entry he became aware of a gradual weight loss, amounting to about 16 pounds in the previous six months. He also began to notice mild anorexia and malaise. Urgency, frequency and dribbling, which had been present for two years, became more intense. Three weeks before admission and five to six hours after ingesting a heavy meal, he was suddenly awakened at night by a severe, constant, periumbilical pain, which radiated to the perineum and to the tip of the xiphoid. So intense was this pain that he vomited and spent the next five hours in agony. He worked the next day, although the pain was still present. It persisted throughout the following week and he was taken to a community hospital. He continued to be nauseated and the abdominal pain shifted from the periumbilical region to the right upper quadrant, where it localized. He remained afebrile. His stool habits and the gross appearance of the stools remained normal. Cystoscopy, a gastrointestinal series and a barium enema were reported as negative. A retrograde pyelogram was negative except for questionable blunting of the middle calyces on the right. An intravenous pyelogram showed no visualization of the right kidney. X-ray studies of the chest were reported to show bilateral basal atelectasis and

diminished excursion. During the four days before entry the pain in the right upper quadrant continued intermittently. He developed a cough, with small hemoptyses, and was transferred to this hospital.

Except for dysuria, nocturia (twice) and frequency the past history was noncontributory.

Physical examination revealed a well-developed, moderately well-nourished man in no acute discomfort. Examination of the heart was negative. The breath sounds were diminished at the right base posterolaterally and as far forward as the anterior axillary line. Over this same area there were fine rales and dullness to percussion. Localized pain with respiration and a friction rub were noted over the left lower chest posterolaterally. The abdomen and extremities were normal.

The temperature was 99.2°F., the pulse 100, and the respirations 20. The blood pressure was 120 systolic, 80 diastolic.

The urine was acid, with a specific gravity of 1.017, and gave a + test for albumin; the sediment contained numerous white cells and bacteria. Examination of the blood showed a white-cell count of 11,100, with 92 per cent neutrophils, and 10.5 gm. of hemoglobin. The serum nonprotein nitrogen, the protein and the chloride were normal.

X-ray studies of the chest revealed retarded motion of both leaves of the diaphragm, the right more than the left. Above them, linear areas of atelectasis were observed at each base, and on the right there were also patchy areas of increased density. It was thought that a small amount of fluid might be present in the right pleural sinus (Fig. 1). There was little change since the last x-ray taken in the other hospital, three days prior to admission.

During the patient's first night in the hospital the pain in the right posterior chest was severe and aggravated by cough. The pain was readily localized to an area under and to the right of the angle of the right scapula. Inspiration was limited, and the respiratory rate was 35. The rectal temperature was 101°F., and the pulse 110. The abdomen was distended, tympanic and tense. There was questionable tenderness in the right upper quadrant. The calves were not tender, and there was no tenderness over the femoral veins. The patient raised a small amount of blood-streaked sputum. Repeated examinations and cultures of the sputum were nega-

*On leave of absence.

abdominal disease but did not know the nature of it. The final episode was, to my mind, pulmonary embolism, and I signed him out with that diagnosis.

CLINICAL DIAGNOSES

Pulmonary embolism.
Intra-abdominal infection of undetermined nature?

DR. KINSEY'S DIAGNOSES

Renal-cell tumor of right kidney, with thrombophlebitis of renal vein and metastases to lung.
Pulmonary infarcts.
Terminal infection: (?) bronchopneumonia or bacterial endocarditis.

ANATOMICAL DIAGNOSES

Pulmonary embolism, massive.
Pulmonary infarcts: multiple, bilateral, recent and healing.
Phlebotrombosis of leg veins.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy showed that the terminal event was a massive pulmonary embolus and that most of the previous symptoms were probably due to smaller pulmonary emboli. At the edge and margin of the anterior surface and posteriorly along the diaphragm were numerous infarcts, which extended up to involve about the lower third of each lung. In several areas they were quite thin because they extended to the edge and had contracted down a bit. Some of them, especially one in the left lung, had a dimple on the pleura indicating that this was a healing infarct and could have been there for a matter of a month or two. Others were more recent. In other words, they varied in age from a couple of months down to a week or ten days. Some were red, and others were black and rather well circumscribed, with beginning encapsulation. The calf veins of both legs were the source of the emboli.

The kidneys were perhaps slightly larger in size than normal and showed evidence of pyelitis, which was apparently the source of the *Staphylococcus aureus*. We were unable to find any infection in the parenchyma of the kidney itself. One microscopic section showed a thrombus in a small vein, and a small focus of tissue nearby was infarcted. There were no large thrombi or emboli. I am sure that this was not the cause of the severe abdominal pain; if so, there would certainly have been a larger infarct. Perhaps all his pain was referred from the pulmonary infarcts. He had them in both lower lobes, and there was an extensive diaphragmatic pleuritis.

DR. JONES: The original pain that sent him into the hospital was in the lower abdomen. That was the one point that he stuck to all the time. It brings out the point that pain arising from the attachment

cellulitis of the forearm, which might have been the focus. I believe that he also had an acute infectious process, such as a bacterial endocarditis or a bronchopneumonia.

DR. CHESTER M. JONES: This case was confusing because from the moment the patient entered the hospital the suggestion was made that he had a subphrenic abscess. That was as near as anyone had approached the diagnosis before he entered the hospital. The striking fact on admission was the clinical picture. He was extremely ill. He was badly distended and had been vomiting. He had a story that was difficult to obtain, but it pointed to an intra-abdominal disturbance, so far as we could find out. He remained extremely distended for several days, and then the distention disappeared after an enema and did not recur. I suppose the distention caused the elevation of the diaphragm.

He continued to complain of abdominal pain, but my feeling, in view of the x-ray studies that had been taken prior to admission, was that intestinal disease had been ruled out and that renal disease probably had been ruled out. I wondered whether or not he had an empyema of the gall bladder with perforation. He was tender in the right upper quadrant, but it was also apparent that he had abundant physical signs, including a friction rub, first in the left chest and later in the right. He had pain over the area of pulmonary signs; in other words, he had pain in the chest over the friction rub. I went over the previous chest films and the ones taken here and discussed them with several members of the x-ray staff. There was no final conclusion concerning what was going on above the diaphragm.

Chemotherapy was started because of a marked rise in temperature. At that time he had a striking cellulitis of the left arm that seemed to be associated with intravenous therapy, initiated because of severe dehydration. The following day he was seen by Dr. Sweet to determine if possible what was going on in the chest and to decide whether or not he had a subdiaphragmatic infection, although the patient was still extremely sick. We went over his legs with the utmost care, besides, although the patient was still extremely sick. Cause the question of pulmonary embolism had been raised, but we could not find any evidence of a thrombotic process. There was no tenderness, and he had a negative Homans's sign. The white-cell count was about 11,000, and at that time we tapped the right chest, inasmuch as the physical signs seemed more striking than the x-ray findings. We found bloody fluid. This was spun down and examined for malignant cells, without result. Furthermore, several specimens of sputum were examined for tubercle bacilli and the chest fluid was put into a guinea pig, also with negative results. Until the last episode we were definitely in doubt about what the patient had. I thought that he had intra-

Had this man one disease process to explain all his symptoms or had he more than one? First let us consider the chest. He had had chest pain for one year and more acute pain recently. Pneumonia occasionally causes acute abdominal pain and sometimes is mistaken for an acute abdomen. The x-ray findings, the white-cell count and the temperature, however, are not in keeping with it. The x-ray examination also rules out tuberculosis. Furthermore, tuberculosis usually does not give a bloody pleural fluid. On the other hand, the bloody fluid, the weight loss and the age of the patient should make one consider metastatic malignancy. A likelier possibility is pulmonary infarction. The chest pain, the cough and the raising of blood-tinged sputum are classic symptoms. Infarctions are usually secondary to thrombophlebitis or thrombosis in the lower extremities. The emboli may originate, however, in any of the large veins or in the right side of the heart itself. The physician who took care of this patient evidently suspected pulmonary infarction because a careful search was made for the focus of the emboli but apparently none was found. Another suggestion of pulmonary infarction is the development of gallop rhythm. An electrocardiogram might have been helpful.

The patient's most acute symptom was abdominal pain, which began in the periumbilical region and radiated to the perineum and to the xiphoid. Frequent causes of periumbilical pain are small-bowel obstruction, — which may be caused by a malignant tumor, — kink, hernia and intussusception. All these things seem to be ruled out because the patient had normal stools, all the x-ray examinations were negative, and the vomiting ceased. The type of pain does not suggest disease of the gall bladder or acute pancreatitis. Cardiac decompensation with a large engorged liver can certainly cause severe abdominal pain of the type described here. We have no evidence, however, that the liver was large and engorged, and the only suggestion of congestive failure was the gallop rhythm. A subphrenic abscess with rupture into the pleural cavity may cause a combination of abdominal and chest pain. The character of the chest fluid and the absence of chills and of a high white-cell count are against this diagnosis. A dissecting aortic aneurysm can also produce abdominal and chest pain. The pain of a dissecting aneurysm, however, usually radiates to the back and down the legs.

May we see the x-ray films?

DR. MILFORD D. SCHULZ: Here is a series of films of the chest. At the time of the original observation, the fluoroscopist saw nothing in the chest. In the film taken ten days later, however, the findings are as described — linear areas of increased density obscuring both leaves of the diaphragm and elevation of the leaves of the diaphragm. These changes persisted throughout the subsequent ob-

servations. This film, after retrograde filling of the right kidney, shows irregularity of the middle calyx. I wonder if it is not the filling that one sees in a retrograde pyelogram that has caused overdistention of the pelvis. All the calyces are blunted. The kidney appears to be normal. I should think it was probably all right.

These are the films of the intravenous pyelogram; unfortunately they do not show much. Because of barium in the colon, the visualization is not too adequate, but you can see fairly distinct calyces and no evidence of obstruction on either side.

DR. KINSEY: Then you can see the right kidney?

DR. SCHULZ: The kidney outline is obscured by overlying material.

DR. KINSEY: You cannot see the calyces?

DR. SCHULZ: I believe that you can in this film. There is a faint shadow that probably represents the pelvis and some of the calyces, but it is not good enough to warrant any statement.

DR. KINSEY: An intravenous pyelogram showed no function of the right kidney but the retrograde pyelogram showed a practically normal kidney, with the exception of blunting of the middle calyces. This indicates or suggests that something was interfering with the blood supply of that kidney. What might interfere with the blood supply? Thrombosis of the renal artery with infarction is a possibility and would have caused pain. It might even have been a thrombosis of the renal veins. A tumor such as a renal-cell carcinoma might explain many of the symptoms and signs, although the three most frequent findings — tumor, hematuria and pain referable to the kidney area — are absent. Renal-cell carcinoma or hypernephroma is very apt to extend up the renal vein into the inferior vena cava and to metastasize to the lungs, and in one case report of this condition from this hospital the outstanding symptoms were gastrointestinal.

Then I thought of one other possibility — subacute bacterial endocarditis of long duration, with mural thrombi giving out infected emboli and causing infarction in various parts of the body. This patient, however, had no evidence of rheumatic valvular lesions, which are usually present in subacute bacterial endocarditis. In fact, not many heart symptoms were noted. It seems that there was an additional terminal infection; those who took care of him probably thought that, because they gave sulfadiazine and penicillin.

In reading the abstract I made the following diagnoses and I shall stick to them even though they do not seem quite so obvious after looking at the x-ray films: tumor of the right kidney, probably renal-cell tumor, with thrombophlebitis of the renal veins and with metastases to the lungs; and pulmonary infarcts, which may or may not be associated with the thrombophlebitis of the renal veins, because we do know that silent emboli may come from the extremities. We were told that he had a

to make our way into this. It soon became apparent that whatever tumor was here had invaded the duodenum directly. The gall bladder and bile ducts formed a solid tumor mass, which was biopsied. We could not identify any portion of normal duct above the tumor mass that could be used for anastomosis. Because of the fact that the duodenum was partially destroyed by the tumor mass, a resection of the distal end of the stomach and the first portion of the duodenum had to be performed. Even this much surgery in the face of a complete and unrelied biliary obstruction was doomed to terminate fatally. About ten days after the operation, the patient slipped into coma and died quietly, a death that I should characterize as being typical of liver failure or cholemia.

CLINICAL DIAGNOSIS

Cholelithiasis, with common-duct stone.

DR. DONALDSON'S DIAGNOSIS

Cholelithiasis, with common-duct stone.
Chronic cholecystitis.

Bile stasis of liver.

ANATOMICAL DIAGNOSIS

Colloid carcinoma of gall bladder, with extension to extrahepatic bile ducts and metastases to head of pancreas and regional lymph nodes.
Cholelithiasis.

Bile stasis of liver.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: When he died the patient was deeply jaundiced. Dr. Moore had resected the distal end of the stomach and proximal portion of the duodenum. This was followed by a gastrojejunostomy and infolding of the duodenal stump. All suture lines were intact, but the proximal end of the duodenum lay in a necrotic mass of fibrinopurulent adhesions. The gall bladder was destroyed by a tumor that was fixed to the surrounding viscera by fibrous adhesions, and its necrotic center contained a 3-by-2-cm. gallstone. The tumor had spread to the cystic and common bile ducts and to both hepatic ducts, leading to complete obliteration of their lumens. The adjacent liver parenchyma was also invaded. The whole mass measured approximately 6 by 4 cm. The head of the pancreas contained a few minute, discrete metastatic nodules. Microscopic sections showed a colloid carcinoma. The liver was large, weighing 1990 gm., and its surface was smooth and dark green. The intrahepatic bile ducts were distended with bile. Microscopic sections showed a rather severe bile stasis without other abnormalities except for degeneration in the neighborhood of the invading tumor.

have been others. These patients were mildly jaundiced and then cleared, only to become icteric again one or two months later. The mechanism of this is hard to explain, but it does occur. Local edema, the rate of bile flow and the type of bile have been offered as explanations. Here again, however, if the obstruction were this far down the biliary tree one would expect gall-bladder distention. Cancer of the gall bladder or upper biliary tree is in the same order of likelihood. In such conditions the patient should be a little less robust than the report leads one to suspect. Primary cholangitis of the stenosing type is unlikely in the absence of chills and fever. Similarly, biliary obstruction from an ascending pyelophlebitis has no historical or clinical support. I shall have to conclude that the operator on opening the abdomen expected to find a slightly enlarged, heavily pigmented liver, a thickened, shrunken gall bladder and a somewhat dilated and edematous common duct. A stone had been passed fifteen months before. Another was probably lodged in the common duct, and more lay in the gall bladder. The epigastric soreness and tenderness were due to this stone. The dark black stools noted on several occasions two weeks before entry probably resulted from erosion by a stone of one of the veins that are so abundant in the common-duct wall. A fistula may have existed between the gall bladder and common duct, but this is unlikely. A prothrombin time, prolonged by obstructive liver damage, prevented early clotting and resulted in the degree of anemia found. Further evidence of the degree of liver damage is found in the lowered albumin-globulin ratio and in the elevated van den Bergh reaction.

DR. ROYALD C. SNIFFEN: Dr. Moore, you operated on this case. Will you tell us about your findings? DR. FRANCIS D. MOORE: An item that might have helped Dr. Donaldson is the fact that the black stools occurred while he was in an outside hospital and while he was receiving iron therapy. They were not guaiac or benzidine positive, and so far as we can make out, he had never had any proved evidence of gastrointestinal bleeding. This is important because gastrointestinal bleeding in cases of common-duct stone is extremely rare, even in the presence of a markedly elevated prothrombin time. In any event, we expected to find approximately what Dr. Donaldson has described, namely, the lithiasis, with a common-duct stone. The situation was quite different, however, from what we expected. The duodenum, large intestine, stomach, pancreas, gall bladder and common duct were all drawn up into the liver hilus, where they were firmly matted together by an extensive neoplastic and inflammatory process. In attempting

of the diaphragm can spread over the distribution of the twelfth intercostal nerve. Another point of which I was not aware is that one can occasionally obtain bloody fluid from the pleural cavity in cases of pulmonary infarction.

DR. CASTLEMAN: I should say that 10 or 15 per cent of pulmonary infarcts have associated hemorrhagic pleural fluid.

CASE 31132

PRESENTATION OF CASE

A fifty-three-year-old man was admitted to the hospital because of deep jaundice.

He had been well until fifteen months before entry, when he suffered an acute onset of dull epigastric pain. At about the same time he noticed the appearance of moderate jaundice, dark urine and light-colored stools. A physician gave him "some pills" and the jaundice allegedly disappeared, having been present only about fifteen to twenty hours. The epigastric pain and a feeling of fatigue, however, lasted several days longer.

Following this episode he was well until about five weeks before admission, when a steady epigastric pain recurred and was associated with occasional nausea and vomiting of liquid material that resembled "olive oil." Three weeks before admission he rapidly developed marked jaundice, with dark urine and light-colored stools. The epigastrium was a little "sore" and slightly tender. The degree of jaundice had fluctuated slightly and there were a few bouts of nausea and vomiting. He had no fever, chills or colicky or radiating pains. He stated that he had had black stools for several days about two weeks before admission.

Physical examination revealed a well-developed, well-nourished man in no distress. The skin and scleras were deeply jaundiced. The heart and lungs were not remarkable. The abdomen was not distended and showed no mass or tenderness.

The temperature, pulse and respirations were normal. The blood pressure was 120 systolic, 65 diastolic.

Examination of the blood showed a red-cell count of 3,690,000, with 10.9 gm. of hemoglobin, and a white-cell count of 11,600, with 85 per cent neutrophils. The urine was dark, acid in reaction and had a specific gravity of 1.012. It gave a + test for albumin and a +++ test for bilè. The sediment contained a few granular casts. A van den Bergh test was 23.5 mg. per 100 cc. direct, and 32.4 mg. indirect. The stool was olive green and guaiac negative. The prothrombin time was 27 seconds (normal, 18 to 20 sec.). The serum nonprotein nitrogen and total protein were normal, with an albumin-globulin ratio of 1.04.

X-ray examination of the abdomen showed no opaque calculi along the course of the renal or biliary tracts. The lumbar spine was not unusual, and the psoas contours were normal. There was no enlargement of the liver or spleen. The right kidney was thought to be somewhat enlarged.

On the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. GORDON DONALDSON: In the absence of the x-ray films, we will have to content ourselves with the written report. On x-ray examination, the liver was not enlarged and no evidence of gallstones was seen. The enlargement of the right kidney can be interpreted as being within the limits of normal.

I think that this man had either cancer or calculi obstructing the outflow of bile from the liver, with the odds heavily in favor of stone. A portal or toxic type of cirrhosis seems unlikely in view of his pain, short story, lack of ascites and general well-being. Moreover, a jaundice of the catarrhal type is reasonably well ruled out by the story and physical findings. Catarrhal jaundice does not recur, particularly after a fourteen-month interval.

The jaundice was obstructive in nature and was of the type that was not accompanied with bouts of chills and fever. The pain, moreover, was probably due to whatever caused the obstruction, and not to the liver itself, since a distention of the liver capsule sufficient to cause pain should result in a palpable liver or one seen to be enlarged by x-ray. From the location of the pain one might suspect a gastric or duodenal ulcer, with secondary distortion and constriction of the common duct. Such deforming ulcers, however, are usually of much longer duration and are found in much sicker patients. An obstructing duodenal diverticulum should be mentioned in passing. Obstructing disease in the pancreas is a possibility, but if present, the location and type of pain are unusual. Patients with cancer of the head or body of the pancreas usually have pain in the midback. Cyst of the pancreas is rare but can cause obstruction. Certainly if the obstruction to the flow of bile is strictly pancreatic in origin, one should be able to feel the distended gall bladder on abdominal examination.

Carcinoma of the ampulla of Vater should be given consideration. To be sure, such a lesion rarely causes pain, and when it does it is not in the mid-epigastrium. Bleeding, however, is a fairly common finding; and in this patient we have a history of black stools and the report of a moderately severe anemia. It is only fair to say that the fecal blood in carcinoma of the ampulla is usually occult. A history of definite jaundice that fades out only to recur does not rule out carcinoma of the ampulla. Such a case was reported here not long ago,* and there

*Case records of the Massachusetts General Hospital (Case 30381). *New Eng. J. Med.* 231:427-429, 1944.

have been others. These patients were mildly jaundiced and then cleared, only to become icteric again one or two months later. The mechanism of this is hard to explain, but it does occur. Local edema, the rate of bile flow and the type of bile have been offered as explanations. Here again, however, if the obstruction were this far down the biliary tree one would expect gall-bladder distention. Cancer of the gall bladder or upper biliary tree is in the same order of likelihood. In such conditions the patient should be a little less robust than the report leads one to suspect. Primary cholangitis of the stenosing type is unlikely in the absence of chills and fever. Similarly, biliary obstruction from an ascending pyelphlebitis has no historical or clinical support. I shall have to conclude that the operator on opening the abdomen expected to find a slightly enlarged, heavily pigmented liver, a thickened, shrunken gall bladder and a somewhat dilated and edematous common duct. SURGERY OVER THERE

THE September issue of the *Annals of Surgery* contains a paper by Colonel Edward D. Churchill, who is on leave from the Massachusetts General Hospital while serving as surgical consultant to the North African and Mediterranean Theater of Operations. This paper has been characterized by Brigadier General Rankin as "one of the finest dissertations on the management of wounds which has been submitted through the Office of The Surgeon General of the United States Army." In a foreword to this article General Rankin writes:

Colonel Churchill has done more than improve the quality of surgery performed in this theater. Uniquely equipped to perform his mission and imbued with the true scientific spirit, he early recognized the inadequacy

of certain preformed concepts in the surgical management of the wounded. With this flexibility of mind and with an elastic organization, he has utilized an investigative approach and drawn upon battlefield experience to evolve more rational and effective methods in the surgical care of the wounded. In this article, he has epitomized these observations and principles which constitute not only a contribution to war surgery but also to the advancement of medical science.

Every surgeon interested in the management of traumatic wounds should read this brief paper in the original. Others will get a great deal of satisfaction from reading it and learning of the methods now being employed in the management of severe battle injuries. Dr. Churchill dispels a number of important misconceptions, particularly concerning the role of blood substitutes and of chemotherapeutic agents, including penicillin, in the management of wounds and indicates the greater importance of prompt and adequate surgical treatment. No better comment on this paper could be made than to quote a few excerpts* that are as applicable to traumatic surgery in civilian life as they are to the management of injuries sustained on the battlefield:

... Plasma alone is not adequate to prepare a seriously wounded casualty to withstand the surgical procedures that are essential, or to carry him through the critical postoperative period. After admission to hospital a limited amount is used to augment the effects of whole blood transfusion. Plasma is a substitute for whole blood only in the sense that it can be packaged and stored in adequate quantity in areas where blood cannot be obtained. Plasma is not a substitute for whole blood in the physiologic sense. . . .

Chemotherapy is initiated in the field by local and oral administration of sulfonamides. The value of this procedure is questioned by many surgeons of experience. Preoperative penicillin therapy is started on all but the lightly wounded casualties on admission to hospitals in the forward area. At operation, topical application of penicillin is carried out only in wounds penetrating the meninges, serous cavities and joints. Parenteral administration is continued beyond the period of the likelihood of infection or until established infection has been controlled. No patient is held in the forward area solely for the purpose of continuing penicillin therapy.

Just as plasma is not a substitute for whole blood in resuscitation, neither are sulfonamides and penicillin substitutes for the surgical excision of devitalized tissue. Chemotherapeutic agents cannot sterilize dead, devitalized or avascular tissue, nor do they prevent the septic decomposition of contaminated blood clot. . . .

In this war there have been two quite different approaches in the application of chemotherapeutic agents to military surgery. The first would utilize these agents to permit delay in wound surgery and minimize the complete-

*Permission to quote these excerpts has been obtained from the copyright owner, J. B. Lippincott Company, Philadelphia

ness of the excision of dead tissue. The second employs chemotherapeutic to extend the scope of surgery and achieve a perfection in results previously considered impossible. The latter policy has guided the surgery of the Alcler-ranean Theater. To reiterate the axiom that penicillin is not a substitute for surgery is not enough. Every surgeon must learn that chemotherapy opens new and startling possibilities in wound management. . . .

Surgeons assigned the responsibility of caring for the wounded in a first priority surgical hospital must be highly trained and experienced, as their tasks are the most exacting of military surgery. . . . If the achievements of surgery in this theater are ever judged noteworthy, they are attributable to the fact that experts rather than inexperienced surgeons are doing the work. All other measures are ancillary items. . . .

It is estimated that during the Italian Campaign alone at least 25,000 soft-part wounds have been closed on the basis of gross appearance only. Healing has resulted in approximately 95 per cent, and no loss of life or limb or serious complications have been reported. . . . The presence of residual dead tissue or established invasive infection at the time of the first dressing is evidenced by discharge of pus and redness and edema of the wound margins. When these are present but minimal, the wound is allowed to "clean up" with moist dressings. Surgical excision of devitalized fragments or removal of retained foreign bodies may speed this process. Secondary closure may then be performed after a few days. If established infection is severe, or if the patient is toxic or anemic, a course of penicillin therapy and blood transfusions is instituted and followed by radical wound revision with staged closure. . . .

The topical use of sulfonamides appears to contribute nothing to the favorable results of reparative wound surgery. Parallel series of closures show as satisfactory or better results without the topical application of sulfonamides at the time of suture as with it. Penicillin therapy is entirely unnecessary as an adjunct to the usual reparative surgery of soft-part wounds. It is used parenterally for cases of established infection and in the reparative surgery of complicated wounds. . . .

The reparative surgery of complicated wounds, including those with extensive muscle damage as well as those with skeletal or joint injury and penetration of the viscera, is a more major undertaking. It is in this group that both the incidence and hazards of infection may be expected to be greater. It is this group of cases that is kept on penicillin therapy during the interval between initial and reparative surgery and so maintained until the likelihood of infection is past. Immediate correction of secondary anemia on arrival at the base is an essential part of the program as the days are few during which the anemia from the initial blood loss may be projected into the anemia of chronic infection and indolent wound healing. The procedures of reparative surgery are frequently of great magnitude and the patients must be adequately supported by whole-blood transfusions, before, during, and subsequent to operation. . . .

The time-lag between wounding and initial surgery referred to as "the golden period" has been greatly reduced by the organization of medical service in the forward area to this end. The time-lag between initial surgery and reparative surgery is now assumed an equal degree of importance. Just as every hour added to the time-lag between injury and initial surgery increases the loss of reparative surgery as every hour added to the time-lag of importance. . . .

MASSACHUSETTS MEDICAL SOCIETY SECRETARY'S OFFICE

The following communication concerning cancellation of the annual meeting of the Massachusetts Medical Society has been sent to the Executive Committee of the Council:

Dear Doctor:

The Office of Defense Transportation has denied our petition to hold the annual meeting of the Massachusetts Medical Society. This applies equally to the annual meeting of the

These events will, therefore, not be held in 1945. Dr. Elmer S. Bagnall, President, has ruled that the carrying on of our Society's affairs during this emergency is the obligation of the Executive Committee of the Council.

The next meeting of the Executive Committee has been set for 10:30 a.m., Wednesday, May 23, 1945, at Sprague Hall, 8 Fenway, Boston. The agenda of this meeting will be sent to each councilor well in advance. On its receipt the president of each District Medical Society should call the councilors of his district together for the purpose of studying it and making determinations with

It is apparent from these excerpts that soldiers, at least those in the Mediterranean area, are receiving the best of surgical care, which is reflected in the end results. Furthermore, one can look forward to a generation of well-trained surgeons who have benefited from their experiences and are prepared to practice and to teach others the best methods of wound management.

The following communication concerning cancellation of the annual meeting of the Massachusetts Medical Society has been sent to the Executive Committee of the Council:

These events will, therefore, not be held in 1945. Dr. Elmer S. Bagnall, President, has ruled that the carrying on of our Society's affairs during this emergency is the obligation of the Executive Committee of the Council.

regard to it, to the end that the executive councilor may come to the meeting in May aware of and fully prepared to express his district's point of view.

The Cotting Luncheon will be served.

Very truly yours,
Michael A. Tighe, *Secretary*

DEATHS

BERGIN — Stephen A. Bergin, M.D., of Worcester, died February 22. He was in his seventy-second year.

Dr. Bergin received his degree from Harvard Medical School in 1900. He was a member of the staff of the St. Vincent Hospital. He was a fellow of the American Medical Association.

His widow, five sons, a daughter and three grandchildren survive.

BUTLER — John E. Butler, M.D., of Taunton, died March 9. He was in his eighty-second year.

Dr. Butler received his degree from Harvard Medical School in 1891. He was a retired Boston specialist in anesthesia.

His widow and a brother survive.

ELIOT — Henry W. Eliot, M.D., of Manchester, Vermont, died October 21, 1944. He was in his seventy-ninth year.

Dr. Eliot received his degree from the University of Vermont College of Medicine in 1898.

His widow survives.

FISHER — John C. V. Fisher, M.D., of West Roxbury, died February 20. He was in his fifty-third year.

Dr. Fisher received his degree from Boston University School of Medicine in 1917. Dr. Fisher served as a surgeon for the United States merchant marine during the first world war. He had practiced in Boston since 1919 and had been obstetrician at Massachusetts Memorial Hospitals since 1928. He was associate professor of obstetrics at Boston University School of Medicine. He was a fellow of the American College of Surgeons, and a member of the New England Obstetrical and Gynecological Society.

His widow and three daughters survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

RETURN OF EMPTY VIALS AND OUTDATED BIOLOGIC PRODUCTS

At the onset of the war emergency, the Antitoxin and Vaccine Laboratory was faced with serious difficulties in procuring containers, circulars and other supplies used in packaging biologic products. An appeal was sent out to physicians, boards of health and hospitals to return used packages or containers of biologic products to the laboratory so that these could be re-used. The return of outdated products, which has always been urged, was particularly stressed because of the wartime shortages of supplies and personnel.

The response has been gratifying. Thousands of outdated packages, empty containers and so forth have been returned. The containers have been re-used, and the products have been re-tested. Those products that could be salvaged have been re-processed and redistributed. These returns have aided tremendously in maintaining the continuity of production and distribution at the laboratory,

and this note is sent out to express the gratitude of the laboratory staff and of the department for the fine co-operation and assistance in this salvage program.

The situation regarding supplies and production is getting no better. Returns are needed as badly as ever and will continue to be welcomed. By returning empty containers and outdated products the physician and others not only help the war effort and save the taxpayers additional expense but also help to keep the supply of such products fresh and thus to avoid the risk of using supplies that are outdated.

FLOODS AND TYPHOID VACCINATION

State and local health and welfare organizations, the American Red Cross and other agencies have already anticipated the possibility that serious floods will occur this spring as a result of the heavy snows of the winter. Although the recent extended thaws may have done much to reduce the likelihood of floods, the possibility remains that floods will occur, and plans must be made for handling the emergencies that may arise.

The organization of such programs in recent years has been developed largely in the Mississippi Valley and those of its tributaries — an area where typhoid fever is widespread and fairly prevalent. Consequently the administration of typhoid vaccine on a mass scale to persons in, or refugees from, flooded areas has become a widely accepted practice. In New England, however, the local conditions that prevail should be given serious study before accepting any such procedure simply because it has been widely used elsewhere.

Typhoid fever is a relatively rare disease in New England and consequently the risk of contamination of drinking waters because of floods is exceedingly slight. The application of mass immunization against typhoid fever is, therefore, not warranted in Massachusetts except in situations where there is sound reason to believe that typhoid infection may exist in the water supply in use. This is particularly true with the present shortage of health and medical personnel, for such immunization programs take a great deal of time and effort on the part of trained personnel, whose services may be more urgently needed in other ways. Another consideration is that the vaccine probably will not prevent the disease in persons already exposed by flood conditions.

If it is decided that vaccination is necessary, the program may be simplified by bearing in mind the value of a single dose of vaccine for anyone who has previously been vaccinated against typhoid fever. Such persons will obtain sufficient protection by receiving one dose of typhoid vaccine, given either as 0.5 cc. subcutaneously or as 0.1 cc. intradermally.

COMMENT

†Pfeiffer-bacillus meningitis only other form reportable previous to 1941.

Alumps is quite prevalent though not up to the February record of 1942 and 1936. However, the number of cases is somewhat more than twice that representing the seven-year median.

Lobar pneumonia is again at a low point, the lowest on record for the month of February. The number of cases is approximately half that of the seven-year median.

Meesles is at the lowest level reported for the month of February since 1907.

Scarlet fever shows a marked drop over the January record, and now is at about the seven-year average.

Pulmonary tuberculosis is tending to decline once more in spite of widespread case-finding activities.

"In short, there was no single point, other than a positive vesicular scraping, which was entirely reliable for diagnosis."

I do not wish to dispute the facts that both smallpox and chicken pox can run very atypical courses and that at times each disease mimics the other, but I hesitate to accept as valid the findings of a new test to differentiate these two diseases when most of the evidence supporting the specificity of the test is based on the study of atypical cases of smallpox, which, except for the findings of the test, would have been called chicken pox.

I would be the first to admit that smallpox can occur in the vaccinated individual, but it is difficult to accept the diagnosis of smallpox in the series of 100 cases studied when all but 4 patients had been previously vaccinated and when 70 had been successfully vaccinated within a two-year period before onset. It is possible that what was read as an immune reaction to smallpox vaccination really represented a feeble response to impotent vaccine. In that event, of course, these persons were not successfully vaccinated. Furthermore, in contrast to the clinical description by these authors of mild smallpox, what little knowledge we do have of second attacks of the disease in the same person and bona-fide cases in vaccinated persons, indicates that, although the disease may be mild, the distribution of the lesions and their description, except for their number, do not differ strikingly from those occurring in the unmodified disease.

I approach this whole subject very much as a layman, since my knowledge of the laboratory aspects of the problem, as well as that of clinical smallpox, is meager. I do think, however, that my argument is pertinent and that additional evidence is needed before one can assume, on the one hand, that the 100 cases of smallpox described from Egypt actually were not, to a large extent, due to chicken pox and, on the other hand, that this interesting diagnostic test does clearly differentiate the two diseases. I intend to write the authors for additional information, but since your editorial has just come to hand, I thought it worth while putting my thoughts on paper for transmittal to you.

ROBERT F. KORN, M.D.
Epidemiologist

State of New York Department of Health
Division of Communicable Diseases
Albany 1, New York

In the article by Majors Illingworth and Oliver one assumes that the difficulty in clinically recognizing the cases of smallpox was in the early stage, when they exhibited either the so-called "modified form," as a result of previous vaccination, or the violent hemorrhagic form, the onset of which sometimes suggests measles or typhus fever. Since these authors state that the positive findings in the scrapings of the early lesions were subsequently confirmed clinically, it appears that the later course of the disease established the diagnosis of smallpox. In addition, some of the more time-consuming laboratory tests may have been employed. As Dr. Korn points out, it is somewhat difficult to rationalize so many cases of smallpox, many of which were severe, in persons who had been successfully vaccinated. Possibly the "success" of the previous vaccinations, as he suggests, should be questioned, since it is well known that, for obvious reasons, vaccine virus stored in the subtropics and tropics is likely to lose its potency rapidly. Furthermore, even 96 cases in vaccinated persons are not particularly surprising when one considers the enormous number of troops that must have passed through this smallpox-infested country at the time that these observations were made. Certainly, any laboratory method by which it is claimed that smallpox can be rapidly differentiated from chicken pox deserves comment to ensure further study by other investigators. — Ed.

NOTICES

NEW ENGLAND HEART ASSOCIATION

The Henry Jackson Lecture of the New England Heart Association will be held at the Boston Medical Library on Monday, April 16, at 8:15 p. m. Professor Dr. Teosilo Ortiz Ramirez will speak on the subject "Heart Disease in Mexico, and the New National Institute of Cardiology." Interested physicians and medical students are cordially invited to attend.

JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

- Wednesday, April 4 — The Problem of Splenic Hemolysis. Dr. K. Singer.
Friday, April 6 — Measurement of Hepatic Blood Flow. Dr. Stanley Bradley.
Wednesday, April 11 — The Present-Day Concept of Streptococci and the Diseases Which They Produce. Dr. L. Weinstein.
Friday, April 13 — The Diagnosis of Infections Due to Filterable Viruses. Dr. C. A. Janeway.
Wednesday, April 18 — Penicillin in Venereal Disease. Dr. Oscar F. Cox.
Friday, April 20 — Advances in Naval Medicine. Rear Admiral J. J. A. McMullin.
Wednesday, April 25 — Treatment of Dermatoses. Dr. John G. Downing.
Friday, April 27 — New Compounds for the Treatment of Hyperthyroidism. Dr. E. B. Astwood.

On Monday mornings (except April 9) clinics will be given by Dr. Samuel Proger. On Tuesday and Thursday mornings Dr. S. J. Thannhauser will give medical clinics on hospital cases. On Saturday mornings clinics will be given by Dr. William Dameshek.

PAPAVERINE IN THE TREATMENT OF CORONARY-ARTERY DISEASE*

WILLIAM GRAY, M.D.,† JOSEPH E. F. RISEMAN, M.D.,‡ AND SAMUEL STEARNS, M.D.§

BOSTON

PAPAVERINE, an opium derivative frequently used to combat vascular spasm, was first ad-

vocated for the treatment of angina pectoris in 1913 by Pail; no data were presented, however. Three years later, Macht¹ reported temporary relief of angina pectoris in 3 patients following injection of 40 mg. of papaverine. In 1923, Pail² described prompt but transient relief of angina pectoris after the injection of 20 to 30 mg. of papaverine intra-venously in an eighteen-year-old patient with aortic stenosis and insufficiency; simultaneous in-

jections of larger doses were not so effective. In 1921, Boehm³ reported marked success in treating patients with angina pectoris with 30 mg. of papav-erine in a mixture with camphor, given three times daily by mouth. In 1933, Evans and Hoyle⁴ re-ported that their studies on 31 patients offered no convincing evidence of the value of orally adminis-tered papaverine over other drugs tested. More re-

cently, interest has been stimulated by the work of Elek and Katz,⁵ 12 of whose 17 patients showed definite improvement when given papaverine by mouth in doses of 100 mg. three times daily. Defi-nite improvement was defined as a reduction of at least 25 per cent in the number of attacks, of 50 per cent in the duration of attacks and of 50 per cent in the number of nitroglycerin tablets used, or an increase in the distance that the patient could walk without pain. These authors stressed the im-

portance of using much larger doses of papaverine than had previously been advocated. All these investigators relied on clinical evalua-tion of the efficacy of therapy. It has repeatedly been shown that such methods fail to differentiate the effects of inert and active therapy,⁶⁻¹² so that objective studies are desirable. Such studies car-ried out in this laboratory between 1935 and 1937 showed no change in the standardized exercise-

*From the Medical Service and Medical Research Laboratories, Beth Israel Hospital, the Department of Medicine, Harvard Medical School, and the Department of Medicine, Tufts College Medical School. Beth Israel Hospital. Resident in medicine, Harvard Medical School; medical resident, Beth Israel Hospital. Associate in medicine, Harvard Medical School; associate resident in medicine, Tufts College Medical School. Associate in medicine, Tufts College Medical School; associate in medicine, Beth Israel Hospital.

tolerance test thirty minutes after the intravenous injection of 30 mg. of papaverine in 4 cases, or in a fifth patient who received this dose orally three times a day.¹³ All these patients had shown bene-ficial responses to other drugs. The purpose of this paper is to present the results of additional objec-tive studies on the use of papaverine in the treat-ment of coronary-artery disease with the larger doses recommended by Elek and Katz.⁵

MATERIALS AND METHODS

The effect of papaverine in angina pectoris was studied in 13 patients who made regular weekly visits to the Angina Clinic of the Beth Israel Hos-pital. These patients varied in age from forty-six to seventy-two years; 11 were men. All had had angina pectoris for six months to fifteen years, and 6 had a history of myocardial infarction in the past. Nine patients had been followed in the clinic for four to ten years, and the other 4 were observed for one to nine months. The ability of these patients to respond to other types of therapy usually ad-vocated for angina pectoris was known and was re-evaluated at frequent intervals during the period of study. Five showed a markedly beneficial re-sponse to nitroglycerin and other therapy and were classified in accordance with the method previously described¹⁴ as Group 1 patients. Six showed a moderate response to these drugs and were called Group 2 patients. The remaining 2 showed little or no response to any of the usual forms of therapy and were termed Group 3 patients. On each visit the patient was questioned care-fully concerning the number of attacks of angina pectoris experienced since the last visit, the number of tablets of nitroglycerin used and the amount of physical and emotional strain sustained during the week. The patient's evaluation of the therapy was recorded, as was any unusual increase in ability to walk without production of angina. On each visit the amount of work necessary to induce angina was measured by the standardized exercise-tolerance test, carried out in a cold room, as previously de-scribed.¹⁴ Many determinations of this tolerance

were made while the patient was taking inert medication or placebos. The usual upper limit of tolerance while the patient was taking inactive medication was selected as a base line for comparison (Fig. 1).

On each visit the patient was given a supply of medication to be taken four times a day for at least one week. The results with papaverine hydrochloride* (100 or 200 mg.) were compared with those with other medications, including placebos.

The effect of papaverine hydrochloride given intravenously was determined in the following manner while the patients were taking inert medication (enteric-coated lactose). A solution contain-

studies a control precordial tracing (Lead 4R) was taken with the patient standing at rest and also for fifteen seconds immediately after the cessation of exercise that induced an attack of angina. At a subsequent visit, identical studies were repeated after the administration of papaverine intravenously. To obtain such tracings, it was necessary for the patient to exercise with the electrodes in place and with the electrocardiograph running. In all cases the degree of RST deviation was measured as the average of ten consecutive complexes.

Clinical observations of the effect of 65 mg. of papaverine hydrochloride given intravenously for

FIGURE 1. Studies of Standard Exercise Tolerance in Case 10 during a Period of 68 Weeks.

N indicates standard exercise tolerance after nitroglycerin, and P, after papaverine given intravenously. The medication during the period was as follows, according to weeks: 1-11, enteric-coated lactose; 12, 30 cc. whisky four times a day; 13-15, none; 16, 100 mg. Syntropan four times a day; 17-19, none; 20-23, enteric-coated lactose; 24-25, 0.3 gm. sodium bicarbonate four times a day (25, test, 2 min. after 0.3 mg. nitroglycerin); 26-33, 0.13 gm. Pavatrine four times a day; 34, 0.2 gm. Theopropinal four times a day; 35-36, 0.3 gm. sodium bicarbonate four times a day; 37, 200 mg. papaverine hydrochloride orally four times a day; 38, 100 mg. Syntropan four times a day; 39, 30 mg. Prostigmin four times a day; 40, 1 gm. potassium chloride four times a day; 41, 2 gm. potassium chloride four times a day; 42-43, 0.3 gm. sodium bicarbonate four times a day; 44, 200 mg. ascorbic acid four times a day; 45-46, none; 47, 1.5 mg. physostigmin salicylate four times a day; 48-61, enteric-coated lactose (55, test, 15 min. after 65 mg. papaverine hydrochloride intravenously; 59, test, 5 min. after same dose; 60, test, 10 min. after same dose; 61, test, 30 min. after same dose); 62-64, none; 65-68, enteric-coated lactose (65, test, 10 min. after 100 mg. papaverine hydrochloride intravenously; 67, test, 15 min. after 100 mg. Ocetin subcutaneously; 68, test, 60 min. after 65 mg. papaverine hydrochloride intravenously).

ing 65 to 100 mg. of papaverine hydrochloride, usually diluted to 10 cc. with physiologic saline solution, was given intravenously, and the standardized exercise tolerance was measured at intervals varying from five to ninety minutes after injection. Each injection required about two minutes. Only one test was carried out on any given visit. The different doses used at varying time intervals served to check the results.

Electrocardiographic studies, according to the method previously described,^{12, 15} were carried out in 2 patients who had shown a beneficial response to intravenously administered papaverine. In these

the relief of pain in 8 patients with acute myocardial infarction and in 3 with acute coronary failure were also made on the wards of the hospital. These patients varied in age from forty-nine to seventy-five years; 9 were men. In most cases, the solution of papaverine used was not diluted with physiologic saline solution.

RESULTS

Oral Administration in Angina Pectoris

Clinical evaluation. The effect of papaverine hydrochloride given by mouth was tested in 11 patients. There were twenty trial periods, in which 10 patients received 100 mg. and 10 received 200 mg.

*The papaverine hydrochloride used in this study was furnished through the courtesy of Eli Lilly and Company, Indianapolis, Indiana.

out times a day for one week. Toxic symptoms developed in 5 patients. One (Case 13) was unable to take more than a single dose of the drug on each of two trials because of severe nausea. This patient had previously developed severe nausea necessitating cessation of therapy while taking Dilaudid (3 mg.) or morphine sulfate (8 mg.) by mouth. Two patients were unable to take doses of 200 mg. because of severe nausea, accompanied in 1 case by abdominal cramps, but were able to tolerate doses of 100 mg. Two patients developed slight nausea after 200-mg. but not after 100-mg. doses. No demonstrable clinical improvement occurred in any of the 10 patients able to tolerate papaverine by mouth (Table I). Only 1 patient (Case 1) stated

tachycardia. In most cases these were not disturbing to the patients, but in 3 cases they were so severe that the patient refused to allow additional injections of the drug after two trials. Dilution with 10 cc. of physiologic saline solution permitted slower injection and decreased the severity of these reactions but did not eliminate them. In patients experiencing severe circulation-time reactions, transient nausea and sweating were frequent. Drowsiness lasting for about an hour followed each injection in 1 patient, but this was not severe enough to necessitate stopping injections. One patient received papaverine hydrochloride intravenously on two occasions during attacks of angina pectoris. On one of these the attack dis-

or frequency of toxic effects following doses of 65 or 100 mg. Objective studies. Six of the 12 patients studied showed no significant increase in exercise tolerance following intravenous injection of papaverine (Fig. 2 and Table 3). In the remaining 6 cases, increases of 25 to 57 per cent were noted (Fig. 3); these comprised 3 of 4 Group 1 and 3 of 6 Group 2 patients. The maximum increase in exercise tolerance oc-

curring after the injection was begun. These consisted of hyperventilation, flushing of the face with a feeling of warmth throughout the body, slight dizziness, a sensation of throbbing in the temples and slight

that he believed papaverine to be helpful, but he actually had more than the usual number of attacks while taking the drug. None of the other patients made any favorable comments about the action of the drug. In 5 cases, the number of attacks of angina pectoris was the same as that while on placebo; in 4, the number of attacks was almost double the control value; in 1, no attacks were experienced while on papaverine but the patient had had the same experience during many weeks on a placebo. Objective studies. In each of the sixteen determinations made on the 10 patients studied, the standardized exercise tolerance was equal or within 16 per cent of the maximum amount of work that could be done when taking inert medication or placebo (Table 2). The results with 100 mg. 200 mg. were no better than those with 100 mg.

Intravenous Administration in Angina Pectoris

Clinical evaluation. Twelve patients were studied and a total of fifty-two injections were given. Typical circulation-time reactions, as described by Ebel and Solarz,¹⁸ occurred in fifteen to twenty-five seconds after the injection was begun. These consisted of hyperventilation, flushing of the face with a feeling of warmth throughout the body, slight dizziness, a sensation of throbbing in the temples and slight

curred in five to fifteen minutes after injection, with a slight effect persisting as long as sixty to ninety

FIGURE 2. Case 7.

minutes. There was no appreciable difference in results following doses of 65 or 100 mg.

Electrocardiographic studies were carried out in 2 patients who had shown a response to intravenous papaverine. In one, the RST segment, after twenty-six trips that produced an attack of angina, was depressed 3.0 mm. After the injection of 65 mg. of papaverine hydrochloride intravenously, the same amount of exercise failed to induce angina, and the RST depression was 2.1 mm. five minutes after injection, 2.5 mm. ten minutes after injection

injection of papaverine the same amount of work failed to induce angina and the RST depression was 2.0 mm.

Intravenous Administration in Acute Myocardial Infarction or Coronary Failure

Mild undesirable side effects were seen in 5 of the 11 cases studied. These consisted of slight dizziness in 1 case, nausea and vomiting in 1, drowsi-

and 2.0 mm. fifteen minutes after injection. Two minutes after the sublingual administration of 0.7 mg. of nitroglycerin, the RST depression was 1.2 mm. (Fig. 4). In the second patient, the RST depression during angina induced by thirty-four trips was 1.6 mm., and fifteen minutes after the

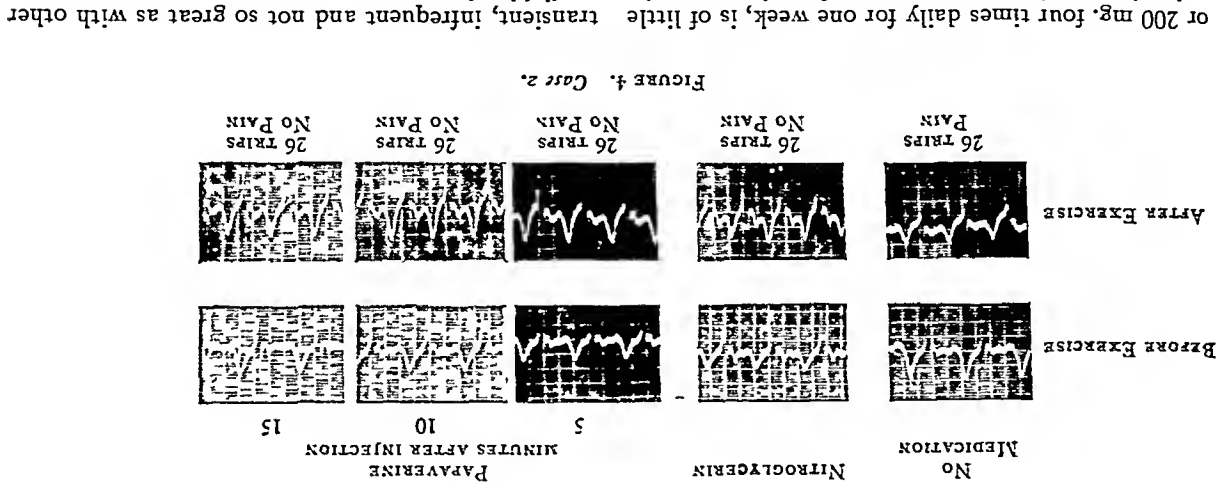

ambulatory less acutely ill patients with angina pectoris.

Sixty-five milligrams of papaverine hydrochloride given intravenously was followed by relief of pain in 5 of 8 cases of acute myocardial infarction and in 1 of 3 cases of coronary failure within forty

seconds to two minutes of injection. In most cases, relief of pain occurred at about the same time as the circulation-time reaction. In 2 cases of myocardial infarction in which the previous administration of morphine and Dillaudid had been unsuccessful in relieving severe pain, the complete relief following injection of papaverine was dramatic. In a third case of myocardial infarction with severe pain, two 65-mg. injections of papaverine hydrochloride at ten-minute intervals afforded no relief, whereas morphine sulfate intravenously was beneficial. In 1 patient with coronary failure, the precordial pain became more severe during the injection of papaverine.

DISCUSSION

It is evident from these studies that papaverine hydrochloride given by mouth, in doses of 33, 100

transient, infrequent and not so great as with other available therapy. Papaverine hydrochloride given intravenously for treatment of the precordial pain of coronary occlusion or coronary failure appears to be of value even though the beneficial action is only temporary. Final decision on its use in such conditions must await further experience, for not all patients are benefited, and the administration of drugs intravenously to such patients is not without some danger.

SUMMARY AND CONCLUSIONS

Papaverine hydrochloride appears to have a definite but limited and temporary vasodilator action in patients with coronary-artery disease. Papaverine hydrochloride appears to have a beneficial but limited and temporary vasodilator action in patients with coronary-artery disease. The administration of this drug intravenously enabled half the patients with angina pectoris to do more work than was possible otherwise and decreased the electrocardiographic changes following exercise. This effect reached its maximum in five to fifteen minutes after injection and was negligible after about sixty minutes. This method of therapy, in results is that Elek and Katz relied on the history for evaluation of the effect. This method has

however, is of little value in the clinical treatment of patients with angina pectoris.

The oral administration of papaverine hydrochloride in doses of 33, 100 or 200 mg. to ambulatory patients did not improve their ability to exercise, and does not appear to be of practical value in the treatment of angina pectoris.

Studies in a small group of patients suggest that the administration of papaverine hydrochloride intravenously in doses of 65 or 100 mg. is of considerable value in treating the pain of coronary occlusion or coronary failure.

PLETHORA OF THE INTRACRANIAL VENOUS CIRCULATION IN A CASE OF POLYCYTHEMIA*

Pathologic Physiology and Diagnostic Considerations

JULIUS LOMAN, M.D.,† AND WILLIAM DAMESHEK, M.D.‡

BOSTON

IN POLYCYTHEMIA vera, symptoms referable to the head greatly outrank in incidence those relating to any other bodily system.¹ Actual cerebral vascular lesions are, furthermore, not infrequent. These include arterial or venous thromboses and hemorrhage, which is either intracerebral or subarachnoid in location. The development of extreme headache, amblyopia, papilledema and increased intracranial pressure in a case of well-marked secondary polycythemia led to studies that are of interest from the standpoint of intracranial dynamics, and to the conclusion that extreme plethora may result in changes indistinguishable from those occurring in other types of increased intracranial pressure.

CASE REPORT

A. F. L., a 41-year-old male, was referred to the Joseph H. Pratt Diagnostic Hospital from the Boston Dispensary on October 2, 1942. He complained chiefly of severe headache and failing vision of 1 year's duration. Since the age of 10, he had suffered from severe perennial asthma, with frequent attacks lasting as long as 12 hours. On several occasions he had had small hemoptyses, which were usually associated with a dull aching sensation in the chest. In recent years, he had been completely incapacitated because of increasing exertional dyspnea. For the past year the vision had become increasingly blurred, and was frequently associated with scintillating scotomas and small black spots

before the eyes. Beginning about a month before admission, the patient developed a continuous and severe occipital headache that was unassociated with nausea or vomiting and unrelieved by aspirin. For 2 weeks there had been occasional staggering with walking.

Examination disclosed an extremely cyanotic man, lying flat in bed without much respiratory distress. The eyeballs were somewhat prominent. The pupils were round and equal and somewhat dilated, and reacted poorly to light and accommodation. The vessels of the scleras were deeply injected. The conjunctivas were deep purple. The retinal vessels, particularly the veins, were greatly distended. Both optic disks showed pronounced choking, particularly marked over the nasal halves. Numerous pinpoint hemorrhages were scattered throughout both fundi.

The anteroposterior diameter of the thorax was greatly increased, with very limited excursion, respirations being almost entirely abdominal. The percussion note was hyperresonant throughout, with complete absence of absolute cardiac dullness. Numerous sonorous and sibilant rhonchi and occasional crepitant inspiratory rales were heard. The heart sounds were distant and heard only over the xiphoid cartilage. There were no murmurs. The blood pressure was 135/90. There was marked distention of the veins in the upper extremities, and large varicosities were present bilaterally. The fingers were not definitely clubbed. Neurologic examination showed intact cranial nerves, active and equal reflexes of the arms, and knee jerks that were equal but barely obtainable on reinforcement. Ankle jerks were equal and active. There was an equivocal Babinski sign on the right and definite Babinski and Chaddock signs on the left. There was no ankle clonus.

The urine showed a +++ test for albumin and a few hyaline and fine granular casts in the sediment. The specific gravity was 1.018, and there was good concentration with a modified Fishberg test. The blood findings were as follows: hemoglobin, 136 to 142 per cent (21.1 to 22.0 gm.); reticulocytes, 0.3 per cent; red-cell count, 8,100,000 to 9,000,000; white-cell count, 6500 and 7400, with 69 per cent polymorphonuclear leukocytes, 14 per cent lymphocytes, 10 per cent

Increased intracranial pressure has occasionally been noted in true polycythemia, and has at times led to the false diagnosis of intracranial neoplasm and even to surgical exploration. The mechanisms of the increased pressure have never been worked out. In the present case, although the increased pressure was obviously related to the effects of the

rather than to actual thrombosis of the cerebral venous channels. With thrombosis of a lateral sinus, one would expect either low or absent pressure in the corresponding internal jugular vein. At the point at which the internal jugular pressure is measured the vein is contiguous to the outlet of the jugular bulb, where it receives no venous con-

disease, it was at first debatable whether this was due to cerebral venous thrombosis or to simple plethora of the intracranial venous system. The information gained by measurement of the pressure and the dynamic responses within the internal jugular circulation, together with the great diminution of the intrajugular pressure following several venesections, almost certainly pointed to the presence of plethora

tributaries. Furthermore, if lateral sinus thrombosis were present, jugular compression would effect no rise in the contralateral jugular pressure. In this case the jugular pressure was not only equally high bilaterally but was increased by homolateral and contralateral jugular compression.

It is furthermore doubtful whether a simple thrombosis of the lateral sinus is sufficiently ob-

changes in pressure. When, however, the venous circulation is already overtaxed, as in polycythemia, it is possible that further slowing, in some cases to the point of thrombosis, may be enhanced by these peculiarities of the intracranial venous system and result in a great increase in cerebral venous pressure. Another possibility that must be considered in any dissociation of the cerebral and the general venous pressure is the presence of an obstructing lesion of the neck or mediastinum, with compression of the great veins. There was no evidence of such an abnormality in the present case. It is furthermore obvious that a rise in cerebral venous pressure by this type of obstruction could not be relieved by venesection alone.

SUMMARY AND CONCLUSIONS

A case is reported of severe secondary polycythemia with increased intracranial pressure, choked disks and amblyopia, in which dissociation between an increased internal jugular venous pressure and a normal general venous pressure was present. Following venesection therapy, the cerebrospinal-fluid pressure and intrajugular venous pressure became normal, and there was complete regression in all the symptoms referable to the head. The possible mechanisms for the dissociation between intrajugular and general venous pressures, with the resulting great increase in cerebrospinal-fluid pressure, are discussed. Other possible causes of this dissociation, including thrombosis of the lateral sinus, are discussed and excluded as having no bearing in the present case. A study of the intrajugular dynamics may be diagnostic in the determination of the presence or absence of thrombosis of the lateral sinus. Severe headaches in polycythemia may be caused by an increased intracranial venous pressure, with a resultant increase in cerebrospinal-fluid pressure.

destructive to the outflow of the intracranial blood to jugular veins or both lateral sinuses, the cerebrospinal-fluid pressure returns to normal within a few hours. Furthermore, Hassin¹¹ has shown that thrombi that completely obstruct both the longitudinal and lateral sinuses have no effect on the absorption of the cerebrospinal fluid from the subarachnoid space; it is probable that under such conditions veins other than the longitudinal sinus are capable of absorbing the cerebrospinal fluid and keeping its pressure at normal values. In addition, if such vascular lesions were present, a return to a normal intracranial pressure should not be expected so soon after venesection. The likeliest explanation of the increased intracranial pressure in the case under discussion is therefore a great increase in cerebral venous pressure. This could be brought about by slowing and damming of venous blood in the rigidly enclosed sinuses and cerebral veins. The resulting increase in venous pressure would readily be reflected to the cerebrospinal fluid by way of the thin-walled cerebral veins. The dissociation between the pressure in the internal jugular vein and that in the general venous system in the absence of obstruction to cerebral venous channels is a unique phenomenon. So far as we know, no other examples have been reported. Certain physical conditions unique to the intracranial cavity may predispose to such a dissociation in pressures. Thus the cerebral veins have features that differ in certain particulars from the veins elsewhere in the body. These may be listed as follows: complete rigidity of the cranial venous sinuses; lack of muscular fibers in the walls of the sinuses; great width of the lumens of the sinuses as compared with the small size of the veins that empty into them; entrance of the many cerebral veins into the longitudinal sinus against the current of blood flow; and tortuosity of the course of the sinuses. In the last, the inferior part of the sigmoid sinus lies at a much lower level than the jugular bulb, which is much wider than the sigmoid sinus. As the sigmoid sinus enters the jugular bulb, there is a marked narrowing. There is also a marked narrowing at the exit of the jugular bulb (Fig. 2). These characteristics seem designed to retard the flow of blood so that under certain conditions, such as sudden changes in posture, the brain is spared the sudden and full brunt of extreme vascular narrowing. The characteristics seem designed to retard the exit of the jugular bulb (Fig. 2).

PSYCHOSOMATIC INTERRELATIONS IN GENERAL MEDICINE

GERTRUDE F. FRISBIE, M.D.*

LOWELL, MASSACHUSETTS

THE efficiency of the general medical practitioner is conditioned by the following factors: first, his knowledge and appreciation of the normal human organism as a complex and integrated whole of physical, mental and emotional elements and his understanding and appreciation of the types of pathologic variations from normality that may arise, with their respective symptomatology and etiology; second, his knowledge of how to determine the nature and extent of these variations; and third, his selection of treatment.

Knowledge and appreciation of the normal human organism of integrated physical, mental and emotional elements include the following concepts: the body as a mechanism made up of cells performing proper physiologic functioning; the nervous system, of which the brain is the integrating center and through which activity of the biologic organism functions from within in a relation compatible to its environment; consciousness, the main function of the brain through which the mind is made rationally aware of the motivating biologic forces in the organism; the emotions, serving as well-balanced, subjective feeling-reactions to perception of these forces; personality, or the subject's usual manner of handling these forces in accordance with his best social adjustment; thoughts and ideas, which are concepts arising from these forces as highly developed adaptations of them to the environment; conscience and ideals, or the ethical and esthetic resultants arising from the mental and emotional conditioning of these forces; and the normal life of the normal human organism, which essentially consists in satisfying these forces—needs, urges and responses—in accordance with conscience and ideals.

An attempt has been made through this brief analysis of the normal human organism, with its balanced, co-ordinated psychosociobiologic functioning, to establish the concept of it as a complex and integrated whole.

Consideration of the pathologic variations that may occur in the normal human organism, with their respective symptomatology and etiology, includes the concepts of pathologic disturbances ranging from trauma of cellular tissue to tensions in the highest levels of the brain. If emotional tensions affect the lower levels of the nervous system and are mediated through the autonomic system, they cause a disturbance called "organ neurosis." In this condition the somatic component is the most pronounced element. If emotional tendencies develop and affect the highest levels of the brain, they cause neurotic and psychotic disturbances, which

are evidenced in thought and behavior. In these cases the psychic symptoms are most evident. Any disruption of balanced, co-ordinated psychosociobiologic functioning in the human organism results in its disintegration or in a pathologic condition.

Clinical study has revealed that in the investigation of functional disturbances there are specific correlations between emotional constellations and physiologic responses. The psychosomatic conditions resulting from these functional disturbances are called "psychosomatic symptoms."

Psychosomatic symptoms are present in all disease. Their psychic and physical components are in direct ratio to the degrees of psychologic and physical etiologic forces involved. Menninger[†] has classified disease in five groups, and indicates the relative degrees of symptomatic expression in terms of psychic reaction and physical reaction for each group. In Group 1, with a valence of 5 on the psychic reaction and a valence of 1 on the physical reaction, are included all the severe functional mental diseases referred to as psychosis. In Group 2, with a valence of 4 on the psychic reaction and a valence of 2 on the physical reaction, is included a class of illnesses generally regarded as mental in that the causative factors are chiefly psychologic but are always associated with physical symptoms, which are often treated as if they were the sole causes. In Group 3, with a valence of 3 on the psychic reaction and a valence of 3 on the physical reactions is included a heterogeneous assortment of diseases—first, organic brain diseases; second, the endogenous toxic and infectious illnesses in which the mental symptoms are produced by toxins; and third, a host of physical diseases that masquerade under the guise of mental symptoms, often appearing to be primarily mental. In Group 4, with a valence of 2 on the psychic reaction and a valence of 4 on the physical reaction, is placed a large class of organic illnesses frequently found in persons in whom are discovered conspicuous psychologic maladjustments but whose complaints are physical and whose diseases are manifested in organic disease. In Group 5, with a valence of 1 on the psychic reaction and a valence of 5 on the physical reaction, are found a great number of illnesses in which almost the entire emphasis seems to be on the somatic side but in which the psychic component, even though inconspicuous, is of great importance.

If the concepts of the human organism as an integrated whole and of disease as the psychosomatic expression of this biologic unit are accepted, the general medical practitioner must seek the etiology

Case 3. An extremely nervous and emaciated 15-year-old girl, who was a bed patient, complained of nausea, vomiting, pain over the lower abdominal region, constipation and scanty and irregular menstrual periods. Repeated enemas brought no relief. The patient lived with her family, the members of which were neurotic. Physicians had referred her to a surgical service, where she had been told that she must undergo an operation if she wished to live. She became hysterical. Since no diagnosis calling for surgery had been given, the attending physician decided to help the abdominal pain elevation of the foot of the bed to help the abdominal organs to rise out of the pelvis, regulation of the diet and the giving of oil to restore the lost body fluid and of sea moss and mineral oil for the constipation, vomiting stopped and the patient became free from pain and much more cheerful. A prostis belt was used to hold up the organs until she gained weight. The physician established a situation

PHARMACOLOGY AND METHODS OF ADMINISTRATION

Fortunately it was found that penicillin could be administered intravenously or intramuscularly with-

an effective blood level was found to be maintained for a slightly longer period of time than after the intravenous injection of a similar quantity of drug. This observation, together with the greater ease of administering the drug intramuscularly, led most workers both in England and in the United States to follow the Floreys¹⁴ in using the intramuscular route for the routine treatment of patients. It is now well established on the basis of clinical experience that this route is fully as effective therapeutically as the intravenous route.

penicillin, subcutaneous injection is not significantly more painful than is intramuscular injection. Herwick et al.¹⁶ have shown that there is a significant correlation between the purity of a penicillin preparation and the irritation resulting from its intramuscular injection. It is therefore not unlikely that, becomes available, the subcutaneous administration of the drug may be more widely practiced.

Several attempts have been made to obviate the need for frequent injections and the irregular blood concentrations that result from this method. Administering penicillin by a continuous intravenous infusion has been the method most frequently used. Some investigators¹⁷ believe that this is the method of choice and use it routinely. Other workers^{18, 19} think that the inconveniences encountered in maintaining a constant intravenous infusion, together with the fairly frequent development of painful thrombophlebitis, outweigh its possible advantages. More recently the use of a continuous intramuscular infusion has been recommended.¹⁹ The total twenty-four-hour dose of penicillin can be administered in a volume of 200 cc. to 500 cc. without undue discomfort into the lateral muscle of the thigh, and quite uniform blood levels can be maintained.²⁰ The levels achieved by this method are approximately the same as those obtained by the continuous intravenous infusion of the same dosage of penicillin.

Two other methods designed to reduce the number of injections have recently been reported. Romanovsky and Rittman²¹ have stated that mixtures of penicillin in beeswax are slowly absorbed and injected intramuscularly, are slowly absorbed and that therapeutic levels of penicillin can be detected

MEDICAL PROGRESS

THE TREATMENT OF INFECTIONS WITH PENICILLIN*

DONALD G. ANDERSON, M.D.†

BOSTON

PENICILLIN is now well established as an effective chemotherapeutic agent for the treatment of many infections. During the past year so many reports attesting to this fact have appeared in the American and English literature that to review them all in a single paper is not possible. The purpose of the present article is to summarize such principles of penicillin therapy as have evolved from the investigations of the past five years and to present the current views on the use of penicillin in the more important infections that are encountered in civilian practice. It is recognized that experience with penicillin is enlarging so rapidly that some or many of these views may be outdated before this article reaches print.

The history of the discovery of penicillin by Fleming¹ in 1928 and of its later development as a practical chemotherapeutic agent by Florey and his associates² is now well known by the medical profession and will not be reviewed. Likewise, it is beyond the scope of this paper to recount the fascinating story of how the large-scale production of the drug was achieved in the face of many difficulties.^{3, 4}

CHEMISTRY

The published information regarding the chemistry of penicillin is meager. Abraham and Chain⁵ have reported that penicillin is an organic acid. Since the free acid is quite unstable, however, only the more stable sodium and calcium salts of penicillin are prepared for clinical administration. These two salts do not differ in therapeutic activity or toxicity. The calcium salt has the advantage that it is less hygroscopic and therefore can be used in powdered form with greater ease.

It is now known that the mould *Penicillium notatum* actually produces several types of penicillin. Sir Henry Dale⁶ has recently revealed that three penicillins have already been isolated in the pure state. These are known in the United States as penicillins F, G and X, and in England as penicillins 1, 2 and 3, respectively. Dale states: "All these penicillins have the specific remedial action in high,

though not quite identical degrees, and there are proportional differences, still to be explored, in their proportional efficiencies against different infective organisms. Penicillin G or 2 is the penicillin which is predominant in most preparations now available." Penicillin G was the first to be obtained in pure crystalline form, the isolation of the crystalline sodium salt being accomplished by MacPhillamy and Wintersteiner of the Squibb Institute in July, 1943.³ This material was found to contain about 1650 Oxford units per milligram.†

Recently the International Conference on Penicillin⁷ has recommended that an international penicillin standard be prepared from crystalline sodium penicillin G and that the international unit of penicillin be defined as the specific penicillin activity contained in 0.6 micrograms of the international penicillin standard. The international unit so defined is approximately equivalent to the Oxford unit.

Although pure crystals of penicillin were first isolated almost two years ago, synthesis of the drug has not yet been accomplished. All the drug produced today is recovered from culture liquor in which *P. notatum* has grown. Because a large amount of active drug is lost in preparing crystalline penicillin, this material is not available at present for the routine treatment of patients. The preparations that are used in clinical practice assay roughly between 200 and 1000 Oxford units per milligram. It is thus evident that they contain between 37 and 88 per cent of impurities.

The preparations of penicillin that were first employed clinically were found to be relatively unstable both in powder form and in solution. The more recently prepared commercial products are a great deal more stable. Kirby⁸ has shown that solutions of penicillin may be kept at room temperature (22° C.) for one week without evidence of deterioration and that most lots of penicillin retain their full activity in solution for ten to twelve days. At 37° C., however, full potency persists for only four days. As a dried powder the drug is even more stable. Regna's⁹ studies indicate that there is no loss of potency during a period of at least three hundred and fifty days when the powder is stored at 0-5° C. Even at 37° C. the powder will retain full potency for at least sixty days.

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†The work in preparing this review was made possible under the terms of Contract OEMCmr-275 between the Massachusetts Memorial Hospitals, Robert Dawson Evans Memorial, Department of Clinical Research and Preventive Medicine and the Office of Scientific Research and Development.

†Instructor in medicine, Boston University School of Medicine, and research fellow in medicine, Evans Memorial, Massachusetts Memorial Hospitals.

†Chemical assay of penicillin is not yet possible. The drug is assayed therefore in terms of its antibacterial activity. The Oxford unit is defined as "that amount of penicillin which, when dissolved in 50 cc. of meat-extract broth, just completely inhibits the growth of the test strain of *Staphylococcus aureus*."

32 guinea-pigs treated with penicillin and a mortality rate of 91 per cent in an equal number of untreated controls. Augustine et al.,³⁷ also using guinea pigs, found penicillin had no curative value after the appearance of clinical manifestations of the disease.

The action of penicillin on viruses and rickettsia is likewise not wholly clear. Heilmann and Herrell³⁸ have reported that mice infected with the viruses of ornithosis and psittacosis can be protected by penicillin, whereas Florey and Greiff³⁹ have shown that penicillin therapy reduces the mortality in mice infected with murine typhus fever. In both studies the dosage per kilogram of body weight was far in excess of that necessary in clinical practice to control infections caused by susceptible bacteria. To date no convincing reports have been published to indicate that penicillin is effective in any virus or rickettsial disease in man. When such infections are complicated by secondary infections due to organisms that are sensitive to the drug, the latter may be successfully treated with penicillin.⁴⁰ In contrast to the susceptible species, many important pathogenic bacteria are not adversely affected by the concentrations of penicillin that can be achieved in the blood and tissues (Table 2).

TABLE 2. *Organisms Not Susceptible to the Action of Penicillin.*

<i>Escherichia coli</i>	<i>Harmophilus duxburyi</i>
<i>Staphylococcus aureus</i>	<i>Streptococcus faecalis</i>
<i>Salmonella dysenteriae</i>	<i>Brucella melitensis</i>
<i>Salmonella paratyphi</i>	<i>Vibrio cholerae</i>
<i>Salmonella enteritidis</i>	<i>Pasteurella pestis</i>
<i>Pseudomonas aeruginosa</i>	<i>Pasteurella tularensis</i>
<i>Klebsiella pneumoniae</i>	<i>Mycobacterium tuberculosis</i>
<i>Harmophilus influenzae</i>	<i>Plasmodium vivax</i>
<i>Harmophilus pertussis</i>	<i>Yeasts</i>
	<i>Molds</i>

These species are generally considered to be insensitive to penicillin. Actually several of these species can be inhibited in vitro by the use of relatively high concentrations of penicillin, indicating that penicillin insensitivity is often a relative rather than an absolute quality.⁴¹ For practical purposes, however, it is recognized that penicillin has no effective clinical action against these organisms.

The development of resistance to penicillin by bacteria as the result of exposure to sublethal concentrations of the drug either in vitro or in vivo has been reported by several workers.⁴²⁻⁴⁵ There is some laboratory evidence to indicate that organisms that develop resistance to penicillin in vitro may become less virulent.^{44, 45} Observations of this kind have not yet been made in human infections. The antibacterial action of penicillin in vitro may be either bactericidal or bacteriostatic.⁴⁶ Most human infections are agreed that in the treatment of penicillin inhibits the growth and multiplication of bac-

teria, but the actual destruction and elimination of the infecting organisms are probably effected by the normal defense mechanisms of the host. This conclusion is well substantiated by clinical experience. With the exception of uncomplicated gonorrhea and meningococccemia, treatment with penicillin has not proved to be effective in any disease unless it has been continued for at least twenty-four to forty-eight hours, and in the great majority of cases much longer periods are necessary. Florey et al.¹⁰ early reported that serum, pus, debrides and the breakdown products of tissue autolysis do not inhibit the action of penicillin, a distinct advantage for this drug over the sulfonamides in many types of infection. Bigger⁴⁷ has recently reported that human serum does inhibit the action of penicillin. He attributes this phenomenon to the absorption of penicillin inactivators formed in the intestinal tract.

It is now well known that *Escherichia coli* and certain other bacteria insensitive to penicillin produce a substance that inactivates penicillin. This substance has been named "penicillinase."⁴⁸ Penicillinase can be prepared by various means,⁴⁹⁻⁵¹ and its incorporation in culture mediums to inactivate patients receiving the drug has been suggested. Experience, however, does not indicate that penicillinase has the same practical value that γ -aminobenzoic acid has in inhibiting sulfonamide activity in culture mediums. Thus, when duplicate cultures with and without penicillinase are made, the number of additional positive cultures obtained is insignificant.⁵⁰

Several different methods have been described for determining the concentrations of penicillin in the blood and body fluids.⁵²⁻⁵⁴ All these methods involve the titration of the antibacterial activity of the unknown specimen against an organism of known sensitivity to penicillin. Although such methods are admittedly crude, they permit an estimation of penicillin concentration that is satisfactory for clinical purposes. The equipment and technical skill necessary to perform these tests are not beyond the reach of the average bacteriologic laboratory, but the information that is gained does not seem to be sufficiently helpful to warrant the routine determination of penicillin blood levels in clinical practice. The clinical response to treatment is, in most cases, all that is needed to determine dosage. A somewhat more useful test for clinical purposes is the determination of the sensitivity of various organisms to penicillin.⁵⁵ In the great majority of cases one can rely on the bacterial species alone as an indication of susceptibility. In particular cases, however, especially those that do not respond to penicillin in the expected manner, determination of the susceptibility of the patient's organism to penicillin is of value.

in the blood for six to seven hours after a single injection. The practicability of this method for prolonged therapy is being investigated.

Rammelkamp and Bradley²² demonstrated in 1942 that when Diodrast is administered simultaneously with penicillin it partially blocks the excretion of penicillin by the renal tubules. More recent experiments with the use of *p*-aminohippuric acid in animals and in man have shown that this substance also partially blocks the excretion of penicillin and prolongs the time during which it can be detected in the blood stream.^{23, 24} This method requires further study before its general adoption can be recommended.

Theoretically the maintenance of a constant blood level of penicillin would appear to be desirable therapeutically, and it might be expected that methods of administration that would provide such a blood level would be the most effective clinically. Actually, there is as yet no convincing evidence that a given daily dose of penicillin is more effective when given by a continuous infusion than when it is administered by intermittent intramuscular injection at three-hour intervals. Further study of this problem is needed.

The distribution of penicillin in the body after intramuscular or intravenous injection has been studied by many workers. The results of these studies contain valuable therapeutic implications.

In patients without meningitis, penicillin cannot be detected in the cerebrospinal fluid after the intramuscular or intravenous injection of the usual therapeutic doses. When large doses of penicillin are administered to such patients, however, minute amounts of the drug are occasionally demonstrable in the spinal fluid.²⁵ Recently there have been reports of the passage of penicillin from the blood into the spinal fluid of patients with purulent meningitis.^{15, 26, 27} The concentration of drug found in the spinal fluid was markedly less than that present in the blood, and in several cases it did not constitute an effective therapeutic level.

There is good clinical evidence that the amount of penicillin that reaches the spinal fluid in bacterial meningitis is probably insufficient to control the infection. Several cases are known in which no improvement either in the clinical condition of the patient or in the spinal-fluid findings resulted after several days of systemic penicillin therapy, but in which prompt improvement followed the intrathecal administration of the drug. Also several cases are known in which meningitis appeared during the course of the intramuscular or intravenous treatment of an extrameningeal infection. In these cases, likewise, no improvement took place until intrathecal therapy was instituted.

Penicillin diffuses poorly, as a rule, into the pleural cavity, and although prolonged intramuscular therapy may occasionally control an infection of the pleura, the introduction of penicillin

into the empyema cavity is recommended as a more economical and certain form of therapy.²⁸

Penicillin has been detected in ascitic fluid and in synovial fluid in significant concentration after parenteral administration.^{15, 25, 29} Occasional cases of suppurative arthritis have responded to systemic treatment. Local treatment, whenever possible, seems to be desirable, however, since penicillin does not injure the joint and systemic therapy may be unsuccessful.³⁰

Struble and Bellows,³¹ working with dogs, have shown that penicillin administered systemically in amounts comparable to therapeutic doses reaches such a slight concentration in the fluids and tissues of the eye that it is not measurable by the usual methods of assay. Von Sallmann³² has stressed the need for employing iontophoresis or a corneal bath to secure an adequate penetration of penicillin into the aqueous humor. Penicillin is excreted in the bile in higher concentrations than it is found in the blood.³³ The drug has not been detected in saliva, tears, pancreatic juice, succus entericus or gastric juice.

ANTIBACTERIAL ACTION

Penicillin is highly selective in its antibacterial activity. In-vitro tests and a study of experimental infections in animals have indicated clearly in what infections penicillin therapy may be of value and in what infections it cannot be expected to have any effect. Table 1 lists the important pathogenic

TABLE 1: *Organisms Susceptible to the Action of Penicillin.*

<i>Staphylococcus aureus</i>	<i>Clostridium novyi</i>

organisms against which penicillin has been found to be active by laboratory studies. In general, penicillin has proved to be effective against infections caused by these organisms, although in single cases the site or extent of the infection, the general condition of the patient or the presence of complications may preclude successful therapy.

Among bacterial species usually susceptible to penicillin, occasional strains are encountered that are naturally resistant to the drug. The susceptible species in which naturally resistant strains have been reported are staphylococci, nonhemolytic streptococci and anaerobic streptococci.^{34, 35}

Reports on the effectiveness of penicillin therapy in experimental Weil's disease differ. Heilman and Herrell³⁶ reported no deaths from the disease in

teria, but the actual destruction and elimination of the infecting organisms are probably effected by the normal defense mechanisms of the host. This conclusion is well substantiated by clinical experience. With the exception of uncomplicated gonorrhea and meningococcemia, treatment with penicillin has not proved to be effective in any disease unless it has been continued for at least twenty-four to forty-eight hours, and in the great majority of cases much longer periods are necessary. Florey et al.¹⁰ early reported that serum, pus, peptones and the breakdown products of tissue autolysis do not inhibit the action of penicillin, a distinct advantage for this drug over the sulfonamides in many types of infection. Bigger¹⁷ has recently reported that human serum does inhibit the action of penicillin. He attributes this phenomenon to the absorption of penicillin inactivators formed in the intestinal tract.

It is now well known that *Escherichia coli* and certain other bacteria insensitive to penicillin produce a substance that inactivates penicillin. This substance has been named "penicillinase."¹⁸ Penicillinase can be prepared by various means,¹⁹⁻²¹ and its incorporation in culture mediums to inactivate patients receiving the drug has been suggested. Experience, however, does not indicate that penicillinase has the same practical value that *p*-aminobenzoic acid has in inhibiting sulfonamide activity in culture mediums. Thus, when duplicate cultures with and without penicillinase are made, the number of additional positive cultures obtained is insignificant.²⁰

Several different methods have been described for determining the concentrations of penicillin in the blood and body fluids.²²⁻²⁴ All these methods involve the titration of the antibacterial activity of the unknown specimen against an organism of known sensitivity to penicillin. Although such methods are admittedly crude, they permit an estimation of penicillin concentration that is satisfactory for clinical purposes. The equipment and technical skill necessary to perform these tests are not beyond the reach of the average bacteriologic laboratory, but the information that is gained does not seem to be sufficiently helpful to warrant the routine determination of penicillin blood levels in clinical practice. The clinical response to treatment is, in most cases, all that is needed to determine dosage. A somewhat more useful test for clinical purposes is the determination of the sensitivity of various organisms to penicillin.²⁵ In the great majority of cases one can rely on the bacterial species alone as an indication of susceptibility. In particular cases, however, especially those that do not respond to penicillin in the expected manner, determination of the susceptibility of the patient's organism to penicillin is of value.

³² Guinea-pigs treated with penicillin and a mortality rate of 91 per cent in an equal number of untreated controls. Augustine et al.,³⁷ also using guinea pigs, found penicillin had no curative value after the appearance of clinical manifestations of the disease.

The action of penicillin on viruses and rickettsia is likewise not wholly clear. Heilmann and Herrell³⁸ have reported that mice infected with the viruses of ornithosis and psittacosis can be protected by penicillin, whereas *Aloragues*, Pinkerton and Greiff³⁹ have shown that penicillin therapy reduces the mortality in mice infected with murine typhus fever. In both studies the dosage per kilogram of body weight was far in excess of that necessary in clinical practice to control infections caused by susceptible bacteria. To date no convincing reports have been published to indicate that penicillin is effective in any virus or rickettsial disease in man. When such infections are complicated by secondary infections due to organisms that are sensitive to the drug, the latter may be successfully treated with penicillin.⁴⁰ In contrast to the susceptible species, many important pathogenic bacteria are not adversely affected by the concentrations of penicillin that can be achieved in the blood and tissues (Table 2).

TABLE 2. Organisms Not Susceptible to the Action of Penicillin.

<i>Escherichia coli</i>	<i>Haemophilus ducreyi</i>

<i>Haemophilus influenzae</i>	<i>Mycobacterium tuberculosis</i>
<i>Haemophilus pertussis</i>	<i>Plasmodium vivax</i>
	<i>Xanthomonas</i>
	<i>Molds</i>

These species are generally considered to be insensitive to penicillin. Actually several of these species can be inhibited in vitro by the use of relatively high concentrations of penicillin, indicating that penicillin insensitivity is often a relative rather than an absolute quality.⁴¹ For practical purposes, however, it is recognized that penicillin has no effective clinical action against these organisms.

The development of resistance to penicillin by bacteria as the result of exposure to sublethal concentrations of the drug either in vitro or in vivo has been reported by several workers.^{42, 43} There is some laboratory evidence to indicate that organisms that develop resistance to penicillin in vitro may become less virulent.^{44, 45} Observations of this kind have not yet been made in human infections. The antibacterial action of penicillin in vitro may be either bactericidal or bacteriostatic.⁴⁶ Most authorities are agreed that in the treatment of human infections its action is bacteriostatic. Penicillin inhibits the growth and multiplication of bac-

in the blood for six to seven hours after a single injection. The practicability of this method for prolonged therapy is being investigated.

Rammelkamp and Bradley²² demonstrated in 1942 that when Diodrast is administered simultaneously with penicillin it partially blocks the excretion of penicillin by the renal tubules. More recent experiments with the use of *p*-aminohippuric acid in animals and in man have shown that this substance also partially blocks the excretion of penicillin and prolongs the time during which it can be detected in the blood stream.^{23, 24} This method requires further study before its general adoption can be recommended.

Theoretically the maintenance of a constant blood level of penicillin would appear to be desirable therapeutically, and it might be expected that methods of administration that would provide such a blood level would be the most effective clinically. Actually, there is as yet no convincing evidence that a given daily dose of penicillin is more effective when given by a continuous infusion than when it is administered by intermittent intramuscular injection at three-hour intervals. Further study of this problem is needed.

The distribution of penicillin in the body after intramuscular or intravenous injection has been studied by many workers. The results of these studies contain valuable therapeutic implications.

In patients without meningitis, penicillin cannot be detected in the cerebrospinal fluid after the intramuscular or intravenous injection of the usual therapeutic doses. When large doses of penicillin are administered to such patients, however, minute amounts of the drug are occasionally demonstrable in the spinal fluid.²⁵ Recently there have been reports of the passage of penicillin from the blood into the spinal fluid of patients with purulent meningitis.^{15, 26, 27} The concentration of drug found in the spinal fluid was markedly less than that present in the blood, and in several cases it did not constitute an effective therapeutic level.

There is good clinical evidence that the amount of penicillin that reaches the spinal fluid in bacterial meningitis is probably insufficient to control the infection. Several cases are known in which no improvement either in the clinical condition of the patient or in the spinal-fluid findings resulted after several days of systemic penicillin therapy, but in which prompt improvement followed the intrathecal administration of the drug. Also several cases are known in which meningitis appeared during the course of the intramuscular or intravenous treatment of an extrameningeal infection. In these cases, likewise, no improvement took place until intrathecal therapy was instituted.

Penicillin diffuses poorly, as a rule, into the pleural cavity, and although prolonged intramuscular therapy may occasionally control an infection of the pleura, the introduction of penicillin

into the empyema cavity is recommended as a more economical and certain form of therapy.²⁸

Penicillin has been detected in ascitic fluid and in synovial fluid in significant concentration after parenteral administration.^{15, 25, 29} Occasional cases of suppurative arthritis have responded to systemic treatment. Local treatment, whenever possible, seems to be desirable, however, since penicillin does not injure the joint and systemic therapy may be unsuccessful.³⁰

Struble and Bellows,³¹ working with dogs, have shown that penicillin administered systemically in amounts comparable to therapeutic doses reaches such a slight concentration in the fluids and tissues of the eye that it is not measurable by the usual methods of assay. Von Sallmann³² has stressed the need for employing iontophoresis or a corneal bath to secure an adequate penetration of penicillin into the aqueous humor. Penicillin is excreted in the bile in higher concentrations than it is found in the blood.³³ The drug has not been detected in saliva, tears, pancreatic juice, succus entericus or gastric juice.

ANTIBACTERIAL ACTION

Penicillin is highly selective in its antibacterial activity. In-vitro tests and a study of experimental infections in animals have indicated clearly in what infections penicillin therapy may be of value and in what infections it cannot be expected to have any effect. Table 1 lists the important pathogenic

TABLE 1: *Organisms Susceptible to the Action of Penicillin.*

<i>Staphylococcus aureus</i>	<i>Clostridium novyi</i>
<i>Staphylococcus albus</i>	<i>Clostridium oedematis-maligni</i>

<i>Clostridium botulinum</i>	<i>Borrelia novyi</i>
<i>Clostridium histolyticus</i>	<i>Actinomyces bovis</i>

organisms against which penicillin has been found to be active by laboratory studies. In general, penicillin has proved to be effective against infections caused by these organisms, although in single cases the site or extent of the infection, the general condition of the patient or the presence of complications may preclude successful therapy.

Among bacterial species usually susceptible to penicillin, occasional strains are encountered that are naturally resistant to the drug. The susceptible species in which naturally resistant strains have been reported are staphylococci, nonhemolytic streptococci and anaerobic streptococci.^{34, 35}

Reports on the effectiveness of penicillin therapy in experimental Weil's disease differ. Heilman and Herrell³⁶ reported no deaths from the disease in

REFERENCES

(To be concluded)

mentioned in the sections that follow. For children it appears that, depending on the size of the patient, from one half to one quarter of the adult dosage is usually adequate.^{15, 61} It has been implied in discussing the action of penicillin that, since the drug is bacteriostatic rather than bactericidal, treatment must be continued until the infection is eradicated or the signs of active infection may reappear. No hard and fast rules have been formulated concerning how long treatment should be continued. In general, penicillin has been given until the temperature has been normal for at least forty-eight hours or until the signs of active infection have been absent for a similar period. In many infections, such as meningitis, bacterial endocarditis, and osteomyelitis, it has usually been necessary to continue treatment for one or more weeks after apparent clinical recovery.

CLINICAL ADMINISTRATION

A number of papers dealing with the general aspects of penicillin therapy have been published by several different groups of investigators.^{10, 14, 17, 18, 29, 55-60} These reports describe the experiences of the various authors with a wide variety of infections. Although there have been differences in the details of treatment, the observations of the various groups are in general agreement. These papers will not be reviewed separately since it would appear more profitable, in discussing the clinical use of penicillin, to follow so far as it is possible an outline based on etiology. The views expressed in these articles will be reflected in the subsequent sections that deal with the treatment of specific infections. To avoid repetition, problems having to do with the site of the infection rather than the etiology of the process will be discussed first. At the end of the paper, recent work on the adaptation of penicillin to problems encountered in certain medical specialties will be considered.

Local Factors

In the section of the pharmacologic properties of penicillin, it has already been mentioned that it appears necessary in the treatment of bacterial meningitis to administer the drug intrathecally. The lumbar sac has been used by most investigators for this purpose, since the drug apparently diffuses from this site throughout the entire subarachnoid space in most cases. There appears to be no need, therefore, to introduce the drug into the cisterna magna or into the ventricles through burr holes, except in unusual circumstances. Twenty-four hours after a single intrathecal injection of penicillin a therapeutic level of the drug can usually be detected in the cerebrospinal fluid. Hence, one intrathecal injection a day is probably sufficient, although many workers prefer to give the drug every twelve hours for the first two to four days of treatment. Solutions containing 5000 to 10,000 units per cubic centimeter are usually employed, and with doses of 10,000 to 20,000 units no significant untoward effects have been observed. Until experience has shown that larger doses can be given with equal safety, it does not seem advisable to give more than 20,000 units in a single injection since this dose usually produces an adequate level of penicillin for at least twelve to twenty-four hours. Because the diffusion of penicillin through the subarachnoid space occasionally may be imperfect for one reason or another, it is strongly advisable, whenever the infecting organism is susceptible to the sulfonamides, to give full doses of an effective sulfonamide concomitantly with penicillin.

In the treatment of empyema the local instillation of penicillin is also recommended.²⁸ The irrigation of the cavity with physiologic saline solution after the aspiration of whatever pus or fluid

is present and before the introduction of penicillin is helpful. Intrapleural injections need be given only once every twenty-four to forty-eight hours, but a minimum of three injections is usually necessary to effect cure, and occasionally more prolonged treatment is required. Solutions containing 1000 units per cubic centimeter are usually employed, although the size of the cavity may make higher or lower concentrations desirable to ensure that the drug is brought into contact with all parts of the cavity.

In suppurative arthritis the local instillation of penicillin, whenever possible, is recommended. Although certain patients have responded to the systemic administration of the drug, this form of treatment is unreliable.

The treatment of bacterial endocarditis, regardless of the etiologic agent, requires prolonged therapy. Not infrequently the blood culture becomes negative after one or two days of treatment and the patient may show striking clinical improvement. Unless treatment is continued for at least two weeks, however, the chances of obtaining a lasting arrest of the infection are small.

The local use of penicillin without concomitant systemic administration in the treatment of soft-tissue wounds and superficial infections of the skin and subcutaneous tissues is occasionally effective.¹⁴ When there is any significant area of cellulitis, however, the systemic administration of penicillin is usually necessary to obtain a maximum therapeutic effect. In selected cases, local penicillin therapy may often be combined with systemic therapy to good advantage. Penicillin is of no value when used as an irrigating solution, since it must remain in contact with infecting organisms for at least six to eight hours before it exerts its maximal antibacterial action.

Dosage

The problem of what constitutes an optimal dosage for the various infections treated with penicillin still requires extended investigation. It seems fairly clear that with the use of very large doses the results obtained are not superior to those following the use of moderate doses. Although excessive dosage has not been shown to be harmful to the patient, it constitutes a waste of a drug that is still not available in amounts sufficient to meet all the demands for its use. Once an effective bacteriostatic level of penicillin is achieved in the tissues, little seems to be gained by increasing the concentration in the tissues. Time is required for the natural defense mechanisms of the body to destroy the infecting organisms. It is doubtful whether this time can be shortened by increasing the dosage of penicillin excessively.

In most infections in adults, a dosage of 15,000 units given intramuscularly every three hours is usually effective. Exceptions to this rule will be

CASE 31141

PRESENTATION OF CASE

A sixty-year-old laborer was admitted to the hospital because of dysphagia.

Sixteen months before admission the patient was unable to swallow solid foods for a period of one week. The food stuck in the lower esophagus and refused to pass into the stomach. This symptom disappeared and he had no more trouble until seven months before entry, when one morning he was unable to swallow his breakfast of oatmeal and prunes. The food was apparently arrested in the lower esophagus and had to be regurgitated, although on the previous day no difficulty whatever had been experienced. Since that time he had repeatedly tried to swallow solid and semisolid foods without success and had subsisted on a liquid diet. After the onset of this difficulty, the passage of food caused burning pain at the lower end of the esophagus. He had lost 12 pounds and had become weak and tired easily. He had never vomited blood or passed bloody or tarry stools. For the previous four years he had worked in a mill scouring wool. He had had a mild nonproductive cough in the evening for the past three or four months. For a year and a half he had had rather sharp nonradiating, precordial pain that came on during exertion and lasted a few minutes; this occurred one to several times a week. For six months he had had dyspnea on exertion and ankle edema.

Physical examination revealed a well-developed, fairly well-nourished, pale man. The skin was dry, and there was little subcutaneous fat. Many teeth were carious, with broken retained roots. The pharynx was moderately injected. Examination of the lungs was negative, no rales being heard. The heart was slightly enlarged to the left. A Grade 2 systolic murmur was heard over the apex and was transmitted over the entire precordium. The abdomen was negative. The ankles showed slight edema.

The temperature, pulse and respirations were normal. The blood pressure was 156 systolic, 62 diastolic.

Examination of the blood showed a red-cell count of 3,470,000 and a white-cell count of 5750, with

60 per cent neutrophils. The blood prothrombin time and the serum nonprotein nitrogen, chloride and protein levels were normal. The urine was negative.

X-ray examination of the teeth revealed retained, decayed root fragments surrounded by abscesses in the upper and lower jaws. X-ray films of the chest showed clear lungs, with no evidence of metastases or other abnormality. The heart was prominent in the region of the left ventricle, and the aorta was tortuous. The ribs showed no destruction. A barium swallow revealed normal function, the esophagus was dilated to a point 9 cm. above the diaphragm, at which level there was sudden and constant narrowing, with failure to distend and with absent peristalsis. An ulcer crater 6 mm. in diameter was present about 1 cm. below the top of the narrowing. Immediately below the narrowing, which extended for about 1 cm., there was dilatation to a maximum of 5.2 cm., which contracted readily and revealed what resembled gastric mucosa in a hiatus hernia (Fig. 1). The remainder of the stomach

FIGURE 1. Roentgenogram Showing Obstruction in the Esophagus and the Herniated Portion of the Stomach Below It.

and duodenum was negative. The patient's teeth were extracted and he was given several transfusions.

One week after admission an esophagoscopy was performed.

DR. SWEET: It always seemed to me that it would take a tremendous amount of inflammatory process to produce enough contraction to pull the stomach up from below the diaphragm to a point opposite the pulmonary vein, where this cardia was. It would have to drag the stomach 10 or 12 cm. DR. SKIFFEN: It is a little difficult to believe. DR. HOLMES: Instead of stating that the lesion was of short duration, I should have said that the obstruction was of short duration. The esophagus would not dilate unless there was some obstruction. DR. SWEET: Is not the contraction likely to be circumferential rather than along the length. As we see them they involve short lengths of the esophagus. DR. BENDICK: I have seen several cases in which the inflammatory contraction was 10 to 15 cm. long. DR. SWEET: With a normally placed cardia? DR. BENDICK: The cardia was not necessarily abnormally placed. CASE 31142 PRESENTATION OF CASE A seventy-two-year-old woman was admitted to the hospital because of inability to swallow solid foods. Ten months before admission the patient first noticed difficulty in swallowing solid foods. This before admission she sought medical advice. She stated that solid food passed part-way down the esophagus, then stopped and was regurgitated. There was no pain. She had lost 25 pounds, had become weak and had experienced a "tight little cough" during the past three to four months. Typical and fatal attacks and occasional dyspnea on exertion had occurred during the previous year. Ten years before entry she had had a radical mastectomy for cancer of the right breast. Physical examination revealed a well-developed woman who showed evidence of recent weight loss. A right radical mastectomy scar was present; no axillary lymph nodes were felt. Examination of the heart, lungs and abdomen was negative. The temperature, pulse and respirations were normal. The blood pressure was 154 systolic, 98 diastolic. Examination of the blood showed a white-cell count of 6100, with 67 per cent neutrophils, and 14 gm. of hemoglobin. The urine was negative. The serum nonprotein nitrogen, the chloride and the protein were normal. A Hinton test was negative. An electrocardiogram suggested some coronary insufficiency. X-ray examination of the esophagus showed that swallows of barium, both liquid and paste, passed through the esophagus with little delay. The esophagus was seen to be narrowed opposite a tortuous, calcified aortic knob, and a small amount of barium was delayed above this narrowing. Peristalsis of the esophagus was rather feeble. The narrowed area showed normal mucosal folds passing through it. There was no definite filling defect at any point. The lower two thirds of the esophagus showed rather marked curling. A 2-cm. hiatus hernia was noted, which emptied freely. The stomach and duodenum were normal. On the fifth hospital day esophagoscopy was attempted. The esophagoscope was passed only to the level of the cricopharyngeus muscle, where there was prolonged delay. On gentle pressure some bleeding was noted in that region, and it was thought unwise to attempt to pass the instrument farther. The patient was given nothing by mouth. Intravenous sulfadiazine was started, and x-ray examinations of the neck and chest were performed on the following two days. No evidence of perforation of the esophagus was found. Following the esophagoscopy the temperature rose to 100°F. for a few days. The pulse and respirations remained normal. On the eighth hospital day, as the patient was dressing to go home, she suddenly became dyspneic and cyanotic, broke out with a cold sweat and felt faint but had no pain. She had had no previous similar episode. The lungs were clear, the respiratory rate 30, and the pulse 160, with marked irregularity and pulse deficit. The blood pressure was 180 systolic, 60 diastolic. There was slight distention of the neck veins. She remained cyanotic and dyspneic, and a few hours later became comatose and expired.

DR. IRA T. NATHANSON: The initial complaint of difficulty in swallowing focuses attention on lesions in or near the esophagus. Of the benign lesions, the Plummer-Vinson syndrome, scleroderma and vitamin deficiencies must be considered. The first can be ruled out by the absence of the usually long history of dysphagia, the age of the patient, the lack of x-ray evidence of webbing of the esophagus and the relatively normal hemoglobin. The visceral manifestations of scleroderma are less easily eliminated because of the increased pulmonary markings and the sluggish peristalsis in the esophagus. In the absence of other clinical signs, both these findings may be attributed to the age of the patient. There are no findings recorded to suggest a vitamin deficiency. One must then consider the malignant lesions that might have been responsible for the clinical picture. Carcinoma of the esophagus may be excluded by the x-ray evidence of normal mucosal folds at the site of narrowing and the absence of a filling defect. Thus, it seems likely that the dysphagia arose from pressure on the esophagus by an extrinsic mass. There are no statements regarding this possibility in the x-ray report. Hence, it would be of help to

DR. RICHARD H. SWEET: I have been much interested in this group of cases, and we now have a small series characterized by the occurrence of a short-esophagus hiatus hernia and inflammatory stricture near the cardia, which in these cases lies well up in the chest.

At exploration in this man we found exactly what we see in the lateral roentgen-ray film, namely, a large portion of the stomach herniated through the diaphragm. The cardia and lower end of the esophagus were thickened. As in all such patients on whom I have operated the area was quite adherent. The adhesions in these cases are different from the ones that are encountered in carcinoma and somewhat more difficult to separate. I believed, as Dr. Wallace did, that this was a benign stricture arising as a result of ulcer in the cardia. This appears to be a definite syndrome. A co-existing duodenal ulcer has been observed in many of the cases. I agree with Dr. Wallace that these lesions should be regarded with suspicion and should be operated on unless it is obvious that they are suitable for dilatation. We have had cases with carcinoma arising apparently in the vicinity of such a stenosed ulcer. A short while ago I had a patient with a similar story, and at operation there was a firm, hard tumor mass, not much larger than 1.5 cm. in diameter, near the fibrous stricture. This led me to be radical in my resection. There was the same kind of stenosed cardia that would appear in a case of fibrosed stricture, but in addition there was a carcinoma, which apparently was extremely early. I know that Dr. Sniffen cannot say that this was a case of carcinoma arising in an ulcer, because of course that is difficult, even in the prepyloric ulcers. At least for the present I should like to think of these lesions in much the same way as we do those in the prepyloric area in the stomach and advise surgery rather than palliative therapy.

DR. BENEDICT: I might say that I have not seen any case with just this setup that had cancer except the one that Dr. Sweet mentioned. I should think that a number of them could be satisfactorily treated by esophagoscopy and dilatation. I am wondering if we ought to do such a radical procedure as partial resection for benign ulcer of the esophagus, except in rare cases.

DR. SWEET: Not unless it is badly stenosed and mechanically obstructed.

DR. BENEDICT: I thought that resection was justifiable in this case, but I am not sure that he could not have been treated with dilatation. We just do not know. A number have been successfully tried. I am inclined to think that the situation is not quite like the prepyloric ulcer, where the danger of malignancy is great.

DR. SWEET: My remarks were intended to direct our thoughts along those lines. I do not believe that we can make a definitive decision but we should

keep an open mind. I have a suspicion that we are going to find quite a number of them with carcinoma.

DR. SNIFFEN: One of the major stumbling blocks is that we cannot depend on the biopsy. Frequently, the sections show chronic inflammation and nothing more, and yet there is a cancer. In other words, the biopsy was not taken through a critical area.

CLINICAL DIAGNOSES

Stricture of esophagus, with ulceration and hiatus hernia.

Carcinoma of esophagus?

DR. WALLACE'S DIAGNOSIS

Benign ulcer of esophagus, with stricture.

ANATOMICAL DIAGNOSES

Short esophagus, with inflammatory stricture and ulceration.

Hiatus hernia.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: Dr. Sweet removed a little more than 2 cm. of the esophagus and a large portion of the part of the stomach that lay above the diaphragm. The upper end of the resected esophagus was dilated to 3.5 cm. in circumference. Below this there was an abrupt narrowing of the lumen, the wall being over 1 cm. in thickness. The stenosis extended for a centimeter or more, ending in the herniated portion of the stomach. In the stenotic area there was a small ulcer, which was not more than 2 mm. in diameter. Histologic sections showed a chronic inflammatory process, with ulceration in the squamous epithelium of the esophagus. There was nothing in the vicinity of the ulcer to lead one to think that there was peptic ulcer of an island of gastric mucosa in the esophagus. We know that these islands may occur anywhere in the esophagus.

I should like to mention the main types of hiatus hernia as enumerated by Harrington.* The first is the true paraesophageal hiatus hernia, in which the termination of the esophagus is below the diaphragm and the fundus has herniated through the esophageal hiatus into the mediastinum. In the second type, the esophagus is again of normal length but the lower end is above the diaphragm. Then there is the group in which the esophagus is congenitally short; he does not consider that this is a true hernia, since the stomach has never been below the diaphragm. Next, there is the acquired short esophagus due to fibrous stricture resulting from tumor or ulcer. I believe that this case falls into that group, except that Dr. Holmes has said that he thought that the process was of short duration. On the other hand, it may have been a congenitally short esophagus with ulceration and stenosis. The last group comprises those cases in which there is dilatation of the lower end of the esophagus without gastric herniation.

*Harrington, S. W. Roentgenologic considerations in diagnosis and treatment of diaphragmatic hernia. *Am. J. Roentgenol.* 49:185-196, 1943.

Dr. Sweet: It always seemed to me that it would take a tremendous amount of inflammatory process to produce enough contraction to pull the stomach up from below the diaphragm to a point opposite the pulmonary vein, where this cardia was. It would have to drag the stomach 10 or 12 cm. Dr. Safford: It is a little difficult to believe. Dr. Holmes: Instead of stating that the lesion was of short duration, I should have said that the obstruction was of short duration. The esophagus would not dilate unless there was some obstruction. Dr. Sweet: Is not the contraction likely to be circumferential rather than along the length. As we see them they involve short lengths of the esophagus. Dr. Benedict: I have seen several cases in which the inflammatory contraction was 10 to 15 cm. long. Dr. Sweet: With a normally placed cardia? Dr. Benedict: The cardia was not necessarily abnormally placed.

CASE 31142
PRESENTATION OF CASE

A seventy-two-year-old woman was admitted to the hospital because of inability to swallow solid foods. Ten months before admission the patient first noticed difficulty in swallowing solid foods. This difficulty gradually became worse, and two months before admission she sought medical advice. She stated that solid food passed part-way down the esophagus, then stopped and was regurgitated. There was no pain. She had lost 25 pounds, had become weak and had experienced a "tight little cough" during the past three to four months. Typical anginal attacks and occasional dyspnea on exertion had occurred during the previous year. Ten years before entry she had had a radical mastectomy for cancer of the right breast. Physical examination revealed a well-developed woman who showed evidence of recent weight loss. A right radical mastectomy scar was present; no axillary lymph nodes were felt. Examination of the heart, lungs and abdomen was negative. The temperature, pulse and respirations were normal. The blood pressure was 154 systolic, 98 diastolic. Examination of the blood showed a white-cell count of 6100, with 67 per cent neutrophils, and 14 gm. of hemoglobin. The urine was negative. The serum nonprotein nitrogen, the chloride and the protein were normal. A Hinton test was negative. An electrocardiogram suggested some coronary insufficiency. X-ray examination of the esophagus showed that swallows of barium, both liquid and paste, passed through the esophagus with little delay. The esophagus was seen to be narrowed opposite a tortuous, calcified aortic knob, and a small amount of barium was delayed above this narrowing. Peristalsis of the esophagus was rather feeble. The narrowed area showed normal mucosal folds passing through it. There was no definite filling defect at any point. The lower two thirds of the esophagus showed rather marked curling. A 2-cm. hiatus hernia was noted, which emptied freely. The stomach and duodenum were normal.

On the fifth hospital day esophagoscopy was attempted. The esophagoscope was passed only to the level of the cricopharyngeus muscle, where there was prolonged delay. On gentle pressure some bleeding was noted in that region, and it was thought unwise to attempt to pass the instrument farther. The patient was given nothing by mouth. Intravenous sulfadiazine was started, and x-ray examinations of the neck and chest were performed on the following two days. No evidence of perforation of the esophagus was found. Following the esophagoscopy the temperature rose to 100°F. for a few days. The pulse and respirations remained normal.

On the eighteenth hospital day, as the patient was dressing to go home, she suddenly became dyspneic and cyanotic, broke out with a cold sweat and felt faint but had no pain. She had had no previous similar episode. The lungs were clear, the respiratory rate 30, and the pulse 160, with marked irregularity and pulse deficit. The blood pressure was 180 systolic, 60 diastolic. There was slight distention of the neck veins. She remained cyanotic and dyspneic, and a few hours later became comatose and expired.

DIFFERENTIAL DIAGNOSIS

Dr. Ira T. NATHANSON: The initial complaint of difficulty in swallowing focuses attention on lesions in or near the esophagus. Of the benign lesions, the Plummer-Vinson syndrome, scleroderma and vitamin deficiencies must be considered. The first can be ruled out by the absence of the usually long history of dysphagia, the age of the patient, the lack of x-ray evidence of webbing of the esophagus and the relatively normal hemoglobin. The visceral manifestations of scleroderma are less easily eliminated, because of the increased pulmonary markings and the slugish peristalsis in the esophagus. In the absence of other clinical signs, both these findings may be attributed to the age of the patient. There are no findings recorded to suggest a vitamin deficiency. One must then consider the malignant lesions that might have been responsible for the clinical picture. Carcinoma of the esophagus may be excluded by the x-ray evidence of normal mucosal folds at the site of narrowing and the absence of a filling defect. Thus, it seems likely that the dysphagia arose from pressure on the esophagus by an extrinsic mass. There are no statements regarding this possibility in the x-ray report. Hence, it would be of help to

DR. SWEET: It always seemed to me that it would take a tremendous amount of inflammatory process to produce enough contraction to pull the stomach up from below the diaphragm to a point opposite the pulmonary vein, where this cardia was. It would have to drag the stomach 10 or 12 cm.

DR. SNIFFEN: It is a little difficult to believe.

DR. HOLMES: Instead of stating that the lesion was of short duration, I should have said that the obstruction was of short duration. The esophagus would not dilate unless there was some obstruction.

DIFFERENTIAL DIAGNOSIS

DR. IRA T. NATHANSON: The initial complaint of difficulty in swallowing focuses attention on lesions in or near the esophagus. Of the benign lesions, the Plummer-Vinson syndrome, scleroderma and vitamin deficiencies must be considered. The first can be ruled out by the absence of the usually long history of dysphagia, the age of the patient, the lack of x-ray evidence of webbing of the esophagus and the relatively normal hemoglobin. The visceral manifestations of scleroderma are less easily eliminated, because of the increased pulmonary markings and the sluggish peristalsis in the esophagus. In the absence of other clinical signs, both these findings may be attributed to the age of the patient. There are no findings recorded to suggest a vitamin deficiency.

One must then consider the malignant lesions that might have been responsible for the clinical picture. Carcinoma of the esophagus may be excluded by the x-ray evidence of normal mucosal folds at the site of narrowing and the absence of a filling defect. Thus, it seems likely that the dysphagia arose from pressure on the esophagus by an extrinsic mass. There are no statements regarding this possibility in the x-ray report. Hence, it would be of help to

DR. RICHARD H. SWEET: I have been much interested in this group of cases, and we now have a small series characterized by the occurrence of a short-esophagus hiatus hernia and inflammatory stricture near the cardia, which in these cases lies well up in the chest.

At exploration in this man we found exactly what we see in the lateral roentgen-ray film, namely, a large portion of the stomach herniated through the diaphragm. The cardia and lower end of the esophagus were thickened. As in all such patients on whom I have operated the area was quite adherent. The adhesions in these cases are different from the ones that are encountered in carcinoma and somewhat more difficult to separate. I believed, as Dr. Wallace did, that this was a benign stricture arising as a result of ulcer in the cardia. This appears to be a definite syndrome. A co-existing duodenal ulcer has been observed in many of the cases. I agree with Dr. Wallace that these lesions should be regarded with suspicion and should be operated on unless it is obvious that they are suitable for dilatation. We have had cases with carcinoma arising apparently in the vicinity of such a stenosed ulcer. A short while ago I had a patient with a similar story, and at operation there was a firm, hard tumor mass, not much larger than 1.5 cm. in diameter, near the fibrous stricture. This led me to be radical in my resection. There was the same kind of stenosed cardia that would appear in a case of fibrosed stricture, but in addition there was a carcinoma, which apparently was extremely early. I know that Dr. Sniffen cannot say that this was a case of carcinoma arising in an ulcer, because of course that is difficult, even in the prepyloric ulcers. At least for the present I should like to think of these lesions in much the same way as we do those in the prepyloric area in the stomach and advise surgery rather than palliative therapy.

DR. BENEDICT: I might say that I have not seen any case with just this setup that had cancer except the one that Dr. Sweet mentioned. I should think that a number of them could be satisfactorily treated by esophagoscopy and dilatation. I am wondering if we ought to do such a radical procedure as partial resection for benign ulcer of the esophagus, except in rare cases.

DR. SWEET: Not unless it is badly stenosed and mechanically obstructed.

DR. BENEDICT: I thought that resection was justifiable in this case, but I am not sure that he could not have been treated with dilatation. We just do not know. A number have been successfully tried. I am inclined to think that the situation is not quite like the prepyloric ulcer, where the danger of malignancy is great.

DR. SWEET: My remarks were intended to direct our thoughts along those lines. I do not believe that we can make a definitive decision but we should

keep an open mind. I have a suspicion that we are going to find quite a number of them with carcinoma.

DR. SNIFFEN: One of the major stumbling blocks is that we cannot depend on the biopsy. Frequently, the sections show chronic inflammation and nothing more, and yet there is a cancer. In other words, the biopsy was not taken through a critical area.

CLINICAL DIAGNOSES

Stricture of esophagus, with ulceration and hiatus hernia.

Carcinoma of esophagus?

DR. WALLACE'S DIAGNOSIS

Benign ulcer of esophagus, with stricture.

ANATOMICAL DIAGNOSES

Short esophagus, with inflammatory stricture and ulceration.

Hiatus hernia.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: Dr. Sweet removed a little more than 2 cm. of the esophagus and a large portion of the part of the stomach that lay above the diaphragm. The upper end of the resected esophagus was dilated to 3.5 cm. in circumference. Below this there was an abrupt narrowing of the lumen, the wall being over 1 cm. in thickness. The stenosis extended for a centimeter or more, ending in the herniated portion of the stomach. In the stenotic area there was a small ulcer, which was not more than 2 mm. in diameter. Histologic sections showed a chronic inflammatory process, with ulceration in the squamous epithelium of the esophagus. There was nothing in the vicinity of the ulcer to lead one to think that there was peptic ulcer of an island of gastric mucosa in the esophagus. We know that these islands may occur anywhere in the esophagus.

I should like to mention the main types of hiatus hernia as enumerated by Harrington.* The first is the true paraesophageal hiatus hernia, in which the termination of the esophagus is below the diaphragm and the fundus has herniated through the esophageal hiatus into the mediastinum. In the second type, the esophagus is again of normal length but the lower end is above the diaphragm. Then there is the group in which the esophagus is congenitally short; he does not consider that this is a true hernia, since the stomach has never been below the diaphragm. Next, there is the acquired short esophagus due to fibrous stricture resulting from tumor or ulcer. I believe that this case falls into that group, except that Dr. Holmes has said that he thought that the process was of short duration. On the other hand, it may have been a congenitally short esophagus with ulceration and stenosis. The last group comprises those cases in which there is dilatation of the lower end of the esophagus without gastric herniation.

*Harrington, S. W. Roentgenologic considerations in diagnosis and treatment of diaphragmatic hernia. *Am. J. Roentgenol.* 49:185-196, 1943.

DR. SWEET: It always seemed to me that it would take a tremendous amount of inflammatory process to produce enough contraction to pull the stomach up from below the diaphragm to a point opposite the pulmonary vein, where this cardia was. It would have to drag the stomach 10 or 12 cm.

DR. SNIFFEN: It is a little difficult to believe.

DR. HOLMES: Instead of stating that the lesion was of short duration, I should have said that the obstruction was of short duration. The esophagus would not dilate unless there was some obstruction.

DR. SWEET: Is not the contraction likely to be circumferential rather than along the length. As we see them they involve short lengths of the esophagus.

DR. BENEDICT: I have seen several cases in which the inflammatory contraction was 10 to 15 cm. long.

DR. SWEET: With a normally placed cardia?

DR. BENEDICT: The cardia was not necessarily abnormally placed.

CASE 31142

PRESENTATION OF CASE

A seventy-two-year-old woman was admitted to the hospital because of inability to swallow solid foods.

Ten months before admission the patient first noticed difficulty in swallowing solid foods. This difficulty gradually became worse, and two months before admission she sought medical advice. She stated that solid food passed part-way down the esophagus, then stopped and was regurgitated. There was no pain. She had lost 25 pounds, had become weak and had experienced a "tight little cough" during the past three to four months. Typical anginal attacks and occasional dyspnea on exertion had occurred during the previous year.

Ten years before entry she had had a radical mastectomy for cancer of the right breast.

Physical examination revealed a well-developed woman who showed evidence of recent weight loss. A right radical mastectomy scar was present; no axillary lymph nodes were felt. Examination of the heart, lungs and abdomen was negative.

The temperature, pulse and respirations were normal. The blood pressure was 154 systolic, 98 diastolic.

Examination of the blood showed a white-cell count of 6100, with 67 per cent neutrophils, and 14 gm. of hemoglobin. The urine was negative. The serum nonprotein nitrogen, the chloride and the protein were normal. A Hinton test was negative. An electrocardiogram suggested some coronary insufficiency.

X-ray examination of the esophagus showed that swallows of barium, both liquid and paste, passed through the esophagus with little delay. The esophagus was seen to be narrowed opposite a tortuous,

calcified aortic knob, and a small amount of barium was delayed above this narrowing. Peristalsis of the esophagus was rather feeble. The narrowed area showed normal mucosal folds passing through it. There was no definite filling defect at any point. The lower two thirds of the esophagus showed rather marked curling. A 2-cm. hiatus hernia was noted, which emptied freely. The stomach and duodenum were normal.

On the fifth hospital day esophagoscopy was attempted. The esophagoscope was passed only to the level of the cricopharyngeus muscle, where there was prolonged delay. On gentle pressure some bleeding was noted in that region, and it was thought unwise to attempt to pass the instrument farther. The patient was given nothing by mouth. Intravenous sulfadiazine was started, and x-ray examinations of the neck and chest were performed on the following two days. No evidence of perforation of the esophagus was found. Following the esophagoscopy the temperature rose to 100°F. for a few days. The pulse and respirations remained normal.

On the eighteenth hospital day, as the patient was dressing to go home, she suddenly became dyspneic and cyanotic, broke out with a cold sweat and felt faint but had no pain. She had had no previous similar episode. The lungs were clear, the respiratory rate 30, and the pulse 160, with marked irregularity and pulse deficit. The blood pressure was 180 systolic, 60 diastolic. There was slight distention of the neck veins. She remained cyanotic and dyspneic, and a few hours later became comatose and expired.

DIFFERENTIAL DIAGNOSIS

DR. IRA T. NATHANSON: The initial complaint of difficulty in swallowing focuses attention on lesions in or near the esophagus. Of the benign lesions, the Plummer-Vinson syndrome, scleroderma and vitamin deficiencies must be considered. The first can be ruled out by the absence of the usually long history of dysphagia, the age of the patient, the lack of x-ray evidence of webbing of the esophagus and the relatively normal hemoglobin. The visceral manifestations of scleroderma are less easily eliminated, because of the increased pulmonary markings and the sluggish peristalsis in the esophagus. In the absence of other clinical signs, both these findings may be attributed to the age of the patient. There are no findings recorded to suggest a vitamin deficiency.

One must then consider the malignant lesions that might have been responsible for the clinical picture. Carcinoma of the esophagus may be excluded by the x-ray evidence of normal mucosal folds at the site of narrowing and the absence of a filling defect. Thus, it seems likely that the dysphagia arose from pressure on the esophagus by an extrinsic mass. There are no statements regarding this possibility in the x-ray report. Hence, it would be of help to

review the x-ray films, particularly those of the chest, concerning which nothing is given in the abstract of the history.

DR. LAURENCE L. ROBBINS: The films of the chest show that the right breast had been removed. There appears to be an increase in the linear markings throughout the lung fields beyond what one can expect simply because of the patient's age. There is probably some increase in the density in the anterior portion of the chest; I am not certain what is the cause of this, although it might have been due to an acute process in the left upper lobe, as it appeared within twenty-four hours.

The spot films of the esophagus show it to be fairly smooth in outline; in the lower portion it appears to pass around an extrinsic mass. I do not believe that all the changes can be explained by curling.

DR. NATHANSON: Could the linear markings in the lungs be due to metastases?

DR. ROBBINS: They could be, but they are not typical. The changes could be on the basis of vascular congestion. There is a hiatus hernia.

DR. NATHANSON: If one assumes that an extrinsic mass was the cause of the symptoms, the question arises whether it was primary or secondary. The possibility of a primary mass in the posterior mediastinum cannot be definitely excluded, nor can the exact nature of such a mass be determined. A tumor of the lymphoma series, sarcoid or tuberculous lymph nodes may occur in this region. The latter two are relatively rare at this age, whereas the former may occur at any age. What is the probability of a secondary tumor? The patient had a radical mastectomy ten years previously for cancer of the breast. It is not known if the axillary lymph nodes were involved in disease. It is a well-established fact that metastases from cancer of the breast may remain dormant and not manifest themselves for many years, even twenty-five to thirty, after removal of the primary tumor. Good evidence exists that a five-year follow-up period is not sufficient to evaluate the curability rate of cancer of the breast. Moreover, metastatic lesions from cancer of the breast may appear in a wide variety of locations. The chest is a fairly frequent site. Thus it is possible that there was a metastatic mass in the posterior mediastinum that had its origin from the cancer of the breast removed many years before. Lesions of this character are not necessarily demonstrable by x-ray. There is no evidence of metastatic disease elsewhere. The evidence for this diagnosis is far from conclusive, but I cannot make any other from the material available.

Death can be explained on the basis of coronary disease or a pulmonary embolus.

CLINICAL DIAGNOSIS

Carcinoma of esophagus.

DR. NATHANSON'S DIAGNOSES

(Carcinoma of right breast.)
Metastatic carcinoma of posterior mediastinum.
Hiatus hernia.
Hypertensive and arteriosclerotic heart disease.
Coronary disease?
Pulmonary embolism?

ANATOMICAL DIAGNOSES

(Carcinoma of right breast.)
Radical mastectomy, old.
Metastatic adenocarcinoma of mediastinal lymph nodes, with compression and erosion of esophagus.
Massive pulmonary embolism.
Moderate bilateral hydrothorax.
Fibrinous pericarditis.

PATHOLOGICAL DISCUSSION

DR. RONALD C. SNIFFEN: The patient died from a massive pulmonary embolus, and the inferior vena cava, as well as both femoral veins, contained large thrombi. In the right upper lobe there was a 5-by-3-cm. infarct of a few days' standing.

The mediastinal lymph nodes were matted together and enlarged by obvious tumor deposits. They surrounded the lower trachea and both main bronchi and on the left had produced stenosis of the left upper lobe bronchus, with partial collapse of the upper lobe as a consequence. The bronchial mucosa had been eroded by invading tumor at several points. Posteriorly these same lymph nodes had compressed a 6-cm. segment of the esophagus. The upper margin of compression was at the level of the aortic arch, and 4 cm. below this point the tumor had invaded the anterior wall of the esophagus and produced an erosion measuring 2 cm. in diameter in the mucosa. Additional findings were a moderate bilateral hydrothorax and a fibrinous pericarditis. No tumor could be found at the site of the previous mastectomy or in the other breast.

Microscopically the tumor in the lymph nodes was a poorly differentiated adenocarcinoma having a morphology quite consistent with a metastasis from a breast cancer. The cells lay in a dense collagenous stroma and had a rather striking proclivity for growth in the perineurial lymphatics. The vertebral bone marrow was the only site in which metastatic tumor could be found.

PENICILLIN: UNEXCELLED AND NOW OBTAINABLE

In a recent poll¹ of a group of leading physicians, penicillin was considered by the majority to be the most valuable drug now used by the medical profession. This recognition was based on two important properties of penicillin, namely, its wide range of effective action in bacterial infections and its lack of significant toxicity for man.

Until a year ago, penicillin could be aptly described as "unexcelled but unobtainable." During the past year the distribution of a limited supply of penicillin through depot hospitals has made it possible for an increasing number of physicians to

become familiar with its action from firsthand experience. On March 15 of this year the War Production Board announced that the production of penicillin had increased sufficiently to meet all the anticipated needs of both the armed services and the civilian population and that all restrictions on its sale had been removed. The solution of the difficult problems inherent in the large-scale production of penicillin is a notable accomplishment. Much credit is due the governmental agencies, private scientific institutions, and pharmaceutical manufacturers who have co-operated so effectively to achieve the goal of making the drug available to every patient who might benefit from its administration.

Although there is no reason to anticipate that the unrestricted distribution of penicillin will result in a shortage of the drug, it seems proper to urge physicians to employ this new therapeutic agent with wisdom and discretion. Elsewhere in this issue of the *Journal*² the present status of the use of penicillin in the treatment of infections is reviewed in detail. Physicians who have not had an opportunity to use the drug extensively will find this review helpful and timely in acquainting themselves with both the possibilities and limitations of penicillin therapy.

The wider use of penicillin should result in a significant lowering of the mortality rate, a decrease in the number of complications, and a shortening of the period of disability in many of the infections that are commonly encountered in medical practice. It is well to remember, however, that although the drug is nontoxic, it is not a panacea. In certain situations it is conceivable that if blind reliance were placed on the use of penicillin to the neglect of other therapeutic measures of known value, harm might result. Penicillin cannot be expected to have a favorable effect on diseases other than infections caused by organisms that are susceptible to its action, and even in such infections the use of adjuvant measures may often be necessary to effect recovery.

MEDICAL SERVICE IN INDUSTRY

EVERY vocational association strives to prevent the following of its trade or profession by unauthorized persons. This was begun by the medieval guilds and has been continued and amplified throughout the subsequent history of mankind. The primary purpose and the cause of its great success have always been the enhancement of the political power of its constituents, while they in turn contribute their aggregate strength to the power of the central organization. There is, however, a less well-known but more important purpose — that of protecting the mass of the people against fraudulent and unscrupulous exploitation. Medical-practice laws are framed to support the latter purpose, and it is the solemn obligation of those who make and enforce them to provide the people with a high standard of medical care. It is likewise the obligation of those who are admitted to practice within the law to keep the practice of medicine on a high plane and available to all people at all times.

What legally constitutes the practice of medicine may be a difficult matter to decide. In hospitals and institutions it is frequently necessary that the behavior of those who have to do with the sick and injured be codified into definite procedures. Such methods may be revised or amended from time to time to keep alive and maintain a complete understanding between all concerned. The ultimate responsibility for the choice and execution of the processes of medical care should be assumed by the doctor. In recognition of this responsibility the medical and nursing professions have long since adopted the principles of "doctor's orders"; doctors expect to issue them and to have them carried out, and nurses universally expect to receive them and to carry them out. They have worked well in hospital and private practice because in these surroundings the doctor is expected to assume command; indeed, hospital trustees generally require him to write his orders, where all may see and where there will never be any question about them.

In the development of modern concepts of industrial health, however, there have appeared new relations. Management as a whole cannot be ex-

pected to have the same interest or insight into medical care in industry that hospital administrators have in the medical care in their institutions. Industrialists naturally and properly utilize nurses and "first-aiders" to administer immediate aid and to carry out minor treatments. It has sometimes been thought that these nurses and first-aiders were not medically supervised. When, for example, does the giving of an aspirin tablet for a headache constitute medical practice, and when is it a minor commercial or friendly transaction? If the headache is due to meningitis, it is certainly medical practice to treat it in any way — from a first-aid medical cabinet, across a counter or in a hospital; but physicians cannot be expected to examine every case of headache on the remote chance that it may be a symptom of serious disease. Neither can they be expected to ignore everything of a minor nature. There are certain occupations in which headache may be a helpful sign of toxicity and may call for timely and expert medical attention.

All these perplexing and complex relations indicate the need for further clarification of the doctor's role in industry. The Council on Industrial Health of the American Medical Association has advocated standing orders for nurses in industry, and standing orders for industrial first-aiders have been privately issued and used. In its statement elsewhere in this issue of the *Journal*, the Committee on Industrial Health of the Massachusetts Medical Society expresses its approval of standing orders for industrial first-aiders, thus indicating its belief that the supervision of first-aid practices in industry is an obligation of the medical profession. It can be claimed that this is a device under which industrial first-aiders will "practice medicine without a license," and it probably would not be difficult to find cases in which such actually was the case. On the other hand, the practical view, and the one that the committee adopts, is that the first-aiders will be less likely to practice medicine if he is forced to work under medical supervision expressed by written standing orders than if he is permitted to proceed independently. This may be a significant step in the protocol of industrial health.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON INDUSTRIAL HEALTH

The Committee on Industrial Health issues the following statement concerning industrial hygiene in Massachusetts.

DWIGHT O'HARA, *Chairman*

* * *

A STATEMENT CONCERNING INDUSTRIAL HYGIENE IN THE SMALL PLANTS OF MASSACHUSETTS

In two previous reports to the Council of the Massachusetts Medical Society,^{1,2} the Committee on Industrial Health has called attention to the fact that three quarters of the workers in Massachusetts are employed in the so-called "small plants" of the Commonwealth, factories where there is still little or no medical supervision of industrial hygiene. The committee has continued to discuss this fact and now ventures to issue a statement about it.

Many of these plants are not so small, — some of them employ 400 or 500 people, which is really a big industry, — but from the point of view of their health standards they are more comparable to the many little industries than they are to those large corporations that have found it feasible and profitable to maintain and staff their own medical departments. In the following discussion the term "small" is therefore used in the sense that it indicates small interest or activity in the field of industrial health.

It is easy to understand why these plants frequently lack this interest. Even though they aggregate a major industrial hazard to the people of Massachusetts, the management of each individual plant can actually concern itself with but a fraction of the total risk. It can insure itself against this fraction and let the matter rest right there. Of course, the chances are that this policy will keep it out of serious trouble, and management naturally is tempted to adopt it and turn its attention to other more pressing matters.

Although this is probably the attitude toward industrial health among many of the small industries, there are today an increasing number of them in which a lively interest in the subject is being shown. When the latter are looked at more closely, it is usually found that an enlightened manager has whipped a doctor into line or an enthusiastic doctor has applied the "bee" to management, or a restless nurse has refused to sink back into the routine of first-aid techniques; and so progress has been made. The development of part-time nursing services for industry by district nursing associations was commented on in the report of a year ago³ and has been described elsewhere.⁴ There are many plants in which no nursing service is used, but in which some sort of first-aid equipment has been installed. This is usually presided over by a certified "first-aid-er" or by someone in the plant who has come to take such responsibilities in the natural course of events. The committee desires to emphasize one point regarding all such persons, from the full-time nurse down to the casual first-aiders, namely, *they need medical supervision*. The complaint that is sometimes heard, or the fear that is sometimes expressed, that some of these people may be "practicing medicine" can mean only one thing — they are not properly supervised by the medical profession.

Such lack of supervision is generally due to one of three kinds of unwillingness: unwillingness on the part of management to employ a plant doctor; unwillingness on the part of the doctor to issue standing orders or to give any advance thought to the health hazards of the particular industry; or unwillingness on the part of first-aid or nursing personnel to refer cases to, or at least to secure advice from, the doctor. A lack of interest and of a sense of responsibility emanating from any one of these three points of view will be an effective barrier to improvement. Positive interest and enthusiasm from all three, on the other hand, will surely raise the standard of industrial health wherever it is applied.

A positive willingness on the part of management to employ a plant doctor must extend beyond the traditional readiness to consult the doctor after something has happened, which is mere medical care. Unless those concerned can look farther

ahead and establish standards of prevention and health, they are going to let many things reach the stage of requiring medical care that might well have been stopped in advance. Management should anticipate such things by analyzing its own risks, by utilizing engineering and medical knowledge to eliminate them or to place safeguards about them and by adopting a first-aid policy suitable to the needs of its particular plant. No first-aid policy is adequate if it has not had, in advance, complete medical approval. Management should expect to secure this and to pay for it, and the doctor should expect to provide it and to be paid for it.

A positive willingness on the part of the doctor to be called for purposes of inspection and observation of the conditions under which future patients may be injured, poisoned or exposed is most necessary. Too often — and especially now when all are overworked — the doctor does not believe that he needs to interest himself or to share in the development of such plant policies. He has many other responsibilities, and he naturally allows himself to be distracted by what, at any given moment, most urgently calls for his attention, but the standards of industrial health in the plant that employs him will never be high until he interests himself and assumes his share of the responsibility for the prevention of industrial disease.

The third type of unwillingness, that of the first-aid or nursing personnel to accept supervision of all their activities, is encountered only under special circumstances. Nurses are trained to work under medical supervision at all times, and first-aiders can be made to follow orders readily if the doctor insists on it. In some cases he has to insist on it, for the overconfident type of personality frequently and naturally establishes itself in first-aid positions, and may seek to exploit itself on that basis. It is, however, difficult to understand how any first-aid-er can overstep his assigned duties if he follows written standing orders from the doctor. On the other hand, when the doctor's interest is not sufficiently forceful, there may develop circumstances under which it may be legitimately charged that someone is practicing medicine without a license.

Chapter 149 of the General Laws of the Commonwealth of Massachusetts (Ter. Ed.), Section 141, states:

Every person operating a factory, shop or mechanical establishment where machinery is used for any manufacturing or other purpose except for elevators, or for heating or hoisting apparatus, shall keep and maintain, free of expense to the employees, such medical or surgical chest, or both, as shall be required by the department, containing plasters, bandages, absorbent cotton, gauze, and all other necessary medicines, instruments and appliances for the treatment of persons injured or taken ill upon the premises. Every person carrying on a mercantile establishment where twenty or more women or children are employed, shall in the manner aforesaid provide such medical and surgical chest as the department may require.

Under the provisions of this chapter the Department of Labor and Industries requires that a specific list of articles be kept and maintained in a clean and dustproof receptacle. Concerning the use of any of these articles the department provides the simple admonition, "WASH HANDS BEFORE USING." Surely the doctor can improve not only on this standing order but on the inventory of the first-aid kit required by the Department of Labor and Industries.⁴

Standing orders for nurses in industry have been endorsed by the Council on Industrial Health of the American Medical Association,⁵ and at least one insurance company has compiled standing orders for industrial first-aiders.⁶ The committee expresses its approval of such contacts between the practicing doctor and the industrial nurses and first-aiders. The nature and extent of the contact cannot be sharply delineated, for even in one industry, plants vary, managements vary, nurses vary, first-aiders vary and, above all, doctors vary in their concepts of what medical supervision is to consist. The written standing order, however, constitutes an authoritative level at which responsibility may rest. Although standing orders can often be only a general statement of principles, they are always subject to amendment, modification or alteration by the doctor in charge, and may conveniently provide him with an instrument wherewith he can assert his authority in an impersonal way.

The purpose of this statement is to indicate that progress in industrial health may be expected in the small plants of

Massachusetts by co-operative efforts on the part of managers, doctors, nurses and first-aiders. The absence of such co-operative effort, on the other hand, will effectually block any substantial improvement of the working conditions and environments. This statement is submitted for publication in the *Journal* in the hope that doctors who read it may better visualize their personal opportunities and responsibility in raising the standards of industrial health in the small plants of the Commonwealth.

DEATHS

BENNETT — William H. Bennett, M.D., of Norwell, died March 5. He was in his seventy-seventh year.

Dr. Bennett received his degree from Baltimore University School of Medicine in 1892. He was a fellow of the American Medical Association. He retired from active practice in 1938.

His widow, a daughter and a granddaughter survive.

KELLEY — Harry N. Kelley, M.D., of Worcester, died February 20. He was in his forty-sixth year.

Dr. Kelley received his degree from Harvard Medical School in 1925. He was on the staff at St. Vincent Hospital. He was a fellow of the American Medical Association.

His widow, a son, a daughter, a brother and two sisters survive.

SANDERSON — Robert Sanderson, M.D., formerly of Dedham, died February 21 in Arlington, Virginia. He was in his forty-second year.

Dr. Sanderson received his degree from Harvard Medical School in 1932. At the time of his death, he was a lieutenant in the medical corps and was stationed at the Navy Department in Washington. He was a fellow of the American Medical Association.

His widow and four children survive.

CORRESPONDENCE

URGENT NEED FOR NAVAL MEDICAL OFFICERS

To the Editor: Because of the constantly increasing demand for naval medical officers, this office has been conducting a minute review of its files in the hope that physicians previously rejected might now be found eligible for a commission. It is therefore evident that for the first time a real opportunity exists for physicians who have been previously disqualified by either the Army or Navy. This action has been precipitated by a communication from Washington in which it was stated that the Bureau wished to review the applications of all doctors wherever there was a possible chance of acceptance. This review includes a large group of rejections based not only on questions of weight, height, color vision, and dental defects, but also such hitherto nonwaivable conditions as history of healed asymptomatic peptic ulcer, sacroiliac strain, history of asthma and several others. Although waivers will not be promised in such cases, the Bureau definitely wishes to scrutinize each individual case. It is the intention of this office to forward such requests to Washington for reconsideration accompanied by x-ray reports, laboratory data and any other pertinent information which will help to paint an accurate picture of the individual's current condition.

In addition, graduates of unapproved medical schools are encouraged to apply. While the professional examination is still a prerequisite, waivers for nonincapacitating physical defects may be granted to this group as well.

For men who have been declared *essential* by Procurement and Assignment, all we can say is that if a man *really wants to join the Navy*, he may appeal his classification with the assurance that his chances of being reclassified are, in most cases, excellent.

Contrary to public opinion, success in the field does not reduce the need for medical officers. Medical responsibilities mount in direct proportion to the number of victories in the field. The need is not an imaginary one — it rests on a definite factual basis.

This office is in possession of some interesting material that includes the most frequently asked questions regarding doctors and explains the various types of duties to which medical officers are assigned. Interested physicians may obtain copies on request.

DEPRIVATION OF LICENSES

To the Editor: At a meeting of the Board of Registration in Medicine held February 21, the Board voted to revoke the license of Dr. Nathan Gaber, 129 Mt. Vernon Street, Boston, to practice medicine because of gross misconduct in the practice of his profession as shown by collusion.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

To the Editor: At a meeting of the Board of Registration in Medicine held March 16, after a re-hearing of the case of Dr. George J. Orlansky, now a captain in the Medical Corps of the Army and formerly of 1234 Blue Hill Avenue, Dorchester, the Board voted to revoke his license to practice medicine in this Commonwealth for not less than three years because of gross misconduct in the practice of his profession as shown by collusion.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

NOTICES

HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the amphitheater of the Peter Bent Brigham Hospital on Tuesday, April 17, at 8:15 p.m. Brigadier Hugh Cairns, Nuffield Professor of Surgery, Oxford University, will speak on the subject "The Use of Penicillin in the Treatment of Pneumococcus Meningitis."

GREATER BOSTON MEDICAL SOCIETY

The next meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital, Boston, on Wednesday, April 18, at 8:15 p.m. Dr. Fuller Albright will speak on the subject "Osteomalacia." Discussion by Drs. Joseph Aub, Siegfried G. Thannhauser and Sidney Farber will follow.

SOUTH END MEDICAL CLUB

A regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, April 17, at twelve noon. Dr. William T. Salter, professor of pharmacology, Yale University School of Medicine, will speak on the topic "The Measurement and Adjustment of Endocrine Function."

Physicians are cordially invited to attend.

TRENCH FOOT AND IMMERSION FOOT*

CAPTAIN JAMES C. WHITE (MC), U.S.N.R., AND CAPTAIN WILLIAM B. SCOVILLE, M.C., A.U.S.

FROSTBITE and kindred injuries to the feet from cold have been recorded as a source of casualties in military campaigns since the epic retreat of the Greeks under Xenophon across the snow-covered mountains of Armenia. Cold does not necessarily produce a single type of injury, as many have supposed, but may result in several distinct syndromes, which become of particular importance in time of war, when clothing, food, heat and shelter are likely to be inadequate and great numbers of indoor dwellers are exposed to the rigors of outdoor life. These clinical and pathologic changes have been summarized by Greene,¹ who has had an unusual opportunity to study them. Wet cold is far more difficult to deal with than are severer degrees of dry frost, as was found by Larrey² in the retreat of the Napoleonic armies from Moscow and by the medical officers on duty with the American troops who landed on Attu.

The two conditions to be considered herein, trench foot and its seagoing counterpart, immersion foot, are both caused by prolonged exposure of the dependent lower extremities to cold and moisture. The knowledge of trench foot as it is occurring during the present war is based largely on information acquired from Army surgeons who have taken care of many of the Aleutian casualties, in particular from Colonel R. H. Patterson and Major F. M. Anderson, of the Letterman General Hospital, and from Captain A. Lesser, with whom one of us (W.B.S.) was formerly associated at the McCaw General Hospital. Recently Captain M. H. Harris and Major G. L. Maltby,³ of Ashford General Hospital, have presented a series of 130 cases resulting from the Italian campaign. These officers have been kind enough to contribute valuable criticism and advice, as well as to permit us to use much of their data for the compiling of this report. Since the writing of this article the War Department⁴ has issued a comprehensive digest on trench foot.

Our information on immersion foot has been acquired largely through personal experience with

survivors of torpedoed vessels who have been exposed to cold water during a prolonged period adrift in the North Atlantic.⁵ The opportunity to examine a large number of these men was obtained through the kindness of Surgeon Commander D. R. Webster, Surgeon Lieutenant F. M. Woolhouse and Surgeon Lieutenant J. L. Johnston, of the Royal Canadian Navy. Others have been examined at the Columbia-Presbyterian Medical Center in New York through the courtesy of Dr. David C. Bull and at the Massachusetts General Hospital, in addition to those cared for at the United States Naval Hospital in Chelsea.

PATHOLOGIC PHYSIOLOGY

In a crowded lifeboat or Carley raft the survivors are forced to sit with their wet feet dependent and immobile. This alone is sufficient to produce edema, and if starvation is an added factor, so that the plasma proteins are reduced, the edema becomes pronounced even in the absence of cold. No lifeboat or raft is dry, and boots are not issued that will keep the feet both dry and warm. Occasionally when a man has been forced to kneel for prolonged periods on the floorboards of a wet boat or to sit on the bottom of a rubber raft, the same condition has involved the knees or the buttocks.

In the landings in the Aleutians men were forced to take cover in foxholes in a semisitting position for periods ranging from three to fourteen days, in melting snow by day and in light frosts at night. During this period they had little to eat, were thoroughly chilled and had no opportunity to change their footgear. No leather boots can keep out the wet under these conditions, and even rubber ones become moist on the inside from perspiration. Under these circumstances all the factors that damage the tissues in a crowded lifeboat in the North Atlantic are present ashore—exposure of the legs to cold just above freezing, wetness, dependency and immobility, and general chilling of the body.

Immersion foot and trench foot differ from frostbite simply because the tissues are not actually

*This article has been released for publication by the Division of Publications, Bureau of Medicine and Surgery, United States Navy. The opinions and views set forth are those of the writers, and are not to be construed as reflecting the policies of the Navy Department. Presented at the annual meeting of the New England Surgical Society, Boston, September 20, 1944.

frozen. Ice crystals do not form in living tissue above the freezing point of sea water or of mud and thawing snow, but at temperatures from this point to above 50°F. the feet gradually become chilled,

crowded lifeboat do not have the opportunity to walk and thus to traumatize their anesthetic feet. When this occurs, infection is likely to follow and to end in moist gangrene. After the recent campaign in the Aleutians, 6 cases of a total of 231 treated by Patterson and Anderson⁹ required amputation of one or both feet, and 18 other patients lost the greater part of one or more toes. At the McCaw General Hospital, 21 of 35 severe cases from Attu required late plastic amputation revisions of toes or distal portions of the feet by Captain Lesser.

After exposure at sea, infection and gangrene are fortunately less frequent than is the case on land. In approximately 100 cases that we have seen, only 1 man lost his leg, — after exposure for a prolonged period adrift in bitter cold off the northern tip of Norway in January, — and 2 others suffered the loss of one or more toes. After comparing our observations of trench foot with those of immersion foot,

FIGURE 1. A Case of Immersion Foot.

These photographs were taken of a patient of Surgeon Commander Webster, R C N.M.C., on the twelfth day after rescue. The man had been in a lifeboat without shoes for four days in the North Atlantic in March. The temperature of the sea water was recorded at 34°F, and his feet had been wet most of the time. The petechial hemorrhages and subcutaneous swelling are well shown. Blisters were present, but shrank following cooling to 70°F. with ice bags. There was threatened gangrene of the third and fifth toes on the left and the second, third, and fifth toes on the right, which eventually necessitated local amputation of several after infection, which entered through areas of epidermophytosis.

numb and swollen (Lewis⁶). Lesions resembling trench foot have been reproduced in rabbits by shaving the legs and keeping the animals standing for a number of days in a refrigerated chamber on wet mud at a few degrees above freezing (Smith, Ritchie and Dawson⁷). Tissue changes similar to those seen in immersion foot have recently been produced experimentally by Blackwood and Russell⁸ in the tails of rats by keeping the floors of the cages wet with sea water at 40°F. for periods of two to four days. In sailors adrift at sea these changes may begin in the course of a few hours, but in the trenches, where the feet get wet and chilled more slowly, an exposure of several days is necessary. The condition at sea differs from that seen in troops campaigning in slush and cold mud simply because men in a

FIGURE 2. A Severe Case of Trench Foot from Attu

In this case, amputation of both feet was eventually necessary because of the depth of tissue necrosis and because gas bacilli were found on smear and culture. (Reproduced by courtesy of Col R H Patterson and Maj F M Anderson, M C, A U S, Letterman General Hospital)

it is our impression that the former causes more extensive and severe damage to the tissues than does the latter.

When first seen after exposure, either ashore or afloat, the feet are cadaveric in color, swollen and

blistered (Fig. 1). Massive gangrene from the ankle down may appear imminent (Fig. 2), but in the absence of infection and with proper treatment the capacity for recovery is amazing. It takes place in two stages, an early hyperemic stage and a later period of fibrosis. If the exposure has been severe and prolonged, pain may be severe in both and may cause prolonged incapacity.

The hyperemic phase develops as soon as the legs become warm and circulation recovers. This vasodilator response is a sterile inflammatory reaction

blistering, as well as the late fibrosis (Drinker and Field¹¹). The combination of heat, which raises the metabolic demands of the cells for oxygen, and of an inadequate superficial circulation results in cutaneous anoxia and burning pain as soon as the nerves recover (White⁸). Recovery of sensation takes place rapidly over the proximal parts of the feet, but in the severer cases the toes may remain anesthetic for weeks.

In the course of one to four weeks the hyperemia subsides and the circulation returns to normal.

Moderate hyperemia and anesthesia, without much cutaneous injury, 2 weeks after rescue.

Appearance of feet: Redness of skin and petechial hemorrhages.

Redness most striking in dependency. Very slight residual swelling. Superficial loss of epithelium on soles.

Arteries: All pulsations strong.

Veins: Very prominent.

Sweating: Began slightly over skin of proximal feet at 13 days.

Neuritis: +++, beginning to subside.

Sensation

Touch, vibration, and detection of figures present except in toes.

Two-point discrimination slightly reduced over dorsum of feet, absent in toes.

FIGURE 3. Sensory Changes and Surface Temperatures in a Case of Immersion Foot.

caused by the absorption of damaged tissue. There are bounding pulsations in the deep vessels, and heat, radiating to the surface, makes the skin fever-hot (Fig. 3). In addition, the circulation of the superficial tissues, which have been more thoroughly penetrated by the cold, may be profoundly impaired. Evidences of this are the petechial hemorrhages caused by ruptured capillaries and the thrombosis of the subcutaneous blood vessels (described by Patterson¹⁰). Capillary permeability is greatly increased, resulting in the extravasation of protein-rich fluid that cannot be removed by the injured lymphatics. This accounts for the gross edema and

The blebs absorb and the skin peels off with a certain amount of scarring. The patients with milder cases are then fit to return to duty, but in those with severer damage the skin is atrophic (Fig. 4), movement of the toes is limited (Fig. 5), and walking is made difficult by pain. No satisfactory explanation for the rigid, weak feet and pain on walking had been given until the past winter. Dr. Shields Warren and one of us (J.C.W.)¹² examined a series of biopsies of skin and superficial muscle from the feet of 6 men who were still incapacitated several months after their exposure. These biopsies showed atrophy and thinning of the epidermis, with intense fibrosis and

deposition of collagen around the nerve endings and subcutaneous blood vessels (Fig. 6). The muscles were also infiltrated and their fibrils separated by

that, in addition to the widespread fibrosis, other contributory factors in this prolonged period of disability are the weakness and deformities of the feet secondary to their long-continued immobilization and the hyperesthesia that frequently ac-

a network of scar tissue (Fig. 7). The extent of this reaction depends on the initial exudation of fibrin and tissue anoxia. It is the logical explanation for the late pain, rigidity and weakness of the feet, a condition that tends to improve spontaneously in six to eight months, the time at which collagen ceases to contract. In some of the worst cases of immersion foot on record, however, pain has remained troublesome for over two years (Ungley¹³).

FIGURE 5. *A Late Case of Immersion Foot*

companies the return of sensation after nerve injury in any part of the body.

A final point to remember in the pathogenesis of these swollen, painful feet after prolonged periods

FIGURE 6. *Photomicrograph of a Section of the Extensor Brevis Digitorum Muscle. Note the perineural fibrous tissue and the edema of the nerves (x 220; Masson trichrome stain). (Reprinted from White and Warren¹² by permission of the publisher.)*

After seven months even the patients with mild cases of trench foot from Attu were for the most part still unable to march on account of hypersensitive feet. Patterson and Anderson⁹ have suggested

of cold and wet is the role of malnutrition and avitaminosis. One of us (J.C.W.¹⁴) has seen extreme swelling, numbness and pain develop after two weeks of dehydration and starvation with exposure in the

warm waters of the Gulf Stream. These conditions were caused not by tissue injury from cold but by hypoproteinemia and avitaminosis—particularly through depletion of the vitamin B complex. Similar conditions are even likelier to be found in the starving inhabitants of Europe and Asia.

TREATMENT

When men with chilled, numb, swollen and blistered lower legs are first seen by a medical officer, they must be kept off their feet and the skin protected against rupture of the blebs and the formation of pressure sores in the weight-bearing areas of anesthetic skin. Once streptococcal infection has begun, moist gangrene and loss of the leg are

directing a blast of air from an electric fan or blower over them. The feet should never be rubbed or the blistered areas painted with a strong disinfectant. Like a second-degree burn, these areas should be handled with aseptic precautions, including masking of the dresser's nose and mouth, sulfonamide therapy and a "booster dose" of tetanus toxoid. Elevating and cooling the legs helps to drain the edema fluid and causes the blisters to shrink. During the period of sterile inflammation the hyperemia of the deeper tissues, which are always less damaged by cold than is the skin, causes the surface temperature to rise to above 90°F. Unless this excessive heat is reduced, cyanosis increases, blisters swell, and pain becomes acute. The explanation of this is that

FIGURE 7. Photomicrograph of a Section of the Extensor Brevis Digitorum Muscle. Note the fibrous tissue about nerves and between the muscle bundles ($\times 35$; phosphotungstic acid-hematoxylin stain). (Reprinted from White and Warren¹² by permission of the publisher.)

likely to follow. First aid should therefore be begun by having the patients carried to the sick bay or hospital near the front lines and kept in bed.

Entirely different forms of treatment are required for the general effects of cold and the local damage from exposure. The body should be warmed externally by covering with blankets and hot-water bottles, and internally by drinking hot soup, coffee or tea. The patients should be given nutritious, easily digested food with a high protein-vitamin content as soon as it can be tolerated. In the sickest survivors, vitality may have been so reduced by cold and starvation that emergency treatment for shock is needed. Transfusion of plasma then plays a double role by restoring depleted fluid volume and combating hypoproteinemia.

It is vitally important to keep the injured feet of the chilled patient cool while the body is warmed. This is best accomplished by exposing the legs below the knees to a cool room temperature and

warming increases the metabolic demand for oxygen on the part of the cutaneous cells to a greater extent than can be met by the impaired supply of blood through the injured subcutaneous vessels. Anoxia therefore ensues, with throbbing pain, increased extravasation of fluid and necrosis of the skin.

After arrival in a naval or Army base hospital the same local treatment should be continued for a week or more, until the hyperemia due to absorption of damaged tissue has subsided and circulation through the thrombosed subcutaneous vascular bed has recovered. The greatest advance in the treatment of the acute hyperemic stage has been the application of continuous cooling by Webster, Woolhouse and Johnston.¹⁵ In general, local cooling should be pushed to the point where pain is relieved. The ideal cutaneous temperature level is between 75 and 70°F. This has been established by Safford and Nathanson¹⁶ both by clinical observation and on theoretical grounds. Cooling lowers the metabolic

need for oxygen to a point at which sufficient quantities can be supplied through the injured capillary bed. When the feet are cooled the appearance of the skin improves, blisters shrink, and pain is relieved. In the severest cases cooling with room air is insufficient and treatment with ice bags may be necessary. When the latter are used, sterile pledgets of cotton are placed between the toes and the whole foot is covered with a sterile towel. Thoroughly dried ice bags are then placed around each foot over the towel, and the whole is encased in an oiled-silk bag, around which in turn are wrapped thick layers of cotton waste or other insulating material. A rubber pillowcase, loosely tied below the knee, forms a satisfactory outer covering. At first, two to four ice bags are necessary to cool the foot to the optimum temperature of 75 to 70°F. Ordinarily it is sufficient to change them every four hours, and at these times the toes should be palpated to make sure that they are not too severely chilled. It may be necessary to carry out this treatment for periods ranging from several days to two weeks, but as hyperemia subsides less ice is required, and finally exposure to cool air alone suffices.

In the rare cases in which edema and blistering are pronounced but pain is so slight that cooling of the skin is not vital, compressive dressings, which are so effective in second-degree burns, deserve a trial. This has been suggested to us by Dr. Sumner L. Koch,¹⁷ but to date no suitable case has been found for trial.

When gangrene has already developed before the patient enters the hospital, periodic débridement and painstaking care of the feet are necessary. In most cases the extremities can be saved, at least in part, by conservative amputation of toes and the distal portions of the feet (Fig. 8). Early amputation of a leg is excusable only in fulminating lymphangitis, threatened septicemia or gas gangrene.

When the products of tissue damage have been absorbed, circulation returns to normal, blebs absorb, and the skin desquamates. In the mildest cases the patients may be fit to return to duty within two weeks, but severe disability may last for months. All severe cases of trench and immersion foot run a prolonged convalescence of six or more months because of interstitial scarring and pain. The scarring results in rigidity and contractures of the toes, as well as atrophy and weakness of the ligaments and intrinsic muscles of the feet. The pain is of two varieties — a burning, hyperesthetic type, probably due to irritation of nerve endings by scar tissue, and a dull ache in the arches and ankle joints, probably due to a combination of muscle weakness, disuse, rigidity and fallen arches. Physiotherapy and orthopedic exercises are helpful in restoring power to the intrinsic muscles and weakened arches, but often fail to give sufficient relief.

A vast saving in man power for the Army, Navy and Merchant Marine can be achieved if a method

is found to shorten this period of pain and rigidity. Although sympathectomy is quite illogical in the early hyperemic stage, it is possible that release of vasoconstrictor tone will reduce these late disabling

FIGURE 8. *The Results of Conservative Treatment of Gangrene in a Case of Trench Foot (Reproduced by courtesy of Col. R. H. Patterson and Maj. F. M. Anderson, M C, A U.S., Letterman General Hospital)*

symptoms by hastening the absorption of collagen and fibrous tissue and by increasing the superficial and collateral circulation through the injured extremities. This operation should therefore be seriously considered in selected cases and warrants extensive trial and critical observation. Although Harris and Maltby³ have been impressed by the frequent association with vasospasm, this has in our experience been the exception rather than the rule. Only 3 of 36 soldiers with severe trench foot from Attu and 2 sailors had this complication to a well-marked extent. All were dramatically improved by sympathectomy (Fig. 9). In addition, a limited number of cases with atrophic, rigid feet, as well as certain cases of delayed wound healing

DISCUSSION

DR. EUGENE E. O'NEIL, Boston: These cases of trench foot and immersion foot, I dare say are not very much unlike those of trench foot that occurred in the last war, several of which I saw. I have seen a few of the present cases at the United States Marine Hospital, and all of them appeared to have taken on the rather late phase that Dr. White has emphasized; that is, they showed marked vasomotor disturbances—so marked, as a matter of fact, that they had all the earmarks of well-advanced Buerger's disease. When subjected to lumbar sympathectomy, as was done if the operation was indicated and if their collateral potential appeared sufficient to be developed in this manner, these patients improved almost without exception.

It occurred to me that, in view of what Dr. White has said about the hyperemic stage of immersion foot, it might be well to inquire from some of these sympathectomized patients what had happened shortly after the trench foot developed. Two of them stated that for two or three weeks following the onset they went through what was apparently a hyperemic stage. The feet were swollen and blistered and were extremely hot. Seeing these cases in the acute stage, one would think that they had been sympathectomized, but as time went on they have taken on the peculiar picture of progressive vasomotor disturbance and have been improved by sympathectomy.

CAPTAIN WILLIAM B. SCOVILLE: Within the Army, trench foot constitutes a most serious disability, far more serious than it is in civilian life. Rarely do any but the mildest cases return to combat duty, and hospitalization generally exceeds six months. This is because the disability prevents marching and standing, especially in inclement weather. I am told that the Russians consider these casualties of so serious a nature that they have gone to extraordinary and unique prophylactic lengths to prevent their recurrence. In their usual definitive fashion, they assign each soldier going to a cold climate to a companion, each man acting as the guardian of the other's feet. If one soldier gets a blister or frostbite, both soldiers are held responsible and both are liable to be shot—so the story goes. By this method, solicitude over one another's feet was simply intense.

In the northwest United States I saw severe cases of trench foot resulting from the Attu campaign. Thirty-five cases were followed by Captain Albert Lesser. All were gangrenous or near gangrenous, and 60 per cent required late conservative amputations of toes or portions of the feet. Even in such severe cases, only 3 showed evidence of vasospasm. From this small series, I concluded that constitutional autonomic instability with vasospasm is not a predisposing cause of trench-foot. This has been borne out by Captain White's studies. On the other hand, I was impressed by the extreme prevalence of vasospastic disease in soldiers stationed in the

cold climates of the Alaskan and Northwest theaters. A great number of these cases occurred in soldiers who had spent their entire life in warm climates. Although vasospasm is rare in trench and immersion foot, sympathectomy may have some place in hastening the reabsorption of scar tissue and collagen—common sequelae in trench foot, as shown by Captain White and Dr. Warren. Only further research can settle this point. Small subcutaneous biopsies taken from both feet before and after a unilateral sympathectomy should give the clue.

My studies on sympathectomized cases of trench foot first whetted my interest in the effects of sympathectomy on the treatment of chronic indolent wounds and infections of the feet. The results of such a procedure in these cases have been most gratifying, so much so that we now recommend it in the majority of cases that have failed to heal within six months' time regardless of the presence of vasospasm. I have in mind several such cases, and mention a case of osteomyelitis of the great toe following a gunshot wound that had drained continuously for eight months, with removal of sequestrum two months previously. Pain and drainage had continued. Nine days after sympathectomy drainage stopped and the pain was immediately and progressively ameliorated. In another case, an indolent low-grade infection in the nail beds of both great toes followed recurrent attempts at removal of the matrix of ingrowing toenails by an overzealous young medical officer who had used every known method to kill the matrix of the nail, including scalding the nail bed with hot fluids. When seen by us, this patient had not put either foot to the ground for over a year because of pain and still had unhealed granulations in the nail beds. Unilateral sympathectomy with the other foot used as a control gave most gratifying results in healing and epithelialization, as well as in subsidence of the pain.

I offer two final words of caution concerning the therapy of trench foot. The first is a plea for extreme conservatism in amputation. In Lesser's series of severe cases, the majority of surgeons who saw such cases on their admission to Army hospitals cheerily advised, "You may as well amputate now as later," but after four to six weeks of conservative and meticulous care the healing of apparently hopelessly ulcerated toes and feet was startling. The second word of caution lies in the psychiatric field. Trench foot is closely akin to low-back pain in its predisposition toward neurosis. The drama of onset, the vagueness of the pain and the absence of objective disease in the mild cases all make it easy for these patients to capitalize on their disability. When patients continue to complain of pain for periods of longer than six months without objective evidence of peripheral vascular disease or tissue damage, a neurosis should be suspected.

DR. JAMES C. WHITE, Boston: The term "Raynaud's disease" has been loosely used here. It should be qualified so as to indicate cold, clammy, cyanotic feet that show a dramatic improvement in circulation following procaine block or lumbar sympathetic ganglionectomy. I do not believe that these men who have been exposed to cold and moisture have actual blanching of the toes, as I have not yet seen one with this condition. They do have continuous excessive vasoconstriction, with a tendency to excessive perspiration in the extremities.

Another question of interest is why this phenomenon is so frequent. Many people have a tendency to cold, moist hands and feet, and this is often greatly increased after emotional stress. Dr. Frank Fremont-Smith and Dr. Stanley Cobb discovered a few cases of typical Raynaud's disease in which the first bouts of phasic asphyxia developed on the breaking off of an engagement, the death of a husband, financial failure or some other cause of severe emotional disturbance. These men whom we have been discussing have, of course, been through an extremely severe emotional disturbance. If they go on having incapacitating pain and are banded about in service hospitals and their compensation is not adjusted, they have every reason to develop chronic vasospasm in their feet.

MEDICAL PROGRESS

THE TREATMENT OF INFECTIONS WITH PENICILLIN (Concluded)*

DONALD G. ANDERSON, M.D.†

BOSTON

Staphylococcal Infections

Penicillin has proved to be the most effective chemotherapeutic agent yet discovered for the treatment of staphylococcal infections.^{65, 66, 62} The usual mortality rate of 80 per cent in untreated cases of staphylococcal bacteremia⁶³ has been reduced with penicillin treatment to 20 per cent or even less. Doses between 150,000 and 300,000 units a day are usually desirable until the infection has been controlled. The daily dosage may then be reduced to 120,000 units. It has been widely recognized that in severe staphylococcal infections striking improvement may not be observed for several days after the beginning of treatment. It is not unusual, however, for the patient to begin to look and feel better several days before the temperature returns to normal. Not infrequently the blood culture may still be positive when the first signs of improvement are noticed. The rapidity of the response to treatment, as well as the end results, are influenced by several factors, including the severity of the primary lesion, the number of metastatic lesions, the accessibility of both primary and secondary foci to surgical drainage and the general condition of the patient. The poorest results are obtained when the infection localizes on the endocardium, giving rise to a bacterial endocarditis. Even this complication, however, occasionally responds to treatment with penicillin.

Although surgical drainage is frequently an important adjunct to penicillin in the treatment of staphylococcal bacteremia, there are certain infections in which, not infrequently, the withholding of operative measures may shorten the recovery period and result in less permanent dysfunction or disfigurement. Since carbuncles, for example, respond very well to penicillin treatment, surgical intervention, except for the evacuation of obvious collections of undrained pus, no longer seems to be necessary. Treatment for ten to fourteen days has usually effected complete resolution of the infection, although the separation of slough and the epithelialization of denuded areas often has not been complete for another one to three weeks.

Acute hematogenous osteomyelitis appears to be best treated without surgical drainage, except in the presence of a large soft-tissue abscess. Under penicillin treatment alone the rapidity of clinical recovery and the extent of healing and repair of the bone appear to surpass that of cases treated with surgical drainage.⁶⁴ An exception to this statement must be made for those cases in which a suppurative arthritis is also present. In such patients there is a great possibility that the joint will be destroyed unless penicillin can be introduced directly into the joint space. When a suppurative arthritis is present, it seems advisable to perform early whatever surgery is necessary to facilitate the local instillation of penicillin into the involved joint once or twice a day. It has been desirable in acute osteomyelitis to continue treatment for at least two or three weeks, and in severe cases with multiple lesions longer treatment has been necessary. Since the roentgenographic changes in the bone do not keep pace with the clinical progress in this disease,^{14, 64} reliance has had to be placed on the clinical signs of recovery in determining when to stop treatment. Not infrequently the destruction of bone has been most extensive at a time when it was obvious clinically that the patient had recovered. Even though treatment was stopped at this point, rapid repair of bone with a striking return toward a normal bone architecture usually took place in the next few weeks or months. In occasional cases that were treated extremely early, no signs of bone destruction developed in the roentgenograms.

Kirby and Hepp⁶⁵ have reported excellent results with penicillin therapy in the treatment of osteomyelitis of the facial bones. When sequestrums were present, surgical treatment in addition to the use of penicillin was necessary to effect complete recovery.

Anderson, Howard and Rammelkamp,⁴³ in a study of the management of chronic hematogenous and traumatic osteomyelitis, found that when sequestrums were present it was necessary to remove them surgically to obtain satisfactory healing. These authors were able to secure an arrest of the disease with the disappearance of all local and constitutional signs of active infection in 70 per cent of their patients with chronic osteomyelitis. Prolonged therapy varying from two to six weeks was found to be necessary to achieve the best results. Occasionally the therapy had to be repeated when relapses occurred. The primary closure of wounds

The work in preparing this review was made possible under the terms of Contract OEMcmr-275 between the Massachusetts Memorial Hospitals, Robert Dawson Evans Memorial, Department of Clinical Research and Preventive Medicine and the Office of Scientific Research and Development.

†Instructor in medicine, Boston University School of Medicine, and research fellow in medicine, Evans Memorial, Massachusetts Memorial Hospitals

after sequestrectomy, together with the local administration of penicillin postoperatively, greatly shortened the recovery period.

Staphylococcal pneumonia has responded well to penicillin. In the absence of secondary foci recovery is usually complete in one to two weeks. The treatment of staphylococcal empyema with penicillin introduced into the empyema cavity has usually resulted in a decrease or disappearance of fever and a marked lessening of toxicity. In most cases, however, the exudate has not become sterile and thoracotomy has been necessary to effect full recovery.

Streptococcal Infections

Hemolytic streptococcus infections are even more susceptible to the action of penicillin than are staphylococcal infections. In general the response has been similar to that seen with the sulfonamides, although in some cases the therapeutic effect has been even more rapid. Doses of 100,000 to 150,000 units a day are usually effective. Depending on the severity of the infection, treatment is continued until the temperature has been normal for two to five days.

Anaerobic streptococcus infections have been irregular in their response to penicillin since there is considerable variation in strain sensitivity to the drug. The sulfonamides are never effective in such infections, and a trial course of therapy with penicillin is indicated when such infections arise. Prolonged treatment may be necessary, particularly if there is an intravascular focus of infection, such as a thrombophlebitis.

Infections due to nonhemolytic streptococci that have been treated with penicillin have consisted almost wholly of cases of subacute bacterial endocarditis. Early attempts to treat this disease with penicillin were unsatisfactory because only small and inadequate doses could be given.⁶⁵ More recent experience, involving the use of doses of 200,000 to 300,000 units a day for periods of two or three weeks, has produced at least temporary arrest of the infection in more than 50 per cent of the cases.⁶⁶⁻⁶⁸ From the evidence now available an initial course of treatment of 200,000 to 300,000 units a day for three weeks should be satisfactory in most cases. If by the end of a week the blood culture has not become negative, the dose should be increased. Patients who have relapsed after two or three weeks of therapy have been treated with more prolonged courses of treatment, with apparently successful results in a few cases. Cases have been encountered, however, in which it has been impossible to control the infection even when treatment has been continued for two or more months. The available evidence indicates that penicillin is just as effective in this disease when given by intermittent intramuscular injection as it is when given by continuous intravenous infusion. The use of heparin in con-

junction with penicillin has been recommended,⁶⁶ but this does not seem to be necessary and may constitute an added hazard to the patient.⁶⁹

Strains of nonhemolytic streptococci vary in their sensitivity to penicillin, although the great majority are sensitive to the drug.³⁵ Enterococci, which cause about 10 per cent of cases of subacute bacterial endocarditis, are relatively insensitive to penicillin, and cases of endocarditis caused by these organisms have not responded to treatment. In view of the large amount of penicillin that must be given in bacterial endocarditis, it is advisable to investigate the sensitivity of the organism in each case before or at the beginning of treatment. In patients who relapse, the infecting organism usually has not shown a significant decrease in its sensitivity to penicillin.

It is of considerable interest that, for several weeks after the completion of treatment, patients whose blood cultures remain negative and who otherwise appear to be free of active disease have often exhibited petechiae and other embolic phenomena. In many of these patients the embolic phenomena have ceased after a short time and the patients have continued to remain well without further treatment. For this reason, it has been assumed that these episodes were caused by bland or sterile emboli. Occasionally embolism of a cerebral vessel has caused death. A few patients after recovering from the infection develop cardiac failure, which may progress and end fatally within a few months after treatment.

Gonococcal Infections

The original observation by Mahoney et al.⁷⁰ that penicillin produces rapid and permanent cures in gonococcal infections has been fully confirmed.⁷¹ About 96 per cent of gonococcal infections that are confined to the lower genital tract in either the male or female are cured by the administration of a total of 100,000 units of penicillin. The remaining 4 per cent usually respond to more intensive or prolonged treatment. No proved cases of penicillin-resistant gonorrhea have yet been encountered. Although varying schedules of administration have been used, the intramuscular injection of 20,000 units every two or three hours for five doses appears to be the most convenient. Such a treatment schedule is readily adaptable to office or outpatient practice. Gonococcal infections complicated by arthritis, prostatitis, salpingitis, epididymitis or endocarditis require more prolonged treatment. Whether penicillin is more effective than the sulfonamides in the treatment of gonococcal arthritis remains somewhat in doubt.

Meningococcal Infections

Experience with the treatment of meningococcal meningitis has varied. Rosenberg and Arling⁷² reported recovery in 65 of 66 patients treated with

penicillin. Their report, however, does not make clear how many of their patients received sulfonamides as well as penicillin. Meads et al.,⁷³ on the other hand, in a more critical study found that neither the bacteriologic nor the clinical signs of improvement were so rapid in patients treated with penicillin as in those treated with sulfonamides. Furthermore, 2 of their 9 patients treated with penicillin eventually required sulfonamide therapy to effect full recovery. At the moment, it appears that the sulfonamides are at least as efficient as penicillin in treating meningococcal meningitis and that they constitute a much more convenient and economical form of therapy. Penicillin may well be found useful in combination with the sulfonamides in the treatment of fulminating cases, and it is certain to have a place in the treatment of patients who do not respond to sulfonamide therapy or in whom sulfonamide treatment is contraindicated.

Pneumococcal Infections

Tillett⁷⁴ has shown that pneumococcal pneumonia and empyema respond readily to penicillin treatment. A dosage of 100,000 units a day for three or four days is adequate in most cases of pneumonia, although occasional patients require more prolonged and intensive treatment. Pneumococcal empyema has been treated successfully by injections of penicillin repeated daily or on alternate days for three to four injections. From the results now available, it seems that a high percentage of cases do not require surgical treatment. A thickened pleura with or without a sterile exudate may persist for several days or even weeks after treatment is completed. Organization of the exudate and permanent collapse of the lung may rarely develop, but the greatly shortened period of illness and disability that results from nonsurgical treatment is a strong endorsement for this form of therapy, provided the physician is alert for the possible appearance of the above-mentioned complications.

Pneumococcal meningitis has been successfully treated with a combination of intrathecal and intramuscular penicillin.⁷⁴ The fatality rate with such treatment in a large unselected series was approximately 55 per cent.⁷⁵ In a smaller group of cases, Waring and Smith⁷⁶ have reported the recovery of 11 of 12 patients following the combined use of penicillin and the sulfonamides. Although even combined therapy has failed in fulminating infections and cases that are treated late,²⁰ the use of both drugs appears to be rational and should give better results than when either drug is used alone. How long to continue therapy in this disease is a difficult question to answer, and undoubtedly the need for therapy varies from patient to patient. In cases that are treated with penicillin alone, it is usually necessary to continue intrathecal and systemic therapy for at least two weeks, but in occasional

cases it is necessary to continue treatment for many more weeks before the infection is eradicated.¹⁸ When patients are receiving both penicillin and a sulfonamide, it has been possible to discontinue penicillin seven to ten days after beginning treatment, but it appears wise to continue the sulfonamide for at least two weeks after apparent recovery. The usual guides by which one measures progress may be lacking. After one or two days of intrathecal penicillin administration, the smears and cultures of the spinal fluid almost invariably fail to demonstrate the presence of organisms. It is known, however, that if treatment is stopped after the first negative bacteriologic reports are received, relapse is likely to occur. In certain patients who recover from the infection, residual damage to the central nervous system of greater or lesser extent has been observed.

Acute pneumococcal endocarditis can be successfully treated with penicillin, but the percentage of recoveries is not so great as in subacute bacterial endocarditis caused by nonhemolytic streptococci.

Clostridial Infections

The in-vitro activity of penicillin against the clostridial group of organisms has been confirmed by clinical studies. Jeffrey and Thomson,⁷⁷ in a study of 33 cases of gas gangrene treated with penicillin, found a mortality rate of 36 per cent. These authors emphasize, as do all other workers who have had experience with the problem, that the adequate surgical removal of all necrotic and devitalized tissue is the most essential therapeutic procedure in the management of gas gangrene. Five of their patients were seen late in the disease when surgery was not possible, and all of them died, despite treatment with penicillin. These authors believe that a dosage of 15,000 units every three hours for three to four days will control the infection in cases in which all the infected tissue can be removed surgically. In cases in which this is not possible, it is desirable to continue treatment for five to ten days. The administration of antitoxin is also of great value. Jeffrey and Thomson believe that with early and adequate surgery, aided by the administration of penicillin and antitoxin, the mortality rate in gas gangrene in battle casualties can be reduced to 20 per cent. Cutler and Sandusky⁷⁸ treated 7 patients with gas gangrene, 6 of whom recovered. It is noteworthy that in 5 of their patients gas gangrene developed while the patients were receiving prophylactic penicillin therapy. Following extirpation of the diseased tissues all these patients recovered.

A few cases of tetanus have been successfully treated with penicillin and antitoxin.⁷⁹ The group is too small to evaluate the role that penicillin played in recovery.

Syphilis

In October, 1943, Mahoney et al.⁸⁰ reported on the favorable action of penicillin in the treatment of early syphilis. Following this report intensive studies of the treatment of early syphilis, neurosyphilis and congenital syphilis have been carried out by a group of co-operating clinics.⁸¹⁻⁸⁴ Final evaluation of their results will not be possible for several years. Preliminary reports indicate that a course of sixty injections of 20,000 units each given intramuscularly at three-hour intervals for seven and a half days probably represents the minimum dosage schedule that is effective in primary and secondary syphilis. It is not unlikely that more prolonged or more intensive treatment will prove to be necessary. Studies on neurosyphilis indicate that even larger doses are needed and that the results are much more irregular than those in early syphilis. Late cutaneous and osseous syphilis apparently respond promptly to penicillin treatment. No work has been reported yet on the action of penicillin in latent syphilis. A few cases of congenital syphilis have been treated in which good results have been obtained. It is agreed by all workers who are investigating the problem that the treatment of syphilis with penicillin is still in the stage of preliminary investigation and that no schedule of treatment can yet be recommended for routine therapy.

In the treatment of syphilis with penicillin, the incidence of Herxheimer reactions has been high. The reactions that have been observed have consisted of fever, malaise, headache, rash and painful swelling of the primary lesion and the regional lymph nodes. These reactions usually occur during the first day of treatment and disappear after twenty-four or forty-eight hours. They are not considered to be an indication for stopping treatment.

Miscellaneous Infections

Most strains of *Actinomyces* are sensitive to penicillin, and a few cases of actinomycosis have been successfully treated.²⁹ Repeated courses are frequently necessary to keep the infection under control.

Anthrax responds well to penicillin, and it seems reasonable to predict that the drug will become the treatment of choice in this disease. Murphy et al.⁸⁵ have reported the successful use of penicillin in 3 cases of uncomplicated cutaneous anthrax. They believe that a dosage of 100,000 units a day for three or four days should be adequate in the average case. At least one patient with bacteremia has been treated, with a prompt and full recovery resulting.

The two causative agents of rat-bite fever, *Spirillum minus* and *Streptobacillus moniliformis*, are both sensitive to penicillin in the laboratory.⁸⁶ Clinical cases caused by the latter organisms have

been reported to respond favorably to treatment with penicillin.⁸⁷

A preliminary report on the successful treatment of yaws with penicillin has recently been published.⁸⁸ One case of Weil's disease has been reported in which penicillin was administered and recovery ensued.⁸⁹ The author admits that the evidence that the drug had an effective therapeutic action in this case is not conclusive.

Penicillin is active in vitro against *Corynebacterium diphtheriae*. A few cases of clinical diphtheria have been treated with a combination of antitoxin and penicillin with results that are difficult to evaluate.⁹⁰ There is no reason to expect that penicillin will supplant antitoxin as the chief therapeutic agent in diphtheria. The supplementing of antitoxin with penicillin in cases of laryngeal diphtheria and diphtheria gravis may, however, prove to be valuable, although the evidence to support this procedure remains to be accumulated. Preliminary efforts to treat diphtheria carriers with penicillin have not met with success.⁹¹

Penicillin is already being adapted to the problems that are peculiar to various medical specialties. Dunnington and Von Sallmann⁹² and Keyes⁹³ have reviewed the use of penicillin in ophthalmology. Infections of the conjunctiva and cornea usually respond well to local treatment when the infecting organism is susceptible to the action of penicillin. The drug may be administered in drops or in an ointment. Infections of the internal structure of the eye are more difficult to treat because of the poor penetration of penicillin. Special methods for administration, such as iontophoresis, the use of a corneal bath and direct injection of the drug into the anterior chamber of the eye, are usually necessary.

Swanson and Baker⁹⁴ have used penicillin in the management of acute otitis media, acute mastoiditis, acute labyrinthitis and chronic otitis media. When the infecting organisms are sensitive to penicillin, excellent results have usually been obtained. In selected cases penicillin therapy alone may be successful; in other cases surgical procedures must also be employed.

Johnson et al.⁹⁵ have shown that the local use of penicillin postoperatively in patients with acute mastoiditis permits the safe primary closure of incisions and greatly shortens the recovery period. Putney⁹⁶ has reviewed the successful use of penicillin in the treatment of some of the more serious complications of infections of the nose and throat. Sale and Diamond⁹⁷ have described the treatment of chronic suppurative maxillary sinusitis by local instillations of penicillin.

In the field of plastic surgery, Hirshfeld et al.⁹⁸ have reported that the systemic administration of penicillin greatly increases the percentage of successful skin grafts applied to infected surfaces.

The use of penicillin in infections of the skin

has been discussed by Roxburgh et al.⁹⁹ and by Taylor and Hughes.¹⁰⁰ Gingivitis and stomatitis caused by the Vincent's organisms have been effectively treated by the use of penicillin pastilles.¹⁰¹

PROPHYLACTIC ADMINISTRATION OF PENICILLIN

The prophylactic use of penicillin is just beginning to be studied. White et al.¹⁰² have shown that penicillin administered intramuscularly for one week preoperatively and for two weeks postoperatively in doses of 150,000 units daily is of great value in preventing postoperative pyogenic infections following lobectomy or pneumonectomy. Their cases included patients on whom operation was performed for bronchiectasis, multiple lung abscesses, tuberculosis and carcinoma. In 21 patients treated prophylactically with penicillin, no cases of empyema developed, whereas in 20 control patients, 12, or 60 per cent, developed pleural suppuration. Cutler et al.,¹⁰³ on the other hand, in a study of the prophylactic use of penicillin in conjunction with early definitive surgery in wounds sustained in aerial warfare did not find that the use of penicillin lowered the incidence of infected wounds.

DISEASES UNINFLUENCED BY PENICILLIN

A review of the present status of penicillin therapy would not be complete unless it included mention of those diseases in which penicillin has not proved to be of therapeutic value. The list of such diseases, as compiled by Keefer,¹⁰⁴ is reproduced, with additions, in Table 3.

Since penicillin has no effect against infections caused by gram-negative bacilli, it is not to be ex-

TABLE 3. *Diseases in Which Penicillin Therapy is Ineffective.*

All gram-negative bacillary infections	Coccidiomycosis
Tuberculosis	Malaria
Toxoplasmosis	Poliomyelitis
Histoplasmosis	Blastomycosis
Acute rheumatic fever	Nonspecific iritis and uveitis
Lupus erythematosus (diffuse)	Moniliasis
Infectious mononucleosis	Virus infections
Pemphigus	Cancer
Hodgkin's disease	Rheumatoid arthritis ¹⁰⁵
Ulcerative colitis	Granuloma inguinale ¹⁰⁶
	Leukemia (acute and chronic)

pected that the drug will prove to be of value in the treatment of peritonitis following a ruptured viscus, except in those cases in which organisms sensitive to penicillin happen to play a significant role. Fauley et al.¹⁰⁷ have reported that penicillin given early will completely control experimental peritonitis in the dog. These workers, however, do not include any bacteriologic findings in their report.

TOXIC REACTIONS

Despite the greatly increased clinical experience with penicillin during the past year, no reports have appeared to cause any revision of the early

opinion regarding the drug's lack of significant toxicity for man. To date no harmful effects on the liver, kidneys or hematopoietic system have been observed following its administration. A few minor untoward reactions have been encountered.

From 2 to 5 per cent of patients treated with penicillin develop urticaria. The urticaria may appear on the first day of treatment, or it may not become apparent until several days after treatment has been completed. It usually develops during the second week of treatment. Occasionally it may be quite severe, but in most cases it is mild and frequently disappears even though treatment is continued. If penicillin is administered at a later date to a patient who developed urticaria with a previous course of treatment, urticaria may or may not reappear. Most workers do not believe that urticaria is a contraindication to the continuation of treatment or to the readministration of the drug at a later date. In the rare case in which urticaria is marked, the patient's severe discomfort may necessitate stopping treatment.

Much more unusual is the appearance of an erythematous vesicular rash.¹⁰⁸ I have seen a patient in whom a very severe rash of this type appeared twenty-four hours after the beginning of treatment in areas where there had been a severe ringworm infection four years previously.

Pain on intramuscular injection is encountered with varying frequency. It has been shown conclusively that impure preparations are the most irritating.¹⁶ There is also no question that the technic of administering the drug has much to do with the amount of discomfort or lack of discomfort that occurs. When a portion of the drug is given subcutaneously by error, the degree of discomfort appears to be increased.

I have seen 4 cases in which foot drop developed in patients who were receiving intramuscular injections of penicillin into the buttocks. For this reason, great care should be taken to avoid injecting penicillin into the sciatic nerve or its immediate neighborhood. If the upper outer quadrants of the buttocks are used for the injections, the nerve should be easily avoided.

After multiple intravenous injections, thrombosis of the veins at the sites of the injection may occur. This event appears to be related more to the technic of performing the venipunctures than to irritation from the injected solution. In patients receiving the drug by a continuous intravenous infusion, however, the development of a painful thrombophlebitis in the vein being used is not infrequent. This reaction is often accompanied by chills and high fever. Changing the needle to another vein usually does not relieve the symptoms, and in most cases it becomes necessary to change from the intravenous to the intramuscular route of administration.

The penicillin preparations that are now being distributed are tested for pyrogens before being

released by the manufacturers. The febrile reactions due to impurities in the drug that were occasionally encountered in the early days of penicillin treatment are no longer seen. Drug fever analogous to that seen in sulfonamide therapy has not been reported. Occasionally patients have been observed who maintain a low-grade fever after the clinical signs of infection have disappeared. In several of these cases, the temperature has returned to normal when penicillin was discontinued.

In rare cases the administration of penicillin has been accompanied by diarrhea, with or without abdominal cramps. Nausea and vomiting caused by penicillin have not been described. On the contrary, a return of appetite is one of the earliest signs of a favorable response to penicillin therapy. With the use of some of the early preparations various minor reactions were seen from time to time, including headache, flushing of the face and pain in the testes. With the preparations now in use, these reactions are not being reported.

The maximum dose of penicillin that can be given safely to man has not yet been determined. Doses as large as 4,000,000 units a day have been given in several cases without ill effect. At present there are no known contraindications to the administration of penicillin, although there may be reason for hesitation in administering large initial doses to patients with cardiovascular or congenital syphilis. So far as is known, penicillin is not incompatible with any other drugs or articles of diet.

* * *

Penicillin has been shown to be a potent, nontoxic, antibacterial agent against many important pathogenic bacteria. In the treatment of almost all infections caused by these organisms, penicillin is the most effective chemotherapeutic agent that has yet been discovered. Its use in many of these infections, either alone or in combination with other established forms of therapy, has resulted in a lowering of the mortality rates, a shortening of the periods of illness and a reduction in the number of complications. In many diseases, sufficient experience has accumulated to permit the formulation of fairly definite concepts regarding the effectiveness of penicillin and the best methods for its employment. In other infections, experience has been limited to a few experimental efforts that merely hint at the possibilities of penicillin therapy.

In the treatment of infections with penicillin, early treatment, adequate dosage and the continuation of treatment until the infection is eradicated are essential for obtaining the maximum results. Likewise, in planning therapy, proper consideration must be given to the known facts concerning the absorption, excretion and distribution of penicillin in man. In many cases the concomitant use of other therapeutic procedures of established value, including general supportive measures, sur-

gery and the administration of specific antisera, are necessary to effect recovery.

The drug cannot be expected to have a favorable effect on the course of diseases other than those infections in which the causative organisms are known to be susceptible to the action of penicillin.

CASE 31151

PRESENTATION OF CASE

A twenty-four-year-old farmer entered the hospital because of severe sacral pain.

Two months before entry, without known preceding trauma, he began to have intermittent dull, aching pain in the right half of the sacrum. Two weeks later he received three blows over this area that caused severe pain. Following this the pain persisted, was sharp and was aggravated by motion, coughing and sneezing. X-ray studies of the lumbosacral spine six weeks before entry were allegedly negative.

One month before admission he spent ten days in a community hospital, where he was found to have fever and slight leukocytosis; he had no bowel movements for eight days. During the month before entry his back had been stiff and cutting pains began to occur, extending across the shoulders and in the arms. These lasted from a few minutes to several hours. One week before admission he felt "pins and needles" in his right hand, arm and shoulder, and a sharp pain just below the right costal margin. The pain frequently shot from the lower back down the posterior aspect of the right leg to the heel. He had spent most of the month preceding entry in bed and finally could scarcely move because of pain. During the earlier part of his illness he lost 25 pounds. He had become extremely weak. For about a month he had noted some difficulty in starting the urinary stream.

Physical examination revealed an emaciated, anemic-looking man who complained of excruciating pain in the lower back on the slightest motion.

*On leave of absence.

There was generalized muscle wasting, most pronounced in the thighs. There were splinting of the chest and marked spasm of the abdominal muscles, with slight, diffuse abdominal tenderness and marked tenderness of the lower thoracic and lumbar spine and over the right sacroiliac joint. The knee and ankle jerks were diminished on the right side. The arm jerks, abdominal reflexes and plantar reflexes were normal. Sensation was normal. There was slight generalized lymphadenopathy. The heart and lungs were not remarkable.

The temperature was 99°F., and the pulse and respirations were normal. The blood pressure was 128 systolic, 68 diastolic.

Examination of the blood showed a red-cell count of 4,250,000, with 12.2 gm. of hemoglobin, and a white-cell count of 12,000, with 88 per cent neutrophils. The differential count and cell morphology were normal. The urine was normal, containing no Bence-Jones protein. The stools were guaiac negative. The serum calcium was 8.5 mg. per 100 cc., the phosphorus 4 mg., and the phosphatase 4.7 Gutman¹ units per 100 cc. The serum protein was 6.3 gm. per 100 cc. The sedimentation rate was 53 mm. in one hour. Hinton and Wassermann reactions were negative. A lumbar puncture revealed an initial pressure equivalent to 250 mm. of water and normal dynamics; the fluid was clear and colorless and contained no cells, the total protein being 21 mg. per 100 cc.

X-ray examinations revealed slight irregularity of the margins of the dorsal vertebrae and of the sacroiliac joints, which were thought to be consistent with rheumatoid arthritis. There was some increased density of the cortices of the internal condyles of the tibiae. A chest film, gastrointestinal series and barium enema were negative. X-ray films of the knees and shoulders were normal.

The pain in the lower back and sacral region continued to be severe. There was occasional urinary and fecal incontinence. The temperature was slightly elevated most of the time, but it was rarely over 100°F., although it did reach 102° on one occasion. The pulse averaged 90, and the respirations remained fairly constant at 20. One week after admission he was awakened by a severe steady pain in the right flank, radiating to the groin and testicle but not to the penis. This lasted twenty minutes. He admitted that he had previously had similar

attacks, always on the right side. The right knee jerk became progressively less active. Two weeks after admission a firm, tender swelling measuring 6 cm. in diameter and elevated 1 to 2 cm. was noted on the upper part of the sacrum to the right of the midline. Additional films of the sacrum and lumbosacral junction showed an area of apparent destruction in the posterior superior spine of the ilium, where it articulated with the sacrum.

On the eleventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM A. ROGERS: May we see the x-ray films?

DR. MILFORD D. SCHULZ: The irregularity described in the dorsal spine looks more like old epiphysitis than anything else. The films show the lumbar spine and the dorsal spine to be otherwise normal, but on the film of the pelvis there is shown an area of rarefaction in the right wing of the sacrum that is indefinite in outline. It does not have sharp borders, and whether it is primary in the sacrum or the result of destruction by something metastatic to it cannot be determined on the information we have.

DR. ROGERS: I agree that the roentgenogram of the thoracic vertebrae in the lateral view reveals an old epiphysitis and is not suggestive of other diseases that might involve the thoracic region, such as, tuberculosis and the rheumatoid group of vertebral-column conditions. The changes are not consistent with trauma, nor is there evidence of pyogenic infection. In the anteroposterior view of the lumbosacral region there is a suspicious area of increased radiability in the right ilium, near the sacroiliac joint, without definite demarcation. There are no appreciable margins about this area. The films are far from conclusive, however, by reason of the circumstance that the gas patterns overlying the right side of the sacrum are such as to make it quite difficult to be certain of definite bone change. The lateral view of the lumbosacral junction does not look abnormal.

The salient features in this case seem to be the patient's age, twenty-four years, and his incapacity of months rather than of days. There was a temperature elevation that averaged 100°F. but had not been over 102, and concomitant with this, the white-cell count had not exceeded 12,000 or, what is more important, it did not go over 15,000. I am struck with the circumstance that he had not only excruciating local pain but also corresponding referred pain, that is, to the posterior aspect of the thigh and leg. Consistent with the referred pain was the sharp diminution in the ankle jerk. The diminished knee jerk is not attributable to a lesion of the first sacral segment, as is the diminished ankle jerk, since it corresponds to the third lumbar segment.

It may have been due to the wasting that was apparent in the quadriceps muscle. We also know that this patient had a good deal of urinary and rectal incontinence. There again, these functional changes are consistent with a serious deep lesion in the sacrum. We also know from the history that this man developed severe pain in the right flank that was accompanied by pain in the ilioinguinal and iliohypogastric distribution, the right groin and the testicle. This distribution of referred pain is consistent with a lesion of the right flank that may be in the right upper lumbar gutter, or it may come from the vertebral column — the twelfth thoracic or first lumbar segment. But the appearance of the twelfth thoracic and first lumbar vertebrae in the roentgenograms does not suggest the presence of a lesion. The films are not too good, but it should be remembered that the man was in excruciating pain, associated with extensive splinting of the thorax and the abdomen, which might make it difficult to place him in the correct position for good films.

Another salient feature in this case is the splinting in the chest and abdomen. It is an outstanding clinical sign. The splinting is a reflex mechanism protecting either the contained viscera or the vertebral column or meninges in the thoracic or lumbar region. When extreme, it is suggestive of meningeal irritation. Lastly, he had no definitely localizing symptoms other than the subjective one of pain in the right side of the sacrum until several days before operation, at which time he developed a firm sizable mass in the upper half of the sacrum on the right side.

Are we dealing with infection, with congenital malformation, with injury, with new growth or with some metabolic disturbance, such as rheumatoid arthritis?

From the standpoint of acute infection, a pyogenic infection could have been the primary cause of this man's trouble. All pyogenic infections are not fulminating, and all do not produce a high elevation of the temperature or white-cell count. Against acute pyogenic infection, however, is the duration, two months, without evidence of abscess formation. Certainly roentgenograms taken one month following acute pyogenic infection of the sacrum should show changes. Usually a history of two or three days is consistent with osteomyelitis. The possibility of osteomyelitis of the sacrum is, however, real, but I do not believe that it is likely. In the chronic infections we have to consider syphilitic osteitis. We know that the Hinton and Wassermann reactions were negative. Tuberculosis should certainly have responded favorably to rest in bed for a month; instead the patient grew steadily worse, his symptoms intensified, and finally the mass appeared. Although this could have been a cold abscess, I believe that the likelihood of tuberculosis is not great.

Among the congenital malformations, low leptomeningeal and cauda-equina lesions can be ruled out by the absence of symptoms prior to two months ago and by the lumbar-puncture findings.

I am far more impressed by the probability of neoplasm in this case. Among the primary tumors, Ewing's tumor would be consistent with the temperature elevation and the leukocytosis. On the other hand, the patient was twenty-four years old, and Ewing's tumor usually, but not always, occurs in the first two decades. Furthermore, Ewing's tumor is usually confined to the shafts of the long bones, although it may occur in the pelvis and may be purely osteolytic. I am inclined to think that this is not a Ewing's tumor, although it is a possibility.

Multiple myeloma must also be considered. The lesion of multiple myeloma is rather apt to be circumscribed, and although it may be solitary for many months or even several years, it would scarcely give the roentgenographic appearance that this case shows.

Neuroblastoma produces osteolytic bone lesions. It is a possibility in this case but does not explain the fever or leukocytosis.

Of course, osteolytic bone sarcoma must be considered. The patient was on the borderline between the young and the old group, so that he could have had an osteolytic sarcoma from any of the elements of the bone. A tumor of the lymphosarcoma group, which includes lymphocytoma, lymphoblastoma and reticulum-cell sarcoma, would not be inconsistent with the findings in this case. There is not uncommonly fever with lymphosarcoma, and such a tumor might cause severe local pain in the right flank.

Because of the pain in the groin and testicle, renal-cell carcinoma should be discussed. This produces an osteolytic lesion in the bone and frequently metastasizes to the pelvic bones. There might have been a rupture of some of the rapidly growing cells in the renal region through the cortex of the cancer, with the initiation of the intense local and referred pain. This tumor, however, is not usually associated with fever. Many other carcinomas may metastasize to the pelvic bones.

In summary, I am inclined to favor neoplasm — either a lymphosarcoma as a primary lesion or a metastasizing osteolytic tumor, such as a renal-cell carcinoma, as a secondary lesion. It is possible that this man had a pyogenic infection or tuberculosis of the sacrum; he might even have had rheumatoid arthritis, but I believe that Dr. Ropes would agree that it is a rather atypical picture of rheumatoid arthritis.

DR. RONALD C. SNIFFEN: Dr. Kubik, will you outline the terminal course regarding the neurologic findings?

DR. CHARLES S. KUBIK: As stated in the abstract, the patient had had pain between the shoulder blades and some numbness in the fingers. Several days after the biopsy, in the course of about two

hours, he developed complete motor and sensory paralysis below the fifth thoracic level; following that he never again had pain below that level but continued to have extremely severe pain in the upper thoracic and lower cervical spine, in the upper part of the chest and in the arms. There were times when he had to be given 65 mg. of morphine subcutaneously every hour. He developed marked weakness and atrophy of the arms and hands and tumor masses in the occipital region. He died about two and a half months after entry or about two months after the biopsy.

DR. WYMAN RICHARDSON: I looked at a blood smear before I saw this patient and was therefore unprejudiced. The smear showed a picture consistent with acute blood loss or tumor involving the bone marrow. Unfortunately I did not describe the smear in the record, but it showed a slight leukocytosis, with an increase in immature red cells and no toxic changes in the neutrophils, which suggested that no infection was present. There was something causing an increased output of cells from the bone marrow. Hemorrhage could have done that, but there was no history of hemorrhage. Therefore, by exclusion, some form of marrow tumor seemed likely. This diagnosis seemed to fit best with the clinical picture. I thought that the likeliest tumor was some type of lymphoma.

CLINICAL DIAGNOSIS

Malignant tumor of ilium.

DR. ROGERS'S DIAGNOSIS

Malignant neoplasm, ? lymphosarcoma.

ANATOMICAL DIAGNOSIS

Ewing's tumor of sacrum, with widespread metastases.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: We made a diagnosis of "probable synovium" on the biopsy material. After reviewing the section I was rather surprised that we gave it a name, for the section was poor and the tumor was undifferentiated.

The patient died eighty-three days after admission. He was extremely emaciated and had a severe anasarca, which included peripheral edema, ascites, hydrothorax and hydropericardium. The muscles of the right arm were atrophic. Over the sacrum on the right there were two decubitus ulcers. The right wing of the sacrum was destroyed by a tumor measuring 6.5 cm. in diameter. The right occipital bone contained a tumor of the same size, and the cerebral dura was studded with nodules that had penetrated that membrane but not the underlying arachnoid. At one point the superior longitudinal sinus had been invaded by the neoplasm. Otherwise the brain was unchanged, except for signs of in-

creased intracranial pressure. The spinal column from the fourth to eighth thoracic vertebra contained tumor, which had penetrated the epidural space and dura but not the arachnoid. The same situation prevailed for a distance of 13 cm. below the twelfth thoracic vertebra. Microscopic sections of the spinal cord showed early ascending and descending degeneration from about the midthoracic level. The ribs contained multiple tumor nodules. The lungs, liver, kidneys, pancreas and retroperitoneal and mesenteric lymph nodes were studded with metastatic nodules averaging a centimeter in diameter, with a maximum size of 4 cm. The adrenal glands weighed 26 gm. together, and each contained several small masses of tumor.

Microscopically the tumor was composed of undifferentiated cells with large, vesicular nuclei and an occasional nucleolus. The cytoplasm was scant and poorly defined. The cells were divided into groups by strands of delicate fibrous tissue. Our diagnosis was Ewing's tumor.

It is interesting to speculate on the origin of this type of tumor. Does it arise from the vascular endothelium, as Ewing² believed? Does it belong in the reticulum-cell-sarcoma group? Is it a bone tumor? One of the more recent ideas is that many of the neoplasms labeled Ewing's tumor are, in reality, metastatic neuroblastoma, a tumor originating from the primitive cells of the sympathetic nervous system. This theory was proposed by Colville and Willis³ in 1933 and again by Willis⁴ in 1940, who point out that there is no satisfactory clinical or roentgenographic distinction between Ewing's tumor and neuroblastoma and that radio-sensitivity is not of real value in differentiating the two. Their first case was quite similar to the one under discussion except that the main and presenting tumor was in the thigh; the adrenal glands contained tumor nodules. The second patient had two large tumors, one in the thigh and the other in the line of the lumbar sympathetic chain, which ran through it. They cite the well-known papers of Hutchison⁵ and Pepper,⁶ who wrote of patients having small adrenal neuroblastomas with massive metastases to the skull or liver, which might have been mistaken for the sites of the primary tumor. It is unusual for a primary bone tumor to metastasize to lymph nodes as Ewing's tumor does so frequently. The complete confusion in the literature regarding the origin of Ewing's tumor cannot be denied.

Regarding the histology of these tumors, in neuroblastoma one often finds an arrangement of cells and fibrils that has the same configuration as the cells from which the sympathetic nervous system and the adrenal medulla develop. One mode of arrangement is in the form of a rosette—a ball-like aggregate of cells enclosing a meshwork of fibrils. These were beautifully demonstrated by Wright⁷ in 1910, and Colville and Willis found

rosettes in their cases. In neuroblastoma one may find more highly differentiated tissue in the form of ganglion cells, but Colville and Willis were unable to demonstrate such areas in their cases.

If there is truth in this theory, several practical points come to mind. Should amputation be undertaken if one is dealing with a metastatic tumor? Should routine roentgen therapy be given to the retroperitoneal tissue when a diagnosis of Ewing's tumor has been made after biopsy of a bone? Certainly the retropleural and retroperitoneal tissues should be investigated thoroughly in view of the fact that they may be harboring the primary tumor.

To come back to this case, and to reach no conclusion, I could find no resemblance between this tumor and a neuroblastoma. Therefore the diagnosis must rest at Ewing's tumor.

CASE 31152

PRESENTATION OF CASE

A thirty-six-year-old graduate nurse was admitted to the hospital because of irregular and profuse menstrual bleeding.

From the time of the menarche, at the age of sixteen, the menstrual periods were irregular and profuse, with considerable loss of blood on each occasion. At times there were long free intervals. At the age of twenty an appendectomy was performed, and a tube, said to be tuberculous, was removed. Following this she had long stretches of amenorrhea, followed by profuse bleeding, occasionally with clots, requiring eight to ten napkins a day for seven days. She received a variety of endocrine preparations, with no apparent effect until about four years prior to admission, when, following the administration of Antophysin, her periods became regular and normal for about two and a half years but then again became infrequent and profuse. For six months preceding entry she had had almost continuous flow.

The patient had always been obese, averaging 230 pounds. Two years before entry, while on a diet, she lost 75 pounds, but she had subsequently regained 50.

The patient's father died of tuberculosis when she was three years old, and a younger sister had pulmonary tuberculosis.

Physical examination revealed an obese woman in no acute discomfort. The skin was warm. There was no palpable adenopathy. The fundi were normal. The thyroid gland was not enlarged. The breasts were pendulous. The heart and lungs were negative. Slight tenderness was present on deep palpation in the left lower quadrant of the abdomen. A pelvic examination revealed a slightly enlarged uterus but was otherwise not remarkable.

The temperature, pulse and respirations were normal. The blood pressure was 120 systolic, 74 diastolic.

Examination of the blood revealed a red-cell count of 3,570,000, with 10 gm. of hemoglobin, and a white-cell count of 5100, with 66 per cent neutrophils, 27 per cent lymphocytes, 5 per cent monocytes and 2 per cent eosinophils. There were no significant red-cell abnormalities on smear. The urine had a specific gravity of 1.020 to 1.030, with a 0 to + test for albumin; a few white cells were found in the sediment. The serum nonprotein nitrogen was normal, and the protein 5.9 gm. per 100 cc. A glucose tolerance test revealed a fasting level of 105 mg. per 100 cc., which rose to 185 mg. at the end of two hours and to 162 mg. at the end of three hours. The basal metabolic rate was +1 per cent. A blood Hinton test was negative. A tuberculin test (dilution unknown) was strongly positive.

Roentgenographic examinations of the skull, spine and urinary tract were negative.

On the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FRED A. SIMMONS: Since this is a teaching clinic, I am going to mention a few points that might be instructive regardless of what the diagnosis may be. In any patient who is bleeding, no matter what age, we should include the tests that are available today for the ruling out of malignant disease. The most frequently practiced and probably the most accurate test at the moment is a diagnostic dilatation and curettage including cervical biopsy. We also have a fairly accurate test, the vaginal smear, which should have been carried out on this patient.¹ The laboratory has now studied vaginal smears from over 1200 cases, with an error of only 4 per cent in 95 cases of proved cancer. The point I am making is that anyone with this history should have cancer ruled out. I assume that this was probably the operation that they intended to do. I should also like to point out that in handling patients with profuse flowing at thirty-six years of age, a dilatation and curettage might better be carried out before giving any endocrine preparation. The assumption that Antophysin regulated the menstrual cycle implies that it was on an endocrine basis, but malignancy still cannot

be ruled out. Antophysin is a proprietary name for chorionic gonadotropin.

That the patient had tuberculosis is quite likely in view of the family history and because of the reported tuberculous tube removed at the age of twenty. I believe that the general opinion of gynecologists in most parts of the country is that the proper treatment for such a condition, if it really were a tuberculous tube, is radical surgery, which would include removal of the uterus and both tubes and ovaries, since the process is apparently a hematogenous infection. This patient, according to the record, had no other signs of tuberculosis, and I rather doubt that she had it. I question then the pathological report of the operation at twenty years of age. Another thing that bothered me was that from the physical findings presented here I was unable to determine whether the patient had been married and whether she had ever borne children. It is fair to point out that the pelvic examination should include some comment whether the patient had a virginal or multiparous introitus.

DR. BENJAMIN CASTLEMAN: The record merely states that the patient was unmarried.

DR. SIMMONS: This fact does not help me unless it is fair to assume that she was a virgin, in which case I shall not go into the possibility of inflammatory disease other than tuberculosis. Of course, irregular bleeding of this nature can be due to gonorrhea and its sequelae. A pelvic examination should also include inspection of the cervix. All that may have been left out for the sake of brevity.

In summary, I am inclined to consider the tuberculous history and findings in the tubes to be irrelevant, although I cannot rule out tuberculous endometritis as the cause of the trouble. I am inclined to think that she did not have carcinoma, because she had lived so long with a history of bleeding. If we can believe the menstrual-cycle history, the amenorrhea followed by profuse flow is the perfect picture of functional uterine bleeding, metropathia hemorrhagica, endometrial hyperplasia or whatever you want to call it.

Metropathia hemorrhagica is a term applied to a specific type of functional uterine bleeding characterized by a state of continuous estrinism with hypoprogestinism, according to Albright.² It is frequently seen in women with general debility regardless of age, presenting itself as alternating amenorrhea followed by continuous flowing, usually without molimen and dysmenorrhea, which may have been present in the patient's normal menstrual cycle. Pathologically the endometrium is markedly thickened, with deep glands having the "Swiss cheese" appearance characteristic of the estrin effect.

Endometrial hyperplasia or what I prefer to call "endometrial dysplasia" is the pathological term applied to the clinical state described above. Func-

tional uterine bleeding or dysfunction of uterine bleeding refers to the abnormal state of flow, with or without amenorrhea, not precipitated by organic pathological disease and is a convenient pigeonhole for cataloguing vague irregular states of uterine bleeding.

I think that on the whole it is wise to suggest the need for diagnostic dilatation and curettage and biopsy. I shall make a diagnosis of endometrial hyperplasia on an endocrine basis; possibly there was a benign endometrial polyp.

DR. FRANCIS M. INGERSOLL: I agree entirely with the diagnosis of metropathia hemorrhagica associated with a hyperplastic endometrium; however, we often see patients with the same history in whom the endometrium is atrophic rather than hyperplastic. Apparently about 20 to 30 per cent of them originally had an overfunctioning endometrium.

CLINICAL DIAGNOSIS

Metropathia hemorrhagica.

DR. SIMMONS'S DIAGNOSIS

Endometrial hyperplasia (metropathia hemorrhagica?).

ANATOMICAL DIAGNOSIS

Tuberculous salpingitis and endometritis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The operation was a curettage, and a large amount of endometrium was removed. The diagnosis on microscopic examination proved to be tuberculosis. Following that operation a laparotomy was performed and the other tube and uterus were removed. We found tuberculosis in both the uterus and tube.

DR. INGERSOLL: Did they take out the cervix? I remember one case in this hospital in which someone first removed one tube, then at a subsequent operation took out the other tube and did a supravaginal hysterectomy and finally did a cervicectomy for tuberculosis.

DR. CASTLEMAN: The cervix was removed in this case.

GOVERNMENTAL SUPPORT FOR MEDICAL RESEARCH

SENATOR PEPPER, as chairman of a subcommittee of the Senate Committee on Wartime Health and Education, recently held a hearing at which a number of highly qualified persons were invited to discuss the question whether the federal government should continue in time of peace, as in war, to offer assistance through grants or in other ways to facilitate progress against disease through research. The Senator did not consider it possible or desirable for the Government to do all the work that its funds would finance. He was interested in determining how the universities, industries and the Government

could best co-operate to achieve the highest development of medical research. Some of the information and opinions brought out at this hearing are of considerable interest.

Brigadier General J. S. Simmons, chief of the Preventive Medicine Service, Office of the Surgeon General, was the first person to be called. He said that one of the most important factors contributing to the excellent record of the Medical Department of the Army during this war has been the unique emphasis placed by the Surgeon General on the necessity for research in all fields of medicine. The comprehensive research program that has been developed and carried out by both military and civilian scientists has produced a wealth of new and fundamental knowledge and resulted in improved methods for the care of the wounded and the prevention and treatment of many of the diseases that afflict troops. The program included investigations in three general categories: projects developed within Army laboratories and field installations; projects developed in civilian institutions under Army contracts negotiated through the Office of the Surgeon General and projects developed for the Army in civilian institutions under contract with the Office of Scientific Research and Development. On the whole, the civilian response and the results obtained during the war afford an inspiring example of what can be accomplished through a well-organized, co-operative research program.

He said that the new knowledge made available had been immediately applied in the field. Three groups of studies were mentioned, any one of which more than justified the total cost of the program — those concerning the development of blood substitutes, of penicillin and of insect repellents and insecticides. In addition, new methods of immunization and other means of prophylaxis have considerably reduced the incidence and mortality of most of the important infectious diseases. The new weapons developed for the fight against these diseases, moreover, have also revolutionized the foreign quarantine program of the Army, Navy and Public Health Service, and they afford better methods for the protection of this country, particularly against insect-borne diseases and their vectors.

General Simmons suggested that plans for postwar medical research as it affects the Army should be based on the following assumptions: that the security of the Nation depends on the health and physical strength of its people, both military and civilian, and that a continuing program of research on military medicine is essential to this security; that the Army will undertake research of importance to the Army in peace or in war and will share the responsibility but, of course, will not attempt to assume the full burden in those fields common to the military and civilian components of the Nation; that in studying medical problems of significance to the Army full use will be made both of the research facilities within the Army and those made available in certain civilian institutions, the Army directing its attention chiefly to problems which can best be carried out under military conditions; and that the need for medical research by and for the Army bears no direct relation to the size of the Army, since the medical problems of future wars must be anticipated.

Brigadier General Stanhope Bayne-Jones, deputy chief of Preventive Medicine Service, Office of the Surgeon General, described the organization and work of the Board for Investigation and Control of Influenza and Other Epidemic Diseases. It consists of a central board, composed of seven members, and ten commissions, which include about a hundred civilian consultants to the Secretary of War, all of whom are experts in their special fields. These consultants are on a part-time basis and are stationed at their home institutions, but they are called to duty under orders issued through the Office of the Surgeon General. They have worked on more than a hundred projects in Army camps and posts, both in this country and overseas. The plans for postwar medical research now under consideration in the Office of the Surgeon General contemplate not only a continuation of research by the Medical Department itself but also the organization, co-ordination and support of medical research on a national scale.

Dr. A. N. Richards, chairman of the Committee on Medical Research of the Office of Scientific Research and Development, described the work of that committee and brought out the need for some such

governmental organization. His committee has discharged its duties through contracts made by the Office of Scientific Research and Development on a "no loss, no gain" basis with colleges, universities, hospitals, research institutions and research groups in commercial companies, as well as through transfer of funds to other agencies of the Government. The contracts cover reimbursements not only for items of equipment, supplies and salaries of assistants but also for salaries of the chief investigators. Nearly five hundred contracts with one hundred and twenty different institutions have been made by this committee, and these involved almost twenty-seven hundred persons, of whom about one fifth were physicians. For the three years ending June 30, 1944, the expenditures for these contracts in successive years amounted to \$2,342,440, \$5,260,110 and \$7,747,276. None of the universities engaged in this work could have undertaken the projects at the expense of their own resources on the scale that the emergency demanded.

The difficulties that Dr. Richards anticipates in developing a peacetime program of this kind are as follows: the vastly broader and more perplexing choice of problems to be studied; the need for a stimulus to replace the ardor for service that imminent national danger has provided, and the need for a type of governmental control so understanding and so flexible that the imagination and scientific passion of investigators will not be dampened; and the increasing difficulties in choosing the institutions to which support shall be given and the definition of the terms with which it shall be offered. He suggested that a thorough survey be undertaken, not only of medical schools and associated hospitals but of the science departments of their universities.

Dr. Lewis H. Weed, chairman of the Division of Medical Sciences, National Research Council, reviewed the work being supported by that council and also described the difficulties that the institutions receiving this aid had experienced in obtaining financial support before the war. He prophesied that in the postwar period it would be even more difficult to obtain the necessary funds. He was convinced that much of medical research will necessarily have to be abandoned in the private and semiprivate institutions of the country unless

governmental subsidies are made available in some form for their support. He thought, however, that any administrative organization created by the Government should take cognizance of the total problem rather than serve merely as a mechanism for handling funds for medical research. It should be an independent agency with broad advisory functions. He added that medical research cannot, in the long run, be divorced from medical schools, from hospitals, from medical practice and from preventive procedures and matters of public health.

Dr. David Heyman, president of the Board of Directors, New York City Public Health Research Institute, described his organization, which he hoped would set a pattern that might be widely followed. This institute is closely associated with the New York City Department of Health but is a completely independent institution. It is governed by its Scientific Council, which initiates and supervises scientific projects, and its Board of Directors, which sets general policies and controls finances. It is financially assisted by the city under a long-term contract but also receives funds from private donors.

Dr. Heyman pointed out the limitations of the various foundations, whose support is necessarily restricted because of their limited resources and because their benefits are spread over a wide field. These foundations usually hope that, when something begins to turn out well, further support will be given by the public and by a governmental agency. He stated that the Government should support medical research by making grants-in-aid to existing nonprofit institutions rather than by setting up new laboratories of its own. In this way, it can provide opportunities for continued service by the many able young scientists now in the armed forces and also provide training for youths who show promise.

From the testimony of these experienced persons, it is obvious that some sort of wide support for medical research must be provided by the federal government if advances in this field are to continue. Incomes from private endowments have dropped off markedly, and the prospects of new funds from similar sources are not particularly good and certainly cannot be expected to keep pace with the

growing needs of medical research. During the past decade manufacturers of pharmaceutical and other products have filled some of the gap by generous support of projects in which they have special interests. They have also developed research organizations of their own that are rapidly becoming pre-eminent in the field of medical research. They cannot, however, be expected to carry too much of the burden, which in the long run rightly belongs to all the people, who are the beneficiaries of the results of this research.

THE DOCTOR ILLUSTRATES HIS TRAVEL NOTES

Young Richard Bright, son of a well-to-do Bristol banker and a student in medicine at Edinburgh, went on an expedition to Iceland at the age of twenty-one. With his gifted pen he not only described the botanical and zoological specimens collected by the Mackenzie party, but he also drew some of the illustrations contained in *Mackenzie's Travels in Iceland*, published in 1811. After graduating from Guy's Hospital in 1812, moreover, Bright toured Holland, Belgium and Germany and spent the winter of 1814-1815 in Vienna. His *Travels from Vienna through Lower Hungary*, published in 1818, contains an account of his wanderings and, again, as in the Iceland tour, he drew his own illustrations. Bright's book is perhaps the most worthy of all self-illustrated travel books by a doctor, but many other physicians, both before and after his time, enlivened their accounts with sketches or paintings. Three other examples may be given, two of which are the product of men whose names are household words in medicine.

William Macmichael, also a son of a banker, became a Radcliffe Traveling Fellow from Oxford in 1811. He made several journeys to Russia and Turkey and visited Moscow in 1814 and again in 1817. As a result of the latter trip he published the book *Journey from Moscow to Constantinople in the Years 1817-1818*, which is finely illustrated by drawings of his own.

In 1863 an uprising in Morocco against the Jews came to the attention of the venerable Sir Moses Montefiore. He decided to go to Saffi to advocate,

in person, the cause of his suffering people and set out with a large party, including his physician Thomas Hodgkin. Hodgkin, long curator of the museum and pathologist at Guy's Hospital, had, after he was sixty-five, given up practice and devoted himself to philanthropy. On conclusion of the affair in Morocco, the party went to the Holy Land, and there Hodgkin died, at Jaffa, in 1866. Hodgkin's account of the trip, however, was saved and published the same year under the title *Narrative of a Journey to Morocco in 1863 and 1864*. It is a delightful account, made more so by the excellent drawings of the author. Like Bright and Macmichael, Hodgkin had great ability as an illustrator.

Of slighter scope, but nevertheless of greater interest because of its contemporary nature, is a brief travel diary by the late Harvey Cushing, with illustrations, some in color, by his own hand.¹ Cushing, straight from four strenuous years as a surgical resident under Dr. Halsted at the Johns Hopkins Hospital, visited Le Puy in Auvergne in the summer of 1900, with a Yale classmate. He kept, as was his custom, a diary and to it added numerous sketches revealing, as Dr. John F. Fulton points out in the introduction to the published diary, Cushing's "unusual powers of observation, draftsmanship and humor." Some of the illustrations are water-colors that show remarkable talent. The sketches are characterized by a boldness of line and accurate perspective so notable in the operative drawings that fill his case-records from the time of his house-pupilage at the Massachusetts General Hospital in 1895² to the end of his surgical career. This charming account of the holiday visit to Le Puy is a worthy addition to the long list of travel books by doctors and, indeed, is one of the best.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

COBB — Albert C. Cobb, M.D., of Marion, died March 21. He was in his seventy-seventh year.
 Dr. Cobb received his degree from Albany Medical College in 1892.
 A brother and five nephews survive.

LAWRENCE — Charles H. Lawrence, M.D., of Brookline, died March 13. He was in his sixty-third year.

Dr. Lawrence received his degree from Harvard Medical School in 1908. He served as lieutenant in the Army Medical Corps during World War I. In 1922, he was appointed to the Evans Memorial Institute for Clinical Research and became chief of the Endocrine Service there. He served as consulting physician to Jordan Hospital, Plymouth, Choate Memorial Hospital, Woburn, and Sturdy Memorial Hospital, Attleboro. He was physician-in-chief of the Endocrine Clinic at the New England Medical Center and associate professor of medicine at Tufts College Medical School. He was a fellow of the American College of Physicians and the American Medical Association, and a member of the Association for Study of Internal Secretions and the American Clinical and Climatological Association.

His widow, four sons and six grandchildren survive.

NOTICES

BOSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held in the Main Lecture Room of the Harvard Biological Laboratories on Wednesday, April 18, at 8 p.m.

PROGRAM

- The Sensitivity of Human Vision to the Spectrum. Dr. G. Wald.
 Water and Electrolyte Exchange Between Blood and the Eye. Drs. E. Kinsey and M. Grant.
 Composition of Typical Mexican Foods. Dr. R. S. Harris.

ALLERTON HOSPITAL

The next meeting of the Medical Staff of the Allerton Hospital, Brookline, will be held on Thursday, April 19, at 8:30 p.m. Dr. Albert E. Sloane will speak on the subject "Cataract in the Newborn."

NEW ENGLAND OPHTHALMOLOGICAL SOCIETY

A meeting of the New England Ophthalmological Society will be held at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, on Tuesday, April 17, at 8 p.m.

Following the business meeting, Drs. V. Everett Kinsey and D. Morton Grant will speak on the subject "Physiology of Aqueous Humor Formation." An informal discussion by Colonel Derrick T. Vail on "Some Aspects of War Ophthalmology" will follow.

NEW ENGLAND ROENTGEN RAY SOCIETY

The next meeting of the New England Roentgen Ray Society will be held at the Harvard Club of Boston on Friday, April 20, at 8 p.m. Dr. E. Granville Crabtree will speak on the subject "Clinical Data on Some Pelvic and Ureteral Dilatations."

Interested physicians are invited to attend.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, APRIL 19

- FRIDAY, APRIL 20
 *9:00-10:00 a.m. Advances in Naval Medicine. Rear Admiral J. J. A. McMullin. Joseph H. Pratt Diagnostic Hospital.
 *9:00-10:00 a.m. Medical clinic Isolation Amphitheater, Children's Hospital.
 10:50 a.m. Postgraduate clinic in dermatology and syphilology. Amphitheater, Mallory Building, Boston City Hospital.
 SATURDAY, APRIL 21
 *10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham Hospital.

CURRENT TRENDS IN BIOLOGIC PRODUCTS*

LIEUTENANT COLONEL ELLIOTT S. ROBINSON, M.C., A.U.S.†

THE following remarks on current trends in biologic products, not being based on a careful survey of current literature or opinion, represent only an expression of the impressions gained through some years of intimate contact with the manufacture of biologic products. Had there been more opportunity for painstaking study and preparation, the comments to be made might have undergone some alteration and doubtless would have greater value; but in these days, time for leisurely consideration has for many people joined those things that have essentially ceased to exist.

Current trends are discernible only against the background of what has happened in the past. For this reason, it is desirable not only to consider what is going on now and what was being done two or three years ago but to go farther back as well, if one is to see clearly how present thoughts and practices have developed and how they differ from those of earlier years. It will also be helpful if the large field of biologic products is divided into smaller portions, namely, antisera, — both prophylactic and therapeutic, — vaccines — both bacterial and viral — and toxoids.

The development of antisera, practically speaking, began with the discovery of diphtheria antitoxin in the 'nineties. The early antitoxins were not highly potent, and the doses required were relatively large. The quality too appears to have been more or less unreliable, and it was in the hope of providing more potent antitoxin that the Massachusetts Antitoxin Laboratory was established. For a number of years the chief improvement was in the direction of increasing the number of units of antitoxin per unit volume, thus reducing the volume required to provide a given dose. This was largely a matter of improvement in methods of toxin production and of immunization of horses.

The next step in development was the discovery that the antitoxic property is not associated with all the constituents of horse serum but only with the globulin fraction. This globulin can be separated

by treatment of the serum or plasma with ammonium or sodium sulfate, and the salt subsequently removed from the precipitated globulin by dialysis. At their best, these methods result in a reduction of volume of the original serum of the order of eight- to ten-fold and an increase in potency of the order of five-fold. This was an important development, for it permitted the administration of much larger doses and undoubtedly saved additional lives. It also led to some reduction in the incidence of serum sickness.

The next advance was not realized for a number of years, although it was discovered within ten years or less of the salting-out methods just described. This advance was the digestion method, brought to practical usefulness by Parfentjef, in which the plasma or serum is subjected to digestion by proteolytic enzymes. The antitoxic globulins are less susceptible to the action of the enzymes than are the other protein constituents of the serum, and their specific activity is not altered provided the enzymes are not allowed to act too long or too vigorously. The final product is often water-clear, and the activity per unit volume is high, permitting the administration of large doses in small volume. Serum sickness following the use of these products is infrequent.

The antibacterial serums have had a somewhat different course of development because of fundamental differences between the two varieties of serum. Prior to 1916, little had been accomplished in the development of antibacterial serums, but at about that time considerable success was achieved in the production of antimeningococcus serum and Type I pneumococcus antiserum. Both these were produced by the injection of horses with the appropriate bacteria. After a time, usually a number of months, the serum of the animals contained protective antibody in such concentration as to be useful therapeutically. Although antimeningococcus serum rapidly gained a recognized place as a useful therapeutic agent, antipneumococcus serum did not, because it was useful against only one type of infection, and also because the volume that it was necessary to administer practically limited its use to large and well-equipped hospitals.

*An address given at the seventy-fifth anniversary of the Massachusetts Department of Public Health, Boston, December 6, 1944.

†Assistant professor of applied immunology, Harvard Medical School, and director, Division of Biologic Laboratories, Massachusetts Department of Public Health (on leave of absence).

In 1924, Felton published the first of a series of studies that marked the next stage in the development of antipneumococcus serum in particular and antibacterial serums in general. He worked on methods of antibody concentration, using sulfate precipitation and also precipitation by means of alcohol. The success of his work led to the widespread use of antipneumococcus serum, which was fostered by the development of statewide pneumonia-control programs. The history of these is too well known to warrant further discussion here, except to recall the leading role played by the Massachusetts Department of Public Health.

At the same time, Felton conducted extensive studies on methods of testing the potency of antipneumococcus serum. In the long run, this may prove to have been the more important contribution, for it focused attention on the difficulties involved in reasonably accurate bioassay of antibacterial serums, which in turn has led to more critical evaluation of the tests employed for other biologic products.

The next marked departure from previous practice was a change in the source of serum. With minor exceptions, the horse was for many years the main source of serums for human use, and this animal has several outstanding advantages for the purpose. Goodner in 1937 announced that more potent antipneumococcus serum could be produced in rabbits and proposed that these animals be substituted for horses. It was also claimed that the rabbit antibody (globulin) was of a smaller molecular size than the corresponding horse antibody, and that this characteristic should increase its ability to penetrate into pneumonic lesions. In my opinion, there has been no clear evidence that, unit for unit, rabbit serum gives better results than horse serum; but the switch to rabbits markedly increased the feasibility of producing serums for the less frequently occurring types of pneumococcal infection, and made possible the production and trial of other serums for which the demand is not great enough to warrant the use of horses.

Prior to the heyday of antipneumococcus serum, the intravenous administration of serums was not widely practiced, and little attention was paid to the occurrence of thermal reactions following intravenous serum therapy. These reactions, however, were of such frequency following the administration of antipneumococcus serum that they became a cause of grave concern, for they were often unpleasant and occasionally lethal. It now appears to be generally conceded that such reactions are produced by specific reaction-producing substances that are referred to as pyrogens. The exact nature of pyrogens does not seem to be clearly settled, although they are widely believed to be, and probably are, extraneous bacterial protein that is introduced into the serum in the process of manufacture. The method of introduction is sometimes obscure, but

scrupulous cleanliness and the use of pyrogen-free water in manufacturing processes seem to decrease markedly or to eliminate the occurrence of thermal reactions.

At the moment the current trend of antibacterial serums for therapeutic purposes is toward oblivion. The introduction of the sulfonamides and penicillin and their demonstrated effectiveness restrict the potential field of usefulness of serums largely to cases in which infection is due to drug-resistant bacterial strains or the patient is drug sensitive. This field is apparently small, much smaller in fact than some authorities feared during the early years of sulfonamide therapy.

Deserving of separate mention is the development of large-scale production of human blood and its fractions. It is important not only in itself but also because the methods developed will doubtless find application in the production of immune serums of animal origin. This development has been so recent, and is so well known that only the high lights and their probable effect on other biologic products need be mentioned here. The first step was the discovery that whole blood can be stored for limited periods for use in emergency transfusions. This was a justifiable but to some extent a wasteful procedure until it was learned that the blood cells can be discarded toward the end of the period of storage and the remaining plasma kept for a somewhat longer time. With the advent of war, the demand for plasma increased tremendously, but the difficulties of storing it in reasonably permanent form were considerable. These were overcome by storage as dried plasma, which was prepared by freezing the liquid plasma and removing the water by evaporation in vacuo. This has proved to be a highly satisfactory preparation for military use.

Just as only a relatively small portion of the serum carries antibodies, so too only a portion of the blood protein—in this case, the albumin—is of great importance in the treatment of shock. Exception can doubtless be taken to this opinion, but there was at any rate sufficient evidence to warrant the investigations undertaken under the direction of Cohn at Harvard to separate the albumin. These led first to the successful large-scale preparation of concentrated albumin solutions that in much smaller volume than plasma had an equivalent osmotic effect.

The methods used, with appropriate modification, have been employed for the separation of other serum-protein fractions. From the public-health standpoint, the most important is the gamma globulin, for this carries the naturally occurring antibodies. At present the most conspicuously useful of these is the antibody against measles. Extensive experiments have shown that human gamma globulin protects children who have been exposed to measles and can be used to modify the disease in such children. Other uses will doubtless be found, but this one alone is of considerable importance.

Let us turn our attention to the field of prevention, which, from the public-health viewpoint, is of greater interest, and first consider bacterial vaccines. Typhoid vaccine may be taken as an example, for it has been extensively studied and used and is of great importance to public-health and military medicine. Starting with its optional use in the British Army and its later adoption for compulsory use in the American Army in 1911, its value was conclusively demonstrated during World War I. The low incidence of typhoid fever in the Army during the years following the war made for a feeling of complacent acceptance of the value of typhoid vaccine, but this confidence was badly jarred by Grinnell's work at Harvard. He showed by experiments on mice and with human volunteers that the Rawlings strain ordinarily used for vaccine production was not particularly effective in producing active immunity in the mice or protective antibody in the human volunteers. This failure was associated with a loss of virulence of the Rawlings strain, probably the result of prolonged cultivation; for vaccines made from recently isolated typhoid strains were definitely superior both in mice and in human subjects. Moreover, a virulent Rawlings strain produced by mouse passage was of distinct immunizing value when used for vaccine production. Grinnell's recommendation of the use of a virulent strain was promptly adopted by the Massachusetts Antitoxin and Vaccine Laboratory. His experiments were confirmed on a large scale by the Army Medical School. His recommendations have for some time been generally accepted, and have been incorporated into current practice with respect to most bacterial vaccines.

A useful bacterial vaccine must be effective and must be safe. Effectiveness seems to be most nearly achieved when the bacterial antigen is present in the form found in the living bacterium. The use of a live bacterial vaccine violates the requirement of safety, so that methods of killing the bacteria must be used that will alter as little as possible the character of the bacterial antigen. For many years heat has usually been relied on for this purpose, although chemicals have been employed more or less widely. Recently irradiation with ultraviolet light has been studied, and to some extent this appears to be more promising than any other measure yet devised. Regardless of the method employed with whole-organism vaccines, it is believed that no more than the minimum dose effective for killing should be used; and even this may be enough to affect the antigen more or less deleteriously.

An entirely different approach to the problem of vaccine production is the attempt to isolate the antigen from the bacterial cell by chemical methods. This is undoubtedly the method most to be desired, for theoretically it provides pure antigenic substance free of extraneous material, and permits determination of dosage in terms of weight of the pure sub-

stance without the necessity for resort to more or less cumbersome bioassays. Furthermore, the pure antigens are probably more stable, at least in concentrated or dry form, than are the corresponding bacterial suspensions. Success in isolating more or less pure antigens has been attained in the case of the typhoid bacillus and, more conspicuously, with the pneumococcus, although in neither instance has the antigen been widely adopted for use. It seems likely, however, that further development of vaccines will follow along this line.

It might have been appropriate to begin the discussion of vaccines with those made from viruses, since historically a virus vaccine — that protecting against smallpox — was the first to be generally used. This particular vaccine, however, has undergone very little change in recent years, and except for relatively minor technical improvements is made essentially as it was forty or more years ago. Smallpox vaccine is obtained by the inoculation of the skin of calves with vaccinia virus and subsequent harvesting of the resultant vesicles. Rabies vaccine is obtained by propagating the virus in rabbits and removing the spinal cords, rich in virus, when the animal shows pronounced symptoms of the disease. Other viruses, too, could for many years be propagated only by inoculation of susceptible animals; and if vaccines were to be made they must represent suspensions of the appropriate animal tissues. For some of the virus diseases, such as chicken pox, vaccination would hardly seem worth while even if it were available, for these particular diseases are usually mild; and for others, no suitable susceptible animal is known.

The most striking advance in recent years was the discovery that many viruses can be grown in chick embryos. The most favorable site and time of inoculation and the part of the embryo in which the virus develops most luxuriantly depend on the particular virus. Although many viruses and rickettsias can be grown in this way, some cannot, so that it is still not possible to develop a vaccine against any and every type of virus. The most extensively used of the chick-embryo vaccines are those for yellow fever and for louse-borne (epidemic) typhus fever. Both these vaccines have been used on a large scale by the Army as well as in civilian groups, and the results have been excellent. There is also in preparation a vaccine against influenza, Types A and B, which it is hoped to have available for military use in the event of an outbreak of influenza. It is to be expected that similar vaccines against other diseases due to viruses will come into more or less extensive use, for there are strong indications that they will have value. Some of these diseases, such as St. Louis encephalitis, are relatively rare, so that vaccines against them may not be widely used even if they become available.

One thing that may curtail the use of vaccines derived from chick embryos is the possible develop-

ment of egg sensitivity in persons inoculated with these vaccines. The possibility of its occurrence has been noted and a case report has been published, but there has so far been little in Army experience to indicate that this is a serious danger. It should not be overlooked, however, that the danger might be increased if the use of such vaccines became general or were extended to the younger age groups.

Another group of prophylactic biologic products deserving of mention comprises the toxoids. Bacterial toxins are ordinarily too poisonous to permit their use as antigens in human beings, the permissible doses being too small to be effective. This is conspicuously true in the case of diphtheria and tetanus. It is relatively easy to destroy their toxicity with formaldehyde without any great destruction of antigenic efficiency. Diphtheria toxoid prepared in this way came into general use in this country in about 1930. The fact that three doses were ordinarily required to produce satisfactory levels of immunity led to the adoption of toxoid precipitated on alum. Not only is such a precipitate a more effective antigen than the unprecipitated toxoid, but the process also eliminates extraneous constituents of the basic material.

Although toxoids are in general reasonably free from undesirable side reactions, diphtheria toxoid and, less frequently, tetanus toxoid may give rise to marked but transient local or general reactions. It has also been found that tetanus toxoid may give rise to reactions of the anaphylactic type, but this difficulty was definitively traced to the use of certain peptones in the medium in which the toxin was produced. These reactions stimulated interest in the use of mediums of known chemical constitution for toxin production, for such mediums contain only substances of relatively low molecular weight and are therefore nonantigenic. The first successful step in this direction was the adaptation by Pappenheimer at the Antitoxin and Vaccine Laboratory of the medium devised by Mueller at Harvard for the growth of diphtheria bacilli. This medium has been in routine use for several years and has yielded high-grade toxin of uniform quality. Equally successful results have not been obtained with tetanus toxin production, but advances have been made. It is undoubtedly in this direction that further improvements will follow.

An outgrowth of the production of diphtheria toxin on a medium of known composition was the isolation of essentially pure diphtheria toxin by Pappenheimer. This was previously done by Eaton, but there was uncertainty of his complete success because of the complex nature of the medium. Actually, Eaton's preparations were excellent. The use of toxoids made from pure toxins has not as yet been practically applied, for the ordinary commercial preparations of both diphtheria and tetanus toxoid have been in general quite satisfactory; but the possibility of using pure preparations is one that may in the future become of increasing importance.

One other trend in current practice is worth mentioning. So many definitely useful prophylactic agents are now available that innumerable injections would be given if advantage were taken of all of them. Therefore a number of combined preparations have been proposed, and several have been more or less generally adopted. Diphtheria and tetanus toxoid together or mixed with pertussis vaccine have been employed in pediatric practice, and a combination of tetanus toxoid with typhoid-paratyphoid vaccine has found some favor for military use. Opinion has at times been divided concerning the efficacy of antigens simultaneously administered, but there seems to be little difference between the results from giving them separately and giving them together, at least when the number of antigens is limited to two or three. The use of such combinations may be expected to increase.

Since this is a celebration of the fiftieth anniversary of the Antitoxin and Vaccine Laboratory as well as of the seventy-fifth anniversary of the Department of Public Health, I should like in closing to call attention to the fact that the laboratory has played a not inconsiderable part in shaping the trends that have been described. This has been possible largely because of the close association of the laboratory with the other scientific institutions in Boston, notably with the Harvard Medical School. Nowhere in this country is there the favorable situation existing here, with a state laboratory actively engaged in the manufacture of biologic products located so close to first-rate medical schools. Let us hope that the future will see the continuance of this mutually profitable association.

ENGINEERS AND ENGINEERING IN THE MASSACHUSETTS STATE BOARD OF HEALTH*

GORDON M. FAIR†

CAMBRIDGE, MASSACHUSETTS

THE story of public health in its modern implications, like that of other great social reforms, is the story of great men whose convictions and leadership, wisdom and toil, temporary failure and ultimate success fashioned a pattern of public opinion that could not be denied and that has left its imprint on a century of human existence.

The public-health movement as it is seen today had its roots in the Industrial Revolution of the nineteenth century. Industry, the child of scientific discovery and invention, created the opportunity for mass employment. In the early stages of industrial development, limitations on the transmission of power and the need for a nearby labor market forced the herding together of people in houses that clustered about the factories. To meet the rapid influx of workers, these mushrooming communities often could not expand their facilities fast enough to satisfy new and often frightening sanitary needs. In particular did the need for more abundant distribution of water, for more effective disposal of human wastes and for more adequate housing force itself on the attention of thoughtful men whose duties, associations or interests brought them into contact with the suffering of the masses of the people.

We can understand, therefore, why engineers were engaged from the very beginning in the modern public-health campaign. The example for so doing was set in England during the great sanitary awakening of the middle-nineteenth century. There Sir Robert Rawlinson was employed by the General Board of Health in 1848 as superintendent inspector, and in this capacity conducted the engineering studies necessary for the construction of sanitary works in growing industrial Britain. The real genius of British public health and the originator of many of its engineering advances, however, was Sir Edwin Chadwick. There is no gainsaying that the main threads of public-health progress in Great Britain tie back to him. In the United States, these threads, too, can be traced to a single man, Lemuel Shattuck, like Chadwick neither a physician nor an engineer, but an enthusiast for sanitation. What Shattuck¹ reports a London periodical of December, 1849, as saying about Chadwick would seem to apply equally well to Shattuck himself:

He was not a man of varied or profound attainments, nor distinguished by any extraordinary brilliancy of intellect. But he was remarkable for his sagacity in extract-

ing from masses of detail the master facts, and bringing these to bear for the elucidation of a master thought. He would confront, undaunted, any amount of intellectual labor, exploring mountains of blue books and statistical returns till he had fully ascertained and brought to light their true riches.

Shattuck's "Report of a General Plan for the Promotion of Public and Personal Health" was presented to the General Court of Massachusetts on April 25, 1850. His conclusions were based on intensive studies of the sanitary movements abroad and at home. Because of the similarity in social background of the two countries, British experience, above all, influenced Shattuck's plan for a sanitary survey of the Commonwealth. Among the measures advocated in this plan were the establishment of a general board of health, composed so far as practicable "of two physicians, one counsellor-at-law, one chemist or natural philosopher, one civil engineer, and two persons of other professions or occupations; all properly qualified for the office by their talents, their education, their experience and their wisdom."² Two reasons were given why the members should not be selected exclusively from one profession. In the first place, Shattuck anticipated that numerous questions, requiring a knowledge possessed by different professions, would be presented for discussion and decision. Second, the promotion of public health, in Shattuck's mind, was a matter that concerned every profession and every person. The services of medical men were indispensable, but the services of other professions, and of every person in their respective spheres, must be put in requisition before reform could be complete.

The civil-engineer member of the proposed board, Shattuck³ suggested, should possess "competent knowledge to determine the best methods of planning and constructing public works, and the best architectural sanitary arrangements of public buildings, workshops and private dwelling-houses."

Although nineteen years elapsed before the Massachusetts State Board of Health was established and five more before John C. Hoadley, of Lawrence, was appointed engineer member of the board, this recommendation of Lemuel Shattuck's seems to be the American wellspring of engineers in public health. About Hoadley, who served from 1874 to 1882, it is known that he began his career as a civil engineer on the enlargement of the Erie Canal and was later placed in charge of locating, constructing and installing textile mills in Massachusetts. In the course of time, his work with textile machinery turned him away from the field of civil engineering to that of mechanical engineering, in

*An address given at the seventy-fifth anniversary of the Massachusetts Department of Public Health, Boston, December 6, 1944.
†Abbott and James Lawrence Professor of Engineering, and Gordon McKay Professor of Sanitary Engineering, Harvard University.

which he became expert. This shift in interest may explain why he did not provide the engineering leadership that he might have exerted in the new board. An examination of the scientific articles and reports published in the regular series of annual reports shows but two articles over Hoadley's signature. During the same years the medical members of the board were, indeed, more active in discussing engineering topics than was the engineer member himself. The board, however, employed as consultants some of the outstanding civil engineers of the period, in particular James P. Kirkwood, who was the first American engineer to build a filtration plant for water purification, and E. S. Cheshbrough, who was to become celebrated for his designs of some of the great sewer systems in the United States.

Investigations of the board that involved problems of chemistry were generally assigned to Professor William R. Nichols, of the Massachusetts Institute of Technology. Nichols, thereby, became the pioneer American water chemist. That the services of a chemist would be needed had been foretold, too, by Shattuck,³ who wrote: "Many questions relating to the influence of the elements on the production or prevention of disease may require the special investigation of an experienced chemical philosopher, and this important branch of science should be ably represented at the Board."

It is a happy coincidence that in 1869, the year in which the Board of Health was organized, there was appointed as chief engineer of the Essex Company in Lawrence one Hiram F. Mills, then thirty-one years of age, for as we shall see the destiny of each was to be deeply influenced by the other. Mills was one of the first graduates of an American school of engineering, the Rensselaer Polytechnic Institute. He had worked with Kirkwood and also with Charles S. Storow and James B. Francis, chief engineers respectively of the Essex Company in Lawrence and the Merrimack Manufacturing Company in Lowell. These men were the leaders of hydraulic engineering in the New World. With the examples of Francis and Storow before him, Mills early determined to prepare a treatise on hydraulics, and set about gathering the necessary experimental information. When he became chief engineer of the Essex Company, which owns the dam and canal on the Merrimack River at Lawrence and controls the water needs of the manufactories, the opportunity presented itself to build a laboratory in which he could and did conduct his contemplated hydraulic researches. John R. Freeman, himself to become an engineer of distinction, was Mills's principal assistant for many years and has commented on "the rare devotion of Mr. Mills to the search for scientific truth and the deep insight, the untiring earnestness, and the consummate skill with which he carried on observations."⁴ This talent for research Mills carried with him when he was appointed a member

of the State Board of Health in 1886, a fact that is probably responsible for the remarkable service that engineers, chemists and biologists were able to perform for the Commonwealth under his leadership. Of Mills's association with the board, which had been reorganized in 1886 under the chairmanship of Dr. Henry P. Walcott, Freeman writes as follows:

His profound interest and zeal as an investigator were then awakened to the importance of advancing scientific knowledge in matters of purification of public water supplies and of prevention of stream pollution, and for about twenty-eight years this work of one kind and another for the Massachusetts Board of Health, for which he received no pecuniary compensation, absorbed a majority of his time, to the neglect of his earlier investigations in hydraulic science. . . .

Later, when in partial retirement long after he had passed three score and ten years he resumed this earlier task, failing strength prevented his continuing these hydraulic investigations or discussions on the scope originally planned.⁵

Mills at the age of eighty years told Freeman with much feeling that he "had put off this work too long." Nevertheless he collected his many notes and from day to-day, up to his eighty-fourth year, worked over them patiently and steadfastly as many hours as his strength would permit, declining the assistance of younger eyes and hands. Although he did not complete his notes for publication, they were made available to the profession by Karl R. Kennison,⁴ now chief engineer of the Boston Metropolitan Water Supply, as a memoir of the American Academy of Arts and Sciences in 1924, three years after Mills's death.

But let us return to the memorable year of 1886. Along with the reorganization of the State Board of Health there was passed in that year a very important act of the Legislature, entitled "An Act to Protect the Purity of Inland Waters."

Briefly, this act placed in the hands of the State Board of Health the general oversight and care of all inland waters, directed that examination of the waters be made to ascertain whether they were adapted for use as sources of domestic supply or likely to imperil the public health, and that recommendations be given as to the prevention of pollution. Authority was given to employ expert assistance, and to conduct experiments to determine the best practicable methods of purification of sewage or disposal of manufacturing refuse. The Board was also ordered to give advice to cities and towns, corporations and individuals as to sources of water supply and methods of sewage and refuse disposal, without expense to persons advised. Provision was also made for the submission to the Board of all plans and schemes in relation to water supply and the disposal of drainage or refuse, for its advice. And, finally, the Board was ordered to bring to the notice of the attorney general all instances of violation of the laws respecting the pollution of water supplies and inland waters.⁵

To carry out the provisions of this act, an engineering department was created in the State Board of Health, with Joseph P. Davis as consulting engineer, Frederick P. Stearns as chief engineer and X. H. Goodnough as assistant engineer. Davis had been chief engineer of the Cochituate Water Board,

the City of Boston and the Boston Main Drainage System, and so brought to his consulting work a wealth of experience. Stearns directed the Engineering Department during its formative years, and would probably not have relinquished his position to become chief engineer of the Metropolitan Water Board, which constructed the Wachusett water supply for the Boston Metropolitan District, had this enterprise itself not been one of the great projects of the State Board of Health. Goodnough succeeded Stearns in 1895 and, on his retirement in 1930, passed on the reins of the Engineering Department to the present incumbent, Arthur D. Weston.

Along with the development of an engineering staff, the Act to Protect the Purity of Inland Waters had made available funds for the systematic analysis of water. This permitted drawing into close association with the engineers a notable group of chemists and biologists, some of whom were on the faculty of the Massachusetts Institute of Technology, in whose laboratories the analytical work was performed until 1896, when a water laboratory was set up in the State House. In order to conduct experiments to determine the best practicable methods of purification of sewage or disposal of manufacturing refuse, Mills placed at the disposal of the State Board of Health his hydraulic laboratory at Lawrence, about which we have already heard. This laboratory was renamed the "Lawrence Experiment Station" and has continued its useful existence ever since. As a laboratory for sanitary research, this station was the first of its kind, and its influence on the progress of sanitary engineering cannot be overestimated. To staff the station, Mills drew heavily on young graduates of the Massachusetts Institute of Technology who had come under the influence of teachers who were then active in the chemical and biologic investigations of the State Board of Health.

Thus was initiated a decade of sanitary investigation the like of which has never been seen again in Massachusetts or anywhere else in the world. With the support of Dr. Walcott, and unified in their objectives by Mills's broad conception of what was needed in the task ahead, the Engineering Department, the Water Laboratory and the Experiment Station collaborated with imagination and zeal to initiate great engineering enterprises, lay the foundation for sanitary analysis and establish the experimental method as a means for determining the scientific and economic basis of public sanitation. The association of young men in this great adventure in sanitation appears to have been mutually so inspiring that there was to be hardly a man among them who did not make a significant contribution to the advancement of knowledge during his stay with the board and who did not, as well, make a name for himself in later life.

A list of these men would include among others the names of Thomas M. Drown, chemist, successor to Professor William R. Nichols at the Massachu-

setts Institute of Technology and later president of Lehigh University; William T. Sedgwick, biologist, later professor of biology at the Massachusetts Institute of Technology; Allen Hazen, engineer investigator, later one of America's greatest practitioners; George W. Fuller, chemist, who later at Louisville, Kentucky, laid the foundation for rapid sand filtration; Gary N. Calkins, biologist; later professor of protozoology at Columbia University; Edwin O. Jordan, bacteriologist, later professor of bacteriology at the University of Chicago; and Harry W. Clark, chemist, later director of the Water Laboratory and the Lawrence Experiment Station.

Notable among the great engineering enterprises of the group were the investigations that produced the Metropolitan Sewerage System of Boston, the Metropolitan Water Supply of Boston and the Charles River Basin, public works that satisfied the highest standards of engineering achievement and that continue to serve their intended function with success and distinction.

Many of the early studies of water purification and sewage treatment at the Lawrence Experiment Station are counted among the classics of sanitary engineering literature. Some of them, in fact, were so fundamental and so well conceived that they have continued to be reprinted in books on sanitary engineering for half a century. The Lawrence Experiment Station eventually became a mecca for engineers, chemists and biologists interested in the purification of water, the treatment of sewage and industrial wastes and the control of stream pollution. The visitors' book of the station is a veritable "Who's Who in Sanitation throughout the World."

The fundamental organization of state sanitation initiated in 1886 has continued up to the present time. The Department of Public Health has undergone two major reorganizations, those of 1914 and 1919, but the Engineering Division itself has pursued the even tenor of its ways with little deviation from its original aims and objectives except as expanding interests have brought new and varied problems to its staff for solution. In the course of time, the Engineering Division has built up a record of service and a background of legal justification that are unique in public enterprise.

The co-operation between the Engineering Division, the Water Laboratory and the Lawrence Experiment Station, which had been so fruitful during the early years of their existence, was allowed to become less close for a number of years. This worked particularly to the disadvantage of the Experiment Station, which lacked the challenge of engineering problems to be solved in practice. During this period some of its investigations appear to have been less well conceived and executed, as well as less productive of useful results. This situation was remedied some years ago, and there are signs that the station is on the way to recapture the fame and

usefulness that it acquired during its first score of years.

The powers of the Division of Sanitary Engineering have been advisory, in accordance with the general policy of the Department of Public Health. Only in times of severe stress has the "grammar of common sanitary legislation acquired the novel virtue of the imperative mood."⁶ In this has probably lain the greatest incentive of the division for service. Throughout its existence, the counsel of the division has been sought as originally contemplated, and the record of applications for advice is one of steady growth. The construction of sanitary works in the Commonwealth has borne a direct relation to the activities of the division. This is exemplified by the progressive introduction of public water supplies. Prior to 1869 there were only seventeen such supplies in Massachusetts; by 1890 this number had increased to one hundred and thirty-eight; and by 1940 the 256 public water supplies of the Commonwealth served no less than 97 per cent of its total population. That these constructions were justified is shown by the declining annual death rate from typhoid fever. In 1873 this rate was 89 per 100,000 population; by 1890 it had dropped to 37, and by 1940 to 0.2.

Such is the story of engineering and its ancillary services within the Massachusetts State Board of Health. Needless to say, the work done has paid for itself over and over again in lives saved and sickness avoided, as well as in the general comfort and well-being of the people of Massachusetts. The influence of this pioneer engineering organization in a public-health department, however, has extended far beyond the borders of the State and, indeed, beyond the boundaries of the Nation. The published reports of the board became one of the most important sources for sanitary information, and young engineers trained in the Engineering Division carried its spirit and its methods with them when they left to join or organize the engineering divisions of other health departments, to take part in the design and construction of great sanitary works or to become teachers of sanitation in schools of engineering and schools of public health.

When Hiram Mills followed the injunctions of Lemuel Shattuck in his attack on the fundamental problems of environmental control by putting in requisition the services of other professions in their

respective spheres, he created, in fact, a new and important discipline of public health as well as engineering and a career to be embraced by young engineers who, like Chadwick and Shattuck, could become enthusiasts for sanitation. Collaboration in sanitary research for the solution of basic engineering problems established above all the desirability of equipping engineers with a knowledge of chemistry and biology, and the study of these subjects has since become a heritage of sanitary engineers in America. The challenge that engineers could build disease or health into their works could either be turned aside by relegating responsibility for public-health decisions to other professions—as was done and has very largely continued to be done abroad, and I may add with less success—or it could be accepted by acquiring an adequate fund of information to be able to evaluate the public-health factors concerned. The engineers of Massachusetts chose to shoulder the responsibility themselves and so to play a significant part in the sanitary control of the human environment by engineering means.

After reviewing these contributions of Massachusetts to public health, I can find no more fitting expression for my own admiration of her accomplishments than is suggested by the last paragraph but one of Lemuel Shattuck's report wherein, after enumerating the many ways in which Massachusetts has stood for social progress, he says:⁷

For these and very many other useful and honorable deeds, which might be specified, she has been named, by distinguished men of other states and countries, "the forefather's land," "the moral state," "the enlightened state," "the patriotic state," "the philanthropic state," "the leading state," "the pattern state," "the noble state," "the glorious old Bay State."

And may I be permitted to add, "the birthplace in America of public health and with it of the engineer in public health."

MEDICAL PROGRESS

THE CLINICAL IMPORTANCE OF THE RH BLOOD TYPE*

LOUIS K. DIAMOND, M.D.†

BOSTON

IN the five years that have elapsed since the Rh factor in human red cells — better known as the Rh blood type — was first discovered, there has been a steadily increasing volume of literature on this subject. In the past two years alone, more than two hundred such articles have appeared in medical journals. Many of these have been concerned with the laboratory aspects of Rh typing, Rh antisera, nomenclature and the heredity of the possible subtypes of the Rh factor, thus suggesting to some physicians that this new field has in it relatively little of clinical value. On the other hand, many more articles have described particular patients and have elaborated on and drawn sweeping conclusions from single case reports of transfusion accidents, of pregnancy difficulties or of anemia in newborn infants. As a result of the latter, the idea has grown that the Rh factor and Rh incompatibility account for many blood transfusion reactions, for most late stillbirths or even early abortions and for all jaundice and anemia in early infancy.

The truth concerning the practical clinical importance of the Rh blood type lies somewhere between the extremes of these two points of view. There now is sufficient and convincing proof of the role of this new blood type in hemolytic transfusion reactions, in certain complications of pregnancy and in neonatal anemias. It is not valid to assume that it accounts for almost all such cases, especially those in which clinical data are incomplete and laboratory confirmation is absent.

In reviewing case reports and experiences with Rh typing and Rh agglutinin detection in the past, some reasons for misinterpretation and confusion become apparent. At first, serum produced experimentally in guinea pigs or weak varieties of human anti-Rh serum were chiefly used for Rh determinations. Because of the poor avidity (slow development of agglutination) and low potency of such serums, weak reactions were often obtained. Also it was not generally appreciated that blood cells vary in their agglutinability with anti-Rh serum, some exhibiting rather weak clumping. In addition, the agglutination reaction tends to become weaker as the cells are stored, even for as little as one or two days. Finally, vigorous shaking of the clumped cells may sometimes break up the agglutinates and thus yield false negative results. The

use of avid, potent serums has produced accurate and valid results.

The difficulties of detecting Rh sensitization by demonstrating anti-Rh agglutinins also were not fully appreciated. The resulting failures of laboratory confirmation of Rh incompatibilities and Rh sensitization detracted from the value of clinical material. Also, since relatively few laboratories were equipped with Rh typing serum and technical experience in demonstrating Rh agglutinins, the patients thought to be suffering from sensitization to the Rh factor could not always be studied in their own hospitals, and valuable clinical observations were not correlated with the laboratory data.

Now that potent and rapidly acting Rh typing serums are more readily available, that technics for testing for the Rh factor and for evidences of Rh sensitization are better understood and standardized and, finally, that clinical correlation on much larger numbers of patients is possible, the practical importance of the Rh blood factor should be clearly evident. The basis for this summary of present knowledge is a critical review of the readily available literature on the subject and the large number of experiences and the large volume of data gathered in the past three years in a single laboratory.‡

THE RH FACTOR

The Rh factor in human blood cells, or the Rh blood type, was first discovered by Landsteiner and Wiener¹ in 1940 as the result of their experimental studies of agglutinins developed in guinea pigs and other experimental animals against the red cells of the rhesus monkey. One of the agglutinins was found to act on bloods of 39 of 45 human subjects. The agglutinin was therefore named the "Rh factor" because it had been found first in the cells of the rhesus monkey. Human cells agglutinated by the anti-rhesus (anti-Rh) serum were designated as Rh+ (Rh positive), and those not agglutinated as Rh- (Rh negative).

The following year the same workers² proved that the Rh factor was present in the red cells of about 85 per cent of the white population (Rh+ persons) and absent in about 15 per cent (Rh- persons). Subsequently, human anti-Rh serums having a wider range of reaction were used to type larger groups of

*From the Department of Pediatrics, Harvard Medical School, the Infants' and Children's Hospital, and the Blood Grouping Laboratory, Boston.

†Assistant professor of pediatrics, Harvard Medical School; visiting physician, Infants' and Children's Hospital; consultant in hematology, Boston Lying-in Hospital; and director, Blood Grouping Laboratory.

‡The Blood Grouping Laboratory was formed in 1942 under the sponsorship of the Boston Lying-in Hospital, the Children's Hospital, the Massachusetts Memorial Hospitals and the Massachusetts General Hospital, for the purpose of performing accurate blood grouping, Rh typing and anti-Rh determinations on the patients of these hospitals and of collecting and preparing Rh typing serum for use locally as well as in outside hospitals needing it. At present, the laboratory averages five hundred Rh tests and fifty anti-Rh determinations per week.

individuals of different racial background. It seems to be well established now that slightly more than 87 per cent of the white population is Rh+, and less than 13 per cent is Rh-. In typing persons of the Negro race, it has been found that about 90 to 95 per cent are Rh+,³ and in the Chinese and the American Indian 99 per cent are Rh+.⁴⁻⁶ Numerous excellent papers have reported on the racial distribution, the inheritance and the subtypes of the Rh factor.⁷⁻²⁰ As a general rule, sensitization to the Rh factor, with the exception mentioned below, occurs only in Rh- individuals. Such persons become immunized against this Rh agglutininogen by means of one or more transfusions of Rh+ blood, or such women by one or more pregnancies involving Rh+ infants.

The exception to the above statement, that sensitization to the Rh agglutininogen occurs only in Rh- subjects, has been demonstrated in about half a dozen cases by us and by Wiener.²¹ Occasionally an Rh+ individual may become sensitized and develop immune bodies against an Rh agglutininogen. This has been found to be dependent on the presence of subtypes of the Rh factor, several of which have been identified by Wiener and by Race and Taylor. In these rare cases, sensitization of an Rh+ woman whose blood belongs to one subtype of the Rh factor (as, for example, Rh₁ or Rh₂) occurs through pregnancy or, more frequently, after transfusion with Rh+ blood of her husband whose blood cells belong to another subtype. Agglutinins may then develop against the Rh fractions foreign to the woman. Subsequently, transfusion reactions or hemolytic disease in a fetus having the same Rh fraction as was used for the transfusion may occur. Such cases, which may be confusing and difficult to resolve by ordinary Rh testing, are fortunately extremely rare. Much more frequently, Rh determinations of persons involved in intragroup hemolytic transfusion reactions show that the recipient of the transfusion is Rh-, and the donor Rh+, and that previous transfusions of unknown or definitely Rh+ blood caused the immune response. Or, in cases of erythroblastosis fetalis the mother is Rh- and the father and child Rh+, with antibodies in the mother against the Rh factor developing as the result of one or more previous pregnancies involving an Rh+ infant.

INTRAGROUP TRANSFUSION REACTIONS

As mentioned above, the typical case of transfusion reaction due to Rh sensitization involves an Rh- recipient who received two or more transfusions of Rh+ blood over an interval of time sufficient to permit the development of antibodies. A typical case history follows.

CASE 1. *Hemolytic reaction following repeated transfusions of Rh+ blood.* A 26-year-old woman, with recurrently severe anemia secondary to menorrhagia, in 1939 received a 500-cc. transfusion from her husband (Donor 1) and 3 days

later a 600-cc. transfusion from her brother-in-law (Donor 2); neither was followed by a reaction. Six months later she was given another transfusion from Donor 1, which was interrupted at 300 cc. because of pain in the flanks and dyspnea; subsequently hemoglobinuria developed. Two days later she received a 600-cc. transfusion from her sister (Donor 3), without reaction. One week later, another transfusion from Donor 2 was begun. This was interrupted after only 200 cc. because of severe dyspnea and signs of shock; anuria and jaundice appeared within 24 hours. One day later she received a 600-cc. transfusion from her brother (Donor 4), without reaction. In 1941, she was given two transfusions, totaling 1300 cc., from professional donors (Donors 5 and 6), without reaction.

Blood typings were as follows: patient, Group 0, Rh-; Donor 1, Group 0, Rh+; Donor 2, Group 0, Rh+; Donor 3, Group 0, Rh-; Donor 4, Group 0, Rh-; Donor 5, Group 0, Rh-; and Donor 6, Group 0, Rh-. Anti-Rh agglutinins were eventually demonstrable in the patient's serum.

This girl required multiple transfusions because of repeated blood loss over a period of more than two years. The first two transfusions, from her husband and from his brother, were given with no untoward results. Six months later, however, another attempted transfusion, again using the husband as donor, produced signs of incompatibility. An attempted transfusion from the second donor produced even severer signs of hemolytic reaction. In the interval, transfusions from the patient's own blood relatives were uneventful. The following year, two transfusions from professional donors, chosen because of their Rh- quality, were administered with no reaction. This patient's course of transfusion reactions was indeed puzzling, since homologous group blood produced serious reaction after a former successful transfusion from the same donor. Only by differentiation on the basis of the Rh testing was the cause of the difficulty revealed.

Another patient whose history is typical of that of many cases of chronic anemia is illustrated by the following case.

CASE 2. *Hemolytic reaction following repeated transfusions of Rh+ blood.* A 42-year-old man with aplastic anemia was given three transfusions within a week, following which his hemoglobin level rose from 35 to 80 per cent. Three months later, he received two more transfusions in rapid succession. These were followed by chills and fever. His hemoglobin level rose from 45 to only 50 per cent. After a week, another transfusion was given; this produced a severe chill, fever, hemoglobinuria and, the next day, mild jaundice. The hemoglobin fell to 30 per cent after this treatment. Blood studies revealed that the last donor used was Group 0, Rh+. The patient was also Group 0 and apparently Rh+, since some clumps of cells were visible, grossly, in the test of his red cells with anti-Rh serum. Microscopically, however, it was evident that only a few red cells were strongly clumped and that most of them were free and unagglutinated. This strongly suggested that the blood cells were mixed. An anti-Rh test of the patient's serum was negative.

Three transfusions, from Rh- donors, were given with no untoward reaction, and the hemoglobin rose from 30 to 85 per cent. Two weeks later, the patient was retyped, and his cells proved to be Rh-. Anti-Rh agglutinins were then demonstrable in his serum. Subsequently, more than twenty transfusions of Rh- blood were administered, with no untoward reactions.

This patient responded favorably to three transfusions, given within a week, of compatible, homologous blood. Three months later, two transfusions of similar blood were given with the development

of chills and fever and the failure of a satisfactory hemoglobin response. About two weeks later, another transfusion of satisfactorily cross-matched blood produced even more serious symptoms of a hemolytic transfusion reaction, with chills, jaundice, hemoglobinuria and a fall in hemoglobin level. At that time, blood grouping and typing proved that the last donor used was Rh+; gross examination of the test tube containing the patient's cells and anti-Rh serum showed some clumping, which suggested an Rh+ reaction. Microscopic examination, however, showed that there were few clumped cells and that most of the cells were unagglutinated. This suggested that the patient's blood was Rh-, with some Rh+ cells from the donor still circulating in his system and agglutinable by the testing serum used. The patient's own serum failed to show any anti-Rh agglutinins. Because of the probability that the patient was Rh-, three transfusions of Rh- blood were given with no untoward reaction and with a satisfactory response in hemoglobin level. Two weeks later, by which time the donor's cells that originally caused the reaction were presumed to have been entirely destroyed, the patient's blood was retyped and was found to be Rh-. The serum of the patient showed the development of anti-Rh agglutinins, which had had a chance to reaccumulate in the elapsed time. Subsequently, this patient received numerous transfusions of Rh- blood with no untoward reactions.

This type of case is not infrequent in a patient who requires multiple transfusions. At first, there may be benefit from the infused cells, but subsequently more and more signs of untoward reactions develop and the treatments become less satisfactory. Because of this, it was assumed that patients with chronic or recurrent anemia from repeated blood loss, leukemia, aplastic or hemolytic anemia were peculiar in their tendency to suffer transfusion reactions. It is now realized that many of these patients probably had been sensitized by the use of blood containing an agglutino-gen foreign to the recipient, and the development of agglutinins against this blood type interfered with future use of similar blood. With precautions, not only for Rh type but also for the subtype of the A blood group, such reactions in patients requiring multiple transfusion over a long period of time can now be minimized.

That such agglutinins may remain in the recipient's system for many months or even years has now been demonstrated in other patients.²² One patient studied by us, who had received several transfusions eight years before and two transfusions twelve years before, developed signs of a hemolytic transfusion reaction when retransfused with Rh+ blood.

The occasional brief period that may elapse between initial stimulation from an Rh+ transfusion and the development of anti-Rh agglutinins is illustrated in the following case.

CASE 3. Hemolytic reaction following repeated transfusions of Rh+ blood. A 14-year-old boy with hemophilia suffered recurrent bleeding from the gums requiring four transfusions on four successive days. These produced an increase in hemoglobin level from 25 to 60 per cent. One week after the first transfusion, and only 4 days after the last, two more transfusions were necessary because of severe hemorrhage. After the second, the patient complained of feeling chilly, had abdominal pain, passed a small amount of bloody urine and then no further urine for 24 hours. His hemoglobin rose from 50 to only 60 per cent. The next day there was slight jaundice.

Blood typings showed that the last donor was Group A, Type M, Rh+. The patient was Group A, Type MN, apparently Rh+, since gross clumping was visible in the test tube. Microscopically most of the cells were unagglutinated. This suggested a mixture of positive and negative blood in the patient's circulation. His serum showed no anti-Rh agglutinins.

The next day two more transfusions were administered from donors who were Group A, Type N, Rh-, with no untoward reaction, and the hemoglobin rose from 40 to 75 per cent. One week later, on retyping, the patient's blood cells were found to be Group A, Type N, Rh-, and his serum contained demonstrable anti-Rh agglutinins.

This boy with hemophilia required four transfusions because of serious blood loss from continued oozing from the gums. One week after the first transfusion and only four days after the last of a series, two more transfusions were given in succession, with evidence of an increasing hemolytic reaction at the end of the second transfusion. Blood typing at that time proved that the last donor used was Rh+, Group A, Type M. The patient appeared to be Group A, Type MN, and apparently Rh+, although under the microscope it was evident that most of the cells were unagglutinated. It was therefore presumed that some of the last donor's blood was still present in the recipient's circulation. The patient's serum failed to show any demonstrable agglutinin against the Rh factor. The following day two transfusions from Rh- donors were given with no untoward results. Nine days after the transfusion reaction, retyping of the patient's cells proved him to be Group A, Type N, Rh-. Therefore, the grouping carried out shortly after the transfusion reaction, which had identified the recipient's cells as belonging to Type MN, Rh+, was in fact performed with a mixture of the donor's Type M, Rh+ cells and the recipient's Type N, Rh- cells. After this last examination, the patient's serum demonstrated anti-Rh agglutinins. Antibodies against the Rh factor may develop in an Rh- recipient within a week, and these may subsequently cause a hemolytic transfusion reaction.

These experiences demonstrate that it is necessary to keep in mind that immediately after a relatively mild transfusion reaction the recipient's circulation may contain a mixture of donor's and recipient's blood cells, and that only careful examination of the results obtained by grouping and typing will disclose whether or not the patient is Rh+. Obviously such a reaction can only be found if the patient's serum contains a very weak agglutinin that fails to destroy all the infused cells.

Numerous cases of intragroup transfusion reaction with signs of hemolysis are now to be found

in the literature.²³⁻³⁸ That the Rh factor is important and that Rh incompatibility between donor and recipient is the probable cause of most of these accidents have been amply proved. In our study of transfusion reactions in 32 patients in whom hemolysis was evident, it was found that errors in grouping were responsible in 3 cases, the presence of weak A₂ or A₂B agglutinin in the donor's blood in 2, and Rh incompatibility in 27. Thus, it seems likely that 80 to 90 per cent of all hemolytic transfusion reactions can be explained on the basis of Rh incompatibility.³⁹

In view of the widespread establishment of hospital and community blood banks during the last few years, particularly since the onset of the present war emergency, and the much more frequent use of the now readily available whole blood in the treatment of hemorrhage, shock and anemia, one may expect an increase in the incidence of hemolytic transfusion reactions, as a result chiefly of the sensitization of the Rh— persons who in previous transfusions had received Rh+ blood. This is of particular importance to the members of the armed forces, many of whom are given whole blood because of anemia and infection resulting from wounds. In contrast to the use of transfusion in civilian blood banks, where the majority of the patients are given only a single transfusion or a single series within a week or less, in the medical services of the armed forces the recipients often receive repeated transfusions. Hence, these Rh— recipients are much likelier to be immunized through the infusion of Rh+ red cells and, with each succeeding transfusion, to develop increasing signs of blood destruction, which may eventually cause damage to the kidneys. Although such patients do not necessarily develop total anuria, the unpleasantness of the post-transfusion reactions causes bitter complaint, and certainly the patient fails to benefit from the infused blood and the illness may be prolonged by anemia and excessive blood destruction.

It is therefore important that all transfusions be preceded by Rh typing of the recipient and, if an Rh— person is so identified, that only Rh— blood be used. This is particularly desirable when multiple transfusions are contemplated. Only under conditions of dire emergency should untyped blood be used or an untyped recipient be transfused. Even in such cases, blood banks in many of the large hospitals have available Rh— blood to give in transfusions when there is not sufficient time to carry out a complete grouping, typing and cross-matching.

An analysis of the transfusion reactions due to Rh incompatibility in 26 cases in which sensitization was due to previous transfusion shows that the reactions were mild (chills, fever and a decrease in hemoglobin level), in 5, moderately severe (pain

in the back, jaundice and slight hemoglobinuria) in 14 and severe (hemoglobinuria and anuria) in 7. No deaths occurred in this series.

(To be concluded)

CASE 31161

PRESENTATION OF CASE

A seventy-year-old retired dentist entered the hospital complaining of a painful swollen right knee.

Three years before admission the patient came to the Out Patient Department because of a stiff and painful back. At that time he gave a vague story of having had pain and stiffness in the right knee for several years. He was definitely relieved after strapping. Twenty-eight months before entry he fell forward to the ground while gardening. Soon afterward he developed pain in the right loin, radiating to the right thigh and leg. He was most uncomfortable while lying in bed. When examined twenty-seven months before entry the lumbar spine was rigid but not tender. The right knee was limited in extension to 15° flexion. X-ray studies at that time showed marked lumbar lordosis and extensive spurring of the lumbar vertebrae, especially the third and fourth. There were marked osteophytes along the tibial joint surfaces of the right knee. Six months before admission he fell again, which caused stiffness and pain on motion in the right knee. He used a cane to get about. The pain and stiffness increased, and the joint became swollen. Two months before entry he began to use crutches. He had remained in bed for the past three weeks.

Physical examination revealed a thin, well-developed man. The right knee was limited in extension to 70° flexion, with approximately 15° of motion. It was swollen, brawny, warmer than the left knee and mottled red; it was tender and painful on motion. The heart was not remarkable, and the lungs were moderately emphysematous. A bifid coccyx was suspected.

The temperature, pulse and respirations were normal. The blood pressure was 170 systolic, 90 diastolic.

Examination of the blood revealed a white-cell count of 6000, with 68 per cent neutrophils, 22 per cent lymphocytes, 8 per cent monocytes and 2 per cent eosinophils. The urine was negative, the specific gravity being 1.012. The fasting blood sugar was 85 mg. per 100 cc., and the uric acid 4.1 mg.

X-ray films of the lumbar spine showed marked hypertrophic changes, with extensive spur forma-

tion and fusing of spurs between the third and fourth lumbar vertebrae, as well as irregularity of the adjoining surfaces of the bodies. The abdominal aorta showed marked arteriosclerosis. An x-ray film of the right knee showed a marked change compared with the examination two years previously. Considerable destruction of the femoral joint surface was seen. A small fracture line appeared to extend through one of the condyles anteriorly. The joint space was markedly narrowed, and there was considerable soft-tissue swelling, with probable fluid in the joint. All the bones of the joint showed marked decalcification extending well into the condyles. X-ray films of the heart and lungs were negative.

The right knee was put into suspension traction, and the joint was aspirated. Thick pus-like synovial fluid was withdrawn, which contained 34,500 white cells, with 92 per cent polymorphonuclears, 3 per cent lymphocytes and 5 per cent monocytes, and 29,000 red cells per cubic millimeter; there was mucin but no sugar. The cell count was probably inaccurate because the purulent material did not mix well in the counting fluid. A culture showed no growth. The sedimentation rate was 24 mm. in 60 minutes. A tuberculin test in a dilution of 1:100,000 was positive, presenting an 8-mm. area of redness and induration. The serum calcium was 8.8 mg. per 100 cc., the phosphorus 3.3 mg., and the phosphatase 3.1 Bodansky units.

In the forenoon of the fifth hospital day the patient had a sharp transient precordial pain, which radiated at once to the back and then disappeared. A few minutes later he again had severe pain, became markedly dyspneic and pulseless and expired.

DIFFERENTIAL DIAGNOSIS

DR. FRIEDRICH W. KLEMPERER: It is obvious that the terminal episode had no direct correlation to the chief complaint that brought the patient to the hospital. I shall try to discuss the joint disease first.

From the history we learn that the patient was suffering from chronic joint disease involving the spine and right knee. The total duration of the illness is not given accurately, but it certainly was greater than three years. The distribution of pain in the low back and loin and the radiation to the thigh are characteristic of involvement of the lumbar spine. It is the rule to see disappearance of back pain after complete fusion has developed. The involvement of the knee had progressed gradually over the course of years, with an acute exacerbation caused by injury six months before admission. This history of chronically progressive arthritis leads us to a differential diagnosis between chronic infection, such as tuberculosis, and rheumatoid arthritis.

Primary bone tumor seems less likely at this age. Metastatic malignancy might be considered, but of course the story is somewhat long and we have no evidence of a primary lesion. Pyogenic infection

*On leave of absence.

also seems unlikely in view of the lack of acute symptoms as well as the duration. Could he have had a chronic osteomyelitis? I do not believe that this is likely, and the x-ray findings probably rule it out.

The physical findings are indicative of a chronic inflammatory lesion but do not rule out tumor. Again, an acute infectious process is ruled out by the absence of marked tenderness, redness and heat. The laboratory examinations are most helpful. First we hear that the aspirated knee fluid was pus-like and sterile. The fact that it was sterile is further evidence against pyogenic infection. A cell count of 34,500 may be seen in rheumatoid arthritis, although frank pus probably does not occur. Effusions due to tumor probably never show cell counts of this magnitude, and I am inclined to discard the diagnosis of tumor on that basis alone. The absence of sugar, frequently found in the presence of a high white-cell count, is often seen in tuberculosis. The elevated sedimentation rate is only a sign of active disease and not helpful in the differential diagnosis. A positive tuberculin test in a man of seventy is not diagnostic, but the violent reaction at a high dilution is in favor of the diagnosis of active tuberculosis. The phosphatase of 3.1 units serves to rule out such diseases as Paget's disease or tumor with osteoblastic activity. The x-ray films may be helpful.

DR. MILFORD D. SCHULZ: These films taken two years prior to the last admission merely show pronounced proliferative changes. The joint space is quite well preserved (Fig. 1). Two years later the joint space is practically gone, the medial surface of the tibia is partially destroyed, and the bones are quite decalcified (Fig. 2). Although the knee had been painful for two years the decalcification of the femur is not too bad. The spine looks just like that of an old man.

DR. KLEMPERER: Do you believe there is destruction in the area of the spine?

DR. SCHULZ: There is a large spur on the side of one vertebra, and I wonder how much of what we see is not this spur projected upon the vertebral body. In the anteroposterior view one cannot trace the vertebral surfaces.

DR. KLEMPERER: Are these areas of decreased density consistent with destruction?

DR. SCHULZ: They did not change in two years, which is curious if they were due to active destruction.

DR. KLEMPERER: It is obvious that at the time the first x-ray films were taken, two years ago, the patient presented the degenerative changes that a man of seventy is entitled to have, but I believe that there is also evidence of destruction in the spine. He had spurs completely bridging the anterior portions of the vertebrae and causing complete immobilization of the spine. If this was tuberculosis, the fusion due to degenerative changes would explain the lack of progression of the lesion, in analogy to what we see after artificial fusion as a therapeutic

measure. The diagnosis of a destructive lesion in the spine in addition to the apparent degenerative changes is also supported by the clinical symptoms. Severe pain is not usual in straight degenerative

FIGURE 1 Film of Knee Showing Proliferative Changes and Intact Joint Surface.

disease of the spine and always requires another explanation, which in this case would be tuberculosis. The rapid progression of destruction and decalcification of the knee are also not consistent with a diagnosis of rheumatoid arthritis. I have never seen a patient with rheumatoid arthritis who had developed such extensive destruction in only two years without showing involvement of many other joints. I believe that rheumatoid arthritis remains a possibility although not a likely one. The rapidity of progression, the degree of destruction and decalcification of the bones around the knee joint, the localization and the character of the joint fluid are certainly best explained by a chronic infectious process, which in all probability was tuberculosis.

In discussing the terminal episode one must remember that observations made during the last few minutes of the patient's life, frequently by unexperienced observers, are notoriously inaccurate. The only thing one can say with a fair degree of assurance is that this man died an acute circulatory death. The most probable assumption in a man of this age who has been put to bed and whose leg has been kept in suspension is that he had developed a phlebitis of the femoral veins that led to a massive pulmonary embolus. He may also have died from acute coronary thrombosis. I admit that both these diagnoses, particularly the first, are the likeliest

ones on a statistical basis. The history, however, fits another condition so well that I should like to hazard a probable diagnosis of dissecting aneurysm. The patient had been known to have hypertension, and according to the roentgenogram, the aorta was markedly calcified. These two conditions predispose to the formation of a dissecting aneurysm. The story of sudden sharp pain with radiation to the back is particularly characteristic of this condition. The second attack of pain may indicate that at that time the aneurysm had dissected upward and had perforated the pericardium and that the patient died

FIGURE 2 Film of Knee Two Years Later Showing Areas of Bone Destruction and Soft-Tissue Swelling.

of cardiac tamponade. I shall make this my first guess for the diagnosis of the final episode.

A PHYSICIAN: Does the fact that he had recurrent pain go against pulmonary embolism?

DR. KLEMPERER: I believe that that is against it.

CLINICAL DIAGNOSES

Suppurative arthritis, right knee.
Coronary thrombosis.

DR. KLEMPERER'S DIAGNOSES

Tuberculosis involving lumbar spine and right knee
Degenerative joint disease.
Dissecting aneurysm of aorta?
Pulmonary embolism?
Coronary thrombosis?

ANATOMICAL DIAGNOSES

Tuberculosis of lumbar spine and right knee.
Massive pulmonary embolus.

PATHOLOGICAL DISCUSSION

DR. RONALD C. SNIFFEN: This man was killed by a massive pulmonary embolus. The fourth and fifth lumbar vertebrae contained many small nodules of soft white material, but they were not compressed. The right knee was swollen, and the joint cavity was filled with yellow pus. The synovia was redundant and rough, and the articular cartilages of the femur, tibia and patella were partially destroyed. Sections of the vertebrae and knee joint showed tuberculosis microscopically, and guinea pigs inoculated with material from the knee died of tuberculosis. The patient had no other signs of tuberculosis except for apical pulmonary adhesions.

CASE 31162

PRESENTATION OF CASE

First admission. A fifty-four-year-old shoe cutter was admitted to the hospital because of swelling of the abdomen.

One year prior to admission the patient developed a generalized itching unassociated with any skin lesion or jaundice. About two months later he noted increasing tiredness, although he was able to continue working. About six months before entry he noted swelling of the legs, brought on by standing for any length of time and disappearing after a night in bed. Soon thereafter he noticed that the abdomen was swollen and continued to enlarge, and a protrusion developed in the region of the umbilicus. Three months prior to entry he developed increasing dyspnea on exertion. A physician prescribed diuretic pills, following which the patient lost about 20 pounds in a few days. His abdomen, however, did not appreciably decrease in size. There was no history of gastric discomfort except for gaseous eructations after meals, and no hematemesis, melena or unusual stools. He had lost a "considerable" amount of weight over a period of six months.

The patient had been a rather heavy drinker of beer, augmented with whisky and rum, before the onset of his symptoms. There was no history of exposure to drugs and chemicals other than alcohol. He had had typhoid fever at the age of twenty. One and a half years before admission he had had a high-vein ligation in the right leg, and the veins of the left leg were injected at the same time.

Physical examination revealed a rather frail, tall man showing evidence of considerable weight loss. The lungs revealed fine moist rales at both bases, and diminished breath and voice sounds over

the entire chest. The diaphragm was high bilaterally. The heart sounds were clear, with splitting of both sounds and a questionable systolic murmur at the apex. The abdomen was markedly distended and tense, with shifting dullness and a fluid wave. A completely reducible umbilical hernia was present. No organs or masses were felt. A massive left scrotal hernia, completely reducible, was present. Both legs revealed evidences of stasis dermatitis. There was pitting edema of both feet, and induration of both legs to the knees. The knee and ankle jerks were not elicited, but other reflexes were normal.

The temperature was 98°F., the pulse 90, and the respirations 22. The blood pressure was 112 systolic, 70 diastolic.

Examination of the blood revealed a red-cell count of 4,300,000, with 12 gm. of hemoglobin, and a white-cell count of 7700, with 76 per cent neutrophils. The urine was negative. The serum non-protein nitrogen was 31 mg. per 100 cc., the protein 5.6 to 6.8 gm., with an albumin-globulin ratio of 1.05, and the chloride 95 milliequiv. per liter. A bromsulfalein test showed retention of 30 per cent of the dye. A cephalin flocculation test was \pm after twenty-four and forty-eight hours. Venous pressures taken in the antecubital space and femoral vein were equivalent to 18.5 and 14.5 cm. of water, respectively, on one occasion and to 20.5 cm. in both places on another. Fluid removed from the left chest had a specific gravity of 1.012, with a cell count of 1419 red cells and 138 white cells, of which 22 per cent were neutrophils, 76 per cent lymphocytes and 2 per cent eosinophils. Fluid from the abdominal cavity had a specific gravity of 1.014, with a cell count of 2610 red cells and 550 white cells, practically all of which were lymphocytes. The latter fluid contained 4.2 gm. of protein per 100 cc., and both the chest and ascitic fluids were negative for tubercle bacilli on smear and guinea-pig inoculation and for tumor cells. A sputum examination was negative for tubercle bacilli on smear. A blood Hinton test was negative.

A roentgenogram of the chest revealed a heart that was slightly enlarged but was within the limits of normal by measurement. There was a considerable amount of fluid in both pleural cavities. No liver shadow could be made out, and the hepatic flexure came almost to the diaphragm. The spleen was not enlarged. A barium swallow revealed a normal esophagus without evidence of obstruction or varices.

An electrocardiogram showed slight right-axis deviation. There were low-voltage QRS complexes and flat T waves in the standard leads.

The patient was placed on a high-calory, high-vitamin diet with fluids restricted to 2000 cc. daily. A peritoneoscopy was performed on the third hospital day. The right lobe of the liver presented a rounded edge that was just below the costal margin.

The left lobe presented a rounded edge that extended down to the level of the umbilicus. The surfaces of both lobes were extremely irregular and in places hobnailed, and they were covered almost everywhere with innumerable white pinpoint tubercles. Some of these tubercles were seen on the peritoneal surface of the abdominal wall, overlying the left lobe of the liver. The transverse colon, small bowel and omentum in the upper part of the abdomen were involved in a red inflammatory mass in which there were a few tubercles. The lower abdomen appeared essentially negative. A biopsy specimen from the anterior surface of the left lobe of the liver showed no obvious abnormality.

On the tenth hospital day a paradoxical pulse was noted, and two days later a pericardial friction rub was heard. A fluoroscopic examination of the chest at that time revealed a small cardiac beat and no localized enlargement. There was no evidence of pericardial calcification, but there seemed to be some evidence of pericardial adhesions about the heart. The circulation time (arm-to-tongue) was 30 seconds. In spite of these findings, the patient continued to improve. He gained 15 pounds without significant accumulation of ascitic fluid and was discharged to his home on the thirtieth hospital day.

Second admission (two months later). Following his discharge the patient felt well except for persistent exertional dyspnea and some increase in abdominal distention. He gained about 10 pounds. He was readmitted for re-evaluation of his condition with a possibility of operation.

Physical findings were essentially unchanged except that a pericardial friction rub was no longer heard. The heart sounds were muffled. The pulsus paradoxicus was still present. The neck veins were pulsating and distended, there was considerable ascites and edema of the legs and feet, and the superficial veins of the abdomen were prominent. A roentgenogram of the chest showed no definite change.

Several chest and abdominal taps were performed, and the patient was given injections of Mercupurin to relieve him of some of the fluid.

On the twenty-eighth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CONGER WILLIAMS: The generalized itching without jaundice did not mean much to me in the light of what happened later, so I shall overlook it for the moment.

In the differential diagnosis of ascites, it is important to know whether or not there is leg edema and, if so, what the time relation of its onset is to that of the ascites. We are told here that swelling of the legs came on before the ascitic swelling was noticed. When the cause of ascites and leg edema is intra-abdominal, ascites develops first and

leg edema later, owing to pressure of fluid on the intra-abdominal veins. If, however, both are due to heart failure, edema of the legs commonly appears first. In the case of constrictive pericarditis, ascites is often out of proportion to the amount of leg edema and may appear first. In this case, the sequence of events is unusual for heart failure in that signs of peripheral congestion preceded dyspnea.

Obviously the diagnosis of cirrhosis of the liver was considered because of the history of alcoholism, but a search for esophageal varices was negative. The appearance of fluid in the legs before the development of ascites is also against the diagnosis. I suppose that the patient had varicose veins, but it does not say exactly why the vein was ligated. Obviously the injection was done for varicosities. Whether or not he had had thrombophlebitis, we do not know.

In brief, the cardiac findings on physical examination were not remarkable. Obviously the degree of ascites was out of proportion to the degree of leg edema.

We know nothing about the course of this man's temperature, either before or after admission.

In the differential diagnosis of edema, determination of the serum protein should be a routine procedure. The value of 5.6 to 6.8 gm. per 100 cc. is a little on the low side, but not low enough to be significant.

Thirty per cent dye retention in the bromsulfalein test is a moderately abnormal finding, but it is found in cases of simple liver congestion, without much in the way of parenchymal liver disease. Also, the cephalin flocculation test was equivocal, and can be explained on a basis of liver congestion alone.

The venous pressure readings were abnormally high, a finding of greater importance in making the differential diagnosis than any other reported physical or laboratory finding. I shall discuss it later in greater detail.

The characteristics of the abdominal fluid suggest an exudate rather than a transudate. The protein was high, the specific gravity was fairly high, and the cell count suggests more of a lymphocytosis than one expects from an ordinary bloody tap. So it is likely that a factor other than increased venous pressure was active in the production of ascites. The question of infection with tubercle bacilli is one of the most important things to consider in the differential diagnosis of ascites. A negative finding, however, especially on examination of the sediment of the ascitic fluid, means nothing. I think one can say that in tuberculous peritonitis one seldom gets a positive smear for acid-fast bacilli. Furthermore, it has been said that guinea-pig inoculations are positive in only about 50 per cent of cases. Thus, the negative findings in both these determinations mean little. Also, the fact that the sputum was negative for tubercle bacilli is of little consequence.

DR. LAURENCE L. ROBBINS: I have not been able to find the films taken on the first admission. I gather, however, that there was no change in the appearance of the heart or lungs. Someone made the statement that the heart was within normal limits of size by measurement. In none of these films is it possible to see the cardiac shadow sufficiently to be certain of it. This observation must have been made by the fluoroscopist. The fact that there was a small beat is of some importance.

DR. WILLIAMS: How about a large amount of pericardial fluid? Is that possible with this sort of right border?

DR. ROBBINS: It depends on how much you mean by a "large amount." There can be a lot of fluid in the pericardial cavity even with that configuration.

The lung fields are not remarkable. So far as I can see there is no evidence of disease in the lower and upper lobes, other than this linear fibrosis in the apices, which indicates a previous infection.

DR. WILLIAMS: Is this shadow the septum of the middle lobe?

DR. ROBBINS: Yes; with some fluid extending into it.

DR. WILLIAMS: These pictures are not particularly helpful, but I did not expect them to be. We know that he had fluid in the chest, because of the findings on physical examination and because of the fact that a goodly amount was withdrawn.

I saw the electrocardiograms, and the low voltage and the flat T waves are suggestive of pericardial involvement, which fits in later in the differential diagnosis.

I wonder whether the apparent hobnailed surface of the liver was related to the tubercles on the peritoneal surface. The record states that the biopsy showed no apparent intrahepatic disease. I do not believe that that means much one way or another. It is definitely stated, however, that tubercles were seen on the edge of the liver. The question I should like to raise is, Were these real tubercles or something simulating them? It is well known that widespread carcinoma may mimic tuberculosis, in the gross at any rate. We have no report of a histologic examination. I think it most probable, however, that these were real. The description of the transverse colon sounds like localized tuberculous infection in the abdomen.

A paradoxical pulse was noted. The question here is whether it actually appeared at that time or whether it was noted for the first time, having been present previously. It seems unlikely that a paradoxical pulse would develop so fast, unless there was a considerable amount of pericardial effusion. The x-ray picture suggests that the effusion, if any, was insignificant. Since there apparently was no great change in the blood pressure, and no sudden change in the clinical state, I am doubtful about the presence of pericardial tamponade. I suspect that pericardial involvement had been present for some time before the onset of symptoms, and that

the paradoxical pulse was also present long before it was observed for the first time. The friction rub suggests that there was acute inflammation of some part of the pericardium. Of course that often takes place in the presence of old pericardial fibrous changes. The small amplitude of heart beat may have been due to old pericardial adhesions. The absence of pericardial calcification means nothing in deciding on the presence of constrictive pericarditis.

It is quite likely that dyspnea at the time of the second admission, as well as on previous occasions, was due to an accumulation of fluid in the chest. Also, dyspnea is a symptom of constrictive pericarditis.

In describing a paradoxical pulse, the variation in systolic blood pressure between inspiration and expiration should be recorded. A good many normal people have a paradoxical pulse of slight degree, and it is often quite marked in bronchial asthma. The use of the term, "pulsus paradoxicus" without qualification is not especially helpful. In this case, however, the finding is significant, especially in association with distended and pulsating neck veins. The latter observation was not recorded until the second admission, but the high venous-pressure measurement suggests that visible venous pulsations in the upright position were also present at the time of the first admission.

I wonder whether the operation mentioned was an abdominal or thoracic procedure. Abdominal exploration is sometimes performed in tuberculous peritonitis. I suspect, however, that this was a thoracic operation and that it probably consisted of a pericardial exploration, because everything in the history points to a diagnosis of constrictive pericarditis—a high venous pressure in association with ascites, leg edema and the finding of a paradoxical pulse. Also the electrocardiographic findings are typical, and the absence of normal pulsation on fluoroscopic examination is suggestive. Also significant is the apparent absence of intracardiac involvement to explain the high venous pressure. I am therefore practically forced to accept the diagnosis of constrictive pericarditis.

The next question is, What is the relation of this to an apparent tuberculous peritonitis? Was the constrictive pericarditis also tuberculous, or was it the much more frequent nonspecific pericarditis, complicated by tuberculous peritonitis? It is more logical to suspect that the picture can be explained on the basis of a long-standing tuberculous constrictive pericarditis in association with tuberculosis of other serous surfaces, including the pleura and peritoneum. Tuberculous peritonitis alone does not explain the increased venous pressure and the findings in the lungs, unless one assumes that there was an independent tuberculous pleural process going on. We therefore must assume that something was going on outside the abdomen. One might say that

the absence of fever and the increased white-cell count are perhaps against the diagnosis of tuberculous peritonitis, but we do not have a detailed record of the temperature. It is possible to have this picture caused by tuberculosis and at the same time to have a normal temperature. It is not usual, however, to have a high white-cell count in association with tuberculous peritonitis.

If this is tuberculosis, and it seems likely that it is, the next question that comes up is, Where was the original focus? So far as I can tell it was not in the lungs; perhaps it was in the mediastinum or elsewhere. It is true that cases like this usually have an obvious primary tuberculous focus. All I can say is that it just was not found.

CLINICAL DIAGNOSES

Polyserositis, with chronic constrictive pericarditis.
Bronchopneumonia.

DR. WILLIAMS'S DIAGNOSES

Tuberculous constrictive pericarditis.
Tuberculous peritonitis.

ANATOMICAL DIAGNOSIS

Polyserositis.

PATHOLOGICAL DISCUSSION

DR. RONALD C. SNIFFEN: I am sorry that Dr. White is not here, since he followed this patient rather closely through his medical career. Neither is Dr. Sweet, who performed the operation. Before he operated, Dr. Sweet made the remark that this type of case was most unfavorable for pericardiectomy, as judged from the experience of this clinic and others, because of the obvious activity of the process. But in view of the patient's continued downhill course he did operate and found a constrictive pericarditis. Thereupon he removed strips of the thickened pericardium from the anterior surface. After operation the patient did extremely well for a few months. It was seven months before he came in again, at which time he was in much the same condition as before operation. It is a little unusual for a patient to do so well postoperatively and then fail rapidly within a few months. Generally speaking, if the operation is not helpful there is no postoperative interval of improvement.

At the time of death the patient showed peripheral edema of the lower extremities to the knees. He had prominent neck and chest veins. In the distended abdomen there were umbilical and left inguinal hernias. The abdominal cavity was striking in that all the peritoneal surfaces were greatly thickened and appeared milky. This process involved the liver and spleen, and had produced adhesions around these organs. The serosa of the gastrointestinal tract was tremendously thickened,

but there were no adhesions between the various loops of bowel. The liver weighed 1980 gm. and, on section, showed a distinct lobular architecture and was quite tough. Microscopically the liver showed advanced central congestion and necrosis leading to an early cardiac cirrhosis. Each pleural cavity was largely obliterated by fibrous adhesions and contained about 100 cc. of fluid. There were also adhesions between the medial surfaces of the lungs and the pericardium. The entire pericardium was tremendously thickened, and the heart was fixed to the anterior chest wall and to the posterior mediastinal structures. The thickening was most impressive over the auricles, especially the right,

where it measured as much as 1 cm. The orifice of the superior vena cava was narrowed to slightly more than 1 cm. in diameter. The orifice of the inferior vena cava, however, was capacious, measuring 3 cm. in diameter. The hepatic veins entering the inferior vena cava were not appreciably narrowed. The heart itself was not enlarged and revealed no intrinsic disease.

A blood culture and cultures of the fluid from the various cavities were negative, and guinea-pig inoculations were negative. Sections from the various serous surfaces showed a nonspecific subacute inflammatory process, with the laying down of many layers of collagen.

CANCER

AGAIN, April, by proclamation of President Roosevelt, is Cancer Control Month. During total war one might expect interest in cancer to assume a lesser place in one's thoughts than in times of peace; on the contrary, interest in it has rapidly increased. Perhaps the fact that cancer maims in an indiscriminate way on the home front and has killed more Americans since 1941 than has the war explains this phenomenon. The problem that cancer poses is formidable but by no means insoluble. As most members of the medical profession know, valuable new knowledge concerning cancer is being discovered daily and each bit of added knowledge

solves or leads to the solution of some small part of the total problem.

For a long time the earnest workers studying cancer have been discouraged by the magnitude of the problem and the narrowness of the fronts on which it has been faced. In spite of generous gifts supporting cancer research, the total amount available is completely inadequate to make sufficiently broad studies.

Until recently, the efforts of the American Cancer Society have been in the fields of lay and medical education and in aiding the care of impoverished patients. This year for the first time, as previously mentioned in the March 22 issue of the *Journal*, the society is tackling the problem of supporting studies of cancer, in addition to increasing its unremitting efforts to spread present knowledge. A statement appearing elsewhere in this issue of the *Journal* describes this new departure in the society's affairs and its organization to an attempt to raise \$5,000,000.

THE RH BLOOD FACTOR

THE modern physician believes that mystery in medicine is as outmoded as is black magic. He is no longer afraid to tell his patients that he does not know a few of the secrets of the human body, and with him the aura of infallibility of a former generation is as obsolete as are its plug hats, its chin whiskers and its calomel measured on a knife blade. Medicine, today, is willing and eager to share its knowledge with its public. It asks only that all the facts be made known, that the case be temperately stated and that the hopes and the fears of human kind be not exploited in the interests of sensational journalism.

Too often, however, the newspapers and the magazines are a jump ahead of us and are peddling their borrowed wares on a bull market before most of us who should be best informed are ourselves thoroughly acquainted with the facts of the case. It is because of the half informed and poorly informed opinion that is already attaching itself to the mysteries of the Rh blood factor that the *Journal*

is presenting on other pages herein a thorough exposition of this recent addition to medical knowledge.

As recently as 1940, Landsteiner and Wiener, studying the agglutinins developed in certain experimental animals against the red blood cells of the rhesus monkey, found that approximately 85 per cent of human bloods contained an antigenic substance that was capable of reacting with this antibody. The agglutininogen was named the Rh factor, and bloods possessing it were called Rh+. Bloods lacking the factor were called Rh-. Persons with Rh- blood may become sensitized to the Rh factor by means of transfusions of Rh+ blood or, in the case of women, by bearing an Rh+ infant, the result of mating with an Rh+ man.

The practical importance of the Rh factor concerns Rh- women and their Rh+ offsprings, since, as has been stated, an Rh- person may become sensitized to Rh+ cells by an Rh+ transfusion, rendering subsequent Rh+ transfusions dangerous. Initial pregnancies with Rh+ infants may similarly sensitize the mother, producing in her blood agglutinins that will destroy the red cells of subsequent Rh+ infants, thus causing the anemia known as erythroblastosis fetalis; even the first infant of a mother who has been previously sensitized by one or more Rh+ transfusions may similarly suffer.

The inferences are obvious. Rh- persons should not receive repeated transfusions from Rh+ donors; Rh- women of child-bearing age should be protected completely against Rh+ transfusions because of the possible dangers to subsequent infants; and Rh- women mated to Rh+ men should, if one or more Rh+ children have been borne, be watched through subsequent pregnancies in order that proper measures may be taken to protect the infants.

An important point to remember is that the Rh factor, recently discovered although present for untold generations, is no cause for panic. In only about one fifteenth of the cases in which an Rh- woman is married to an Rh+ man is the infant likely to develop erythroblastosis unless Rh+ transfusions have been previously given to the mother, and less than one sixth of the infants so affected who recover suffer serious consequences in later life. As the author points out:

Since the placental barrier is assumed to hold back cellular elements, since some persons do not respond to Rh antigen by anti-Rh production, since 49 per cent of Rh+ men are heterozygous and can father Rh- children and since two or more pregnancies are usually necessary to produce infants suffering from erythroblastosis fetalis, this disease remains a fairly rare complication of Rh differences between mates. It may even be suggested that other incompatibilities between man and wife are more hazardous to married life than differences in the Rh factor.

MASSACHUSETTS MEDICAL SOCIETY COMMITTEE ON CANCER

The following statement signed by the Massachusetts members of the American Cancer Society is endorsed by the Committee on Cancer and recommended to the members of the Massachusetts Medical Society for careful study and action.

G. A. MOORE, *Chairman*

* * *

By the time this appears in print the medical profession and the public will have heard over the radio and seen in print many statements concerning the campaign of the American Cancer Society to raise \$5,000,000 for cancer research and other aid to cancer patients. This society was formerly known as the American Society for the Control of Cancer. It was founded some forty years ago and has shown a steady, sound growth in activities and strength during this time. It has been particularly active in the fields of lay and professional education. During the last eight years its growth has been aided by the large number of members of its Field Army. This subsidiary organization has given devoted service in promoting cancer education and in providing financial and other aid to impecunious cancer patients. It is active in every state except Massachusetts, where the Department of Public Health carries on these activities in an efficient manner.

Although several foundations spend sums of money for the support of cancer research, the money available for organized research each year amounts to less than \$1,500,000 for the country as a whole. On the other hand, cancer is killing over 160,000 people annually, and causing an expense and loss totaling many hundred millions of dollars. The officers of the American Cancer Society have long believed that this was not nearly enough support for a sufficiently broad study of this complicated disease and have secured the aid of far-sighted laymen in an effort to broaden the financial base supporting research on cancer and the care of patients with cancer. This lay committee is headed by Mr. Eric A. Johnston, president of the United States Chamber of Commerce, and the Executive Council is made up of distinguished men all over the country. Included are Mr. Robert Choate, publisher, *Boston Herald*, Mr. William K. Jackson, vice-president, United Fruit Company, and Mr. Sinclair Weeks, former United States senator and chairman of the Board of Directors, Reed and Barton. This committee ensures that the money-raising campaign will be well carried out.

Plans for spending the money raised provide for an equitable division of funds, with slightly more than 50 per cent to be allocated to the subsidiary state organizations, subject to approval of the parent society, and the remainder to the American Cancer Society. The bulk of the funds expended by the latter will go to cancer research in all its aspects, and some of the locally administered funds will also go to research. In addition, care of patients, facilities for treatment and many other cancer activities will be aided by increased support. That these activities will be efficiently carried out is indicated by the character of the officers, who are as follows: chairman of Board of Directors, Herman C. Pitts, M.D., consultant, Department of Cancer Research, Rhode Island Hospital, Providence; president, Frank E. Adair, M.D.,

chairman, Cancer Commission, American College of Surgeons, and surgeon-in-chief, Memorial Hospital, New York City; vice-president, Edwin P. Lehman, M.D., chief surgeon, University of Virginia Hospital and professor of surgery, University of Virginia Medical School, Charlottesville, Virginia; and treasurer, James J. Ripley, M.D.; and secretary, Eugene P. Pendergrass, M.D., director of radiology, University of Pennsylvania Hospital, Philadelphia. The Executive Committee is composed of these officers and the following: James B. Murphy, M.D., director of cancer research, Rockefeller Institute, New York City; Colonel C. P. Rhoads,

MISCELLANY

"A SPOT ON THE LUNG"

Joseph Conrad once said, "A word carries far — very far — deals destruction through time as the bullets go flying through space." Medicine has a few such words. Too often these are used when a serious or potentially serious condition must be explained to an apprehensive patient. When words treacherously lull either the patient or the physician into a false sense of security, then words may ultimately maim or destroy as

The Journal lacks extra copies of the February 1 and March 8, 1945, issues. If any subscribers who do not bind their copies have the above-mentioned issues on hand, the Journal will gladly pay 15 cents for each copy left at or mailed to its office (8 Fenway, Boston 15).

chief, Medical Division, Chemical Warfare Service, and director, Memorial Hospital, New York City; Edwin B. Wilson, Ph.D., professor of vital statistics, Harvard School of Public Health, Boston; and John T. Morton, M.D., surgeon-in-chief, Strong Memorial Hospital, and professor of surgery, University of Rochester, Rochester, New York. Dr. Clarence C. Little, director of the Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine, is managing director of the American Cancer Society, and Rear Admiral Charles S. Stevenson (MC), U.S.N. (ret.), is director of research.

To co-operate with the American Cancer Society, we, the physician members of the society who live in Massachusetts are forming a subsidiary organization. A layman's campaign committee has been appointed, with Mr. Arthur T. Lyman, of Westwood, as chairman, Mr. Ralph Lowell, of Westwood, as treasurer, Mr. Herbert T. Hand, Jr., of Boston, as director of publicity, Mr. George A. Baker, of Milton, as vice-chairman in charge of Greater Boston, and Mrs. William Brace Pratt, of Milton, as chairman of the Women's Division.

The American Cancer Society will welcome any aid that physicians can give to the success of this campaign. Doctors can well afford to give themselves and should urge their patients to give. Send a check today; do not wait for a solicitor to ask you for money because this year's campaign is so organized that personal solicitation cannot be made. Remember that you, in spite of being a physician, have as much chance of dying of cancer as any of your patients. This chance is one in eight for men, and one in five for women. Your money now may save your life later. An office has been opened at 186 Tremont Street, Boston, the telephone number being LIBerty 0240. Checks made out to the American Cancer Society may be sent to the above address or merely mailed to "Cancer," care of your local postmaster.

surely as if they were bullets. The following statement (Pinner, M. A spot on the lung. *N.T.A. Bull.* January, 1945) is pertinent.

* * *

It is futile to search in dictionaries or medical textbooks for a definition of the term "a spot on the lung." But the term is being used with great frequency by physicians, nurses and laymen alike. If this term is subjected to scrutiny, it is found that it may mean anything and everything that produces either a shadow or an area of decreased density in a chest roentgenogram or anything and everything that causes abnormal physical signs over the lungs. If, then, this expression has no meaning that cannot be stated more precisely in other terms, it remains to be found out why it is being used. If this is one of the terms that does not express a definite meaning, does it possibly obscure a meaning?

Nobody who has searchingly studied the histories of patients with pulmonary disease can doubt that the real function of the phrase, "a spot on the lung," is to cloud the facts. It is a cloak for a great variety of pulmonary diseases, a protective screen for the inability or unwillingness of the physician to arrive at a diagnosis acceptable to himself, a disguise for a bitter truth that the physician hesitates to tell the patient, an escape for the patient who tries to elude further diagnostic work and necessary treatment. After all, one does not die of "a spot on the lung," but one can die of bronchial carcinoma and one might die of pulmonary tuberculosis. Along with much other evasive, medical double-talk, "a spot on the lung" is a verbal mechanism of escape from reality. In the same category belongs the term "a touch of tuberculosis" and, improperly applied, "nothing but a little thickened pleura."

No physician needs to be told that "a spot on the lung" is no diagnosis. He realizes that it is evidence, on the one hand, of healed disease which calls neither for treatment nor for alarming its bearer, or, on the other, of active disease in need of treatment. The physician sometimes uses the term in patients in whom he has failed to establish, with a certainty that carries conviction for himself, the difference between an active disease and obsolete scar. "A spot on the lung" has a pleasantly innocent sound. It lulls into inertia and indifference whatever doubts or curiosity the patient and, even in some cases, the doctor may have. But still it is, for the physician, a mental reservation. It seems to beckon as a safe place to stand if "a spot on the lung" later turns out to be carcinoma, tuberculosis or bronchiectasis.

Admittedly, this judgment may be harsh. But I dare say that it will be resented only by those who, with the instrumentality of this ambiguous term, neglect their obligation of persevering until "a spot on the lung" has been accurately diagnosed. No person need be told that he has "a spot on the lung." If the condition is as clinically insignificant as the term suggests, the patient should be told that he has a scar from a previous tuberculous infection — one that needs an occasional checkup or one that needs no further observation. Or when the diagnosis is certain, the patient should be told that his lungs are normal. For, while "a spot on the

lung" is often the obscured beginnings of destructive disease, it is, in other cases, the starting point for tuberculo-phobia and anxiety neuroses, conditions that are no less crippling and hardly more easily curable than tuberculosis itself.

But, though every reflecting physician knows that "a spot on the lung" is a meaningless and dangerous term, the utter convenience of the expression — and others like it — militates against their prompt extinction. Past experience justifies a pessimistic outlook. No amount and intensity of medical education are likely to eliminate entirely the term from medical parlance. Medical education, however, is being overtaken by the information that the public, including the prospective patient, is acquiring. People are learning to realize fully the confusing ambiguity of the term, they are beginning to refuse its acceptance just as an enlightened consumer protests against ambiguous and misleading labels on packaged goods. And the comparison is eminently proper: for all intents and purposes, "a spot on the lung" is ambiguous and misleading labeling. It may well be that through the protest of the consumer, by the refusal of every layman to be satisfied with the pseudo-diagnosis of "a spot on the lung" the term will eventually disappear.

It is high time for the medical and nursing professions and everyone engaged in tuberculosis work to bury a medical term that has quite literally buried so many patients. — Reprinted from *Tuberculosis Abstracts*, April, 1945.

CORRESPONDENCE

PENICILLIN THERAPY OF NEUROSYPHILIS

To the Editor: Following the use of penicillin for the treatment of early syphilis, there has been wide interest in its use in neurosyphilis. A study of this problem has been in progress at the Boston Psychopathic Hospital for over a year. Under the direction of the Department of Therapeutic Research of this hospital, working under contract with the Committee on Medical Research of the Office of Scientific Research and Development, Drs. Harry C. Solomon, Augustus S. Rose and Laurence D. Trevett have been treating cases of asymptomatic neurosyphilis, general paresis, tabes dorsalis, meningo-vascular syphilis, syphilitic optic atrophy and syphilitic meningitis. In some cases, malaria or fever-cabinet (diathermy) therapy has also been employed.

Physicians and clinics having such cases under their care are invited to send them to the Out-Patient Clinic at 74 Fenwood Road on Tuesday or Saturday morning from 8:30 to 10:00. A consultation will be held at that time, and arrangements will be made for the admission and treatment of suitable cases. There is no charge for the penicillin, and the ward rates for the patients are reduced in case of need. There are suitable wards for asymptomatic and other nonpsychotic cases. In each case, the welfare of the patient is the primary consideration.

HARRY C. SOLOMON, M.D., *Director*
Boston Psychopathic Hospital

74 Fenwood Road
Boston 15

CAUSE OF DEATH IN DIABETES

To the Editor: Everyone will welcome the article "The Cause of Death in Diabetes," by Drs. S. L. Robbins and A. W. Tucker, which appeared in the December 28, 1944, issue of the *Journal*. First of all, it again permits hope for those with diabetes, because the authors state that significant changes in the pancreas were observed in only 36 per cent of the 184 patients in whom the condition of the pancreas was noted. Von Noorden never saw nor have I ever seen a patient who was 100 per cent diabetic. Although the authors found significant changes in only 36 per cent of their cases, they did note some degree of change in the pancreas in an additional 6.5 per cent, which brings the total percentage of pancreatic lesions up to 42.5 per cent, as compared with the 74 per cent noted by Dr. Shields Warren.²

What enables one to make a diagnosis of diabetes post mortem must remain for pathologists to decide, but to me it hardly seems proper that this should be based solely on "glycogen nephrosis" or so-called "Armanni-Ebstein cells" in the tubular epithelium of the loops of Henle, because the authors frankly state that, with the passing years, the finding of glycogen nephrosis has become increasingly less frequent, suggesting that adequate therapy may prevent this

type of secondary lesion. In contrast to the labile character of glycogen nephrosis, I should like to point out that hyalinization or fibrosis of the islands of Langerhans after it has once occurred does not disappear. Their criterion is of interest because of the recent article by Laipply, Eitzen and Dutra³ on intercapillary glomerulosclerosis in which an incidence of 63.7 per cent of this type of lesion in diabetic autopsies is recorded and is used as their diagnostic criterion of diabetes. Robbins and Tucker, on the other hand, found intercapillary glomerulosclerosis, all degrees combined, in only 20 per cent of their cases. Such a seeming divergence of views is confusing to a clinician. I suspect that, if slides from 100 autopsies on diabetic patients were prepared and submitted to Drs. Robbins and Tucker, to Drs. Laipply, Eitzen and Dutra and to Dr. Shields Warren, there would be far less difference of opinion than now appears to exist. It might also be advantageous in this connection to have an additional report on the diagnostic value of lesions of the kidneys in alloxan diabetes.

Coma as a cause of death occurred in a surprisingly small number of cases, there being but 22 in the 307 analyzed. Good as these figures are, I believe that, if the staff physicians of the Boston City Hospital now reviewed the treatment of these 22 cases, they would be able to state that, if these patients were to re-enter the hospital, the number of deaths could be materially reduced, possibly by as much as a half. That would be a worth-while study, and I hope that my suggestion will be considered constructive. Incidentally, it would be of interest to know the average age at death of the 22 patients with diabetic coma.

The authors draw comparisons between causes of death in the diabetic and nondiabetic groups, as recorded in their Table 1. There are similarities and differences that are of interest. Thus, vascular disease caused 35.2 per cent of the deaths in the diabetic group, and 27.1 per cent in the nondiabetic cases. It is interesting to compare the figures for these two groups with that for our group of 929 clinical cases.³ Obviously, a sizable difference in any one item in one group will, other things being equal, force a consistent disparity in the others. Doctors Robbins and Tucker recognize this difficulty and call attention to it when they state that they threw the coma cases out of consideration. Furthermore, they explain the disparity in the percentages of coronary deaths in their two series and in the generally accepted clinical figure by the statements that their definition of coronary occlusion as a cause of death is quite precise and that "a certain percentage of acute coronary deaths are handled by the Medical Examiner's Office and hence are not available for inclusion within this series." In our clinical series, vascular disease was listed as the cause of death in 60 per cent of the cases.

Pulmonary infections in the diabetic series amounted to 25.6 per cent, and in the nondiabetic group to 24.2 per cent, as compared with 11.3 per cent in our clinical series.

Cancer was the cause of death in only 8.4 per cent of the diabetic group, as compared with 14.7 per cent in the nondiabetic group. This agrees with the 8.2 per cent in our clinical series, but the latter, however, is overweighted because of the influence of the numerous cancer cases in the Palmer Division of the New England Deaconess Hospital, which are included in our series. It is not at all surprising that the diabetic group at the Boston City Hospital showed a lower cancer death rate than did the nondiabetic group. It is true that the ages at death were the same, but the length of exposure to cancer of the diabetic patient is limited to the period that involves the duration of his diabetes and is quite different from that of the nondiabetic patient. In order to make accurate comparisons of this nature, what is needed, of course, is material by which one can compute death rates for the representative groups. If the higher mortality of the diabetic patient, as compared with the nondiabetic, were taken into account, many differences, on a percentage basis, would be wiped out; at the same time, those conditions to which the diabetic patient was prone would be thrown into even sharper relief. It might well be found, for example, that the cancer death rate was little different among diabetic and nondiabetic patients. All this indicates that, although this usual type of analysis is useful, one must keep in mind that the interpretation of such analyses should recognize its limitations. Furthermore, there is the fundamental consideration that there may be an association between the two diseases. This is discussed in detail by Wilson and Maher.⁴

chairman, Cancer Commission, American College of Surgeons, and surgeon-in-chief, Memorial Hospital, New York City; vice-president, Edwin P. Lehman, M.D., chief surgeon, University of Virginia Hospital and professor of surgery, University of Virginia Medical School, Charlottesville, Virginia; and treasurer, James J. Ripley, M.D.; and secretary, Eugene P. Pendergrass, M.D., director of radiology, University of Pennsylvania Hospital, Philadelphia. MISCELLANY

"A SPOT ON THE LUNG"

Joseph Conrad once said, "A word carries far — very far — deals destruction through time as the bullets go flying through space." Medicine has a few such words. Too often these are used when a serious or potentially serious condition must be explained to an apprehensive patient. When words treacherously lull either the patient or the physician into a false sense of security, then words may ultimately maim or destroy as

The Journal lacks extra copies of the February 1 and March 8, 1945, issues. If any subscribers who do not bind their copies have the above-mentioned issues on hand, the Journal will gladly pay 15 cents for each copy left at or mailed to its office (8 Fenway, Boston 15).

chief, Medical Division, Chemical Warfare Service, and director, Memorial Hospital, New York City; Edwin B. Wilson, Ph.D., professor of vital statistics, Harvard School of Public Health, Boston; and John T. Morton, M.D., surgeon-in-chief, Strong Memorial Hospital, and professor of surgery, University of Rochester, Rochester, New York. Dr. Clarence C. Little, director of the Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine, is managing director of the American Cancer Society, and Rear Admiral Charles S. Stevenson (MC), U.S.N. (ret.), is director of research.

To co-operate with the American Cancer Society, we, the physician members of the society who live in Massachusetts are forming a subsidiary organization. A layman's campaign committee has been appointed, with Mr. Arthur T. Lyman, of Westwood, as chairman, Mr. Ralph Lowell, of Westwood, as treasurer, Mr. Herbert T. Hand, Jr., of Boston, as director of publicity, Mr. George A. Baker, of Milton, as vice-chairman in charge of Greater Boston, and Mrs. William Brace Pratt, of Milton, as chairman of the Women's Division.

The American Cancer Society will welcome any aid that physicians can give to the success of this campaign. Doctors can well afford to give themselves and should urge their patients to give. Send a check today; do not wait for a solicitor to ask you for money because this year's campaign is so organized that personal solicitation cannot be made. Remember that you, in spite of being a physician, have as much chance of dying of cancer as any of your patients. This chance is one in eight for men, and one in five for women. Your money now may save your life later. An office has been opened at 186 Tremont Street, Boston, the telephone number being LI Bert 0240. Checks made out to the American Cancer Society may be sent to the above address or merely mailed to "Cancer," care of your local postmaster.

surely as if they were bullets. The following statement (Pinner, M. A spot on the lung. *N.T.A. Bull.* January, 1945) is pertinent.

* * *

It is futile to search in dictionaries or medical textbooks for a definition of the term "a spot on the lung." But the term is being used with great frequency by physicians, nurses and laymen alike. If this term is subjected to scrutiny, it is found that it may mean anything and everything that produces either a shadow or an area of decreased density in a chest roentgenogram or anything and everything that causes abnormal physical signs over the lungs. If, then, this expression has no meaning that cannot be stated more precisely in other terms, it remains to be found out why it is being used. If this is one of the terms that does not express a definite meaning, does it possibly obscure a meaning?

Nobody who has searchingly studied the histories of patients with pulmonary disease can doubt that the real function of the phrase, "a spot on the lung," is to cloud the facts. It is a cloak for a great variety of pulmonary diseases, a protective screen for the inability or unwillingness of the physician to arrive at a diagnosis acceptable to himself, a disguise for a bitter truth that the physician hesitates to tell the patient, an escape for the patient who tries to elude further diagnostic work and necessary treatment. After all, one does not die of "a spot on the lung," but one can die of bronchial carcinoma and one might die of pulmonary tuberculosis. Along with much other evasive, medical double-talk, "a spot on the lung" is a verbal mechanism of escape from reality. In the same category belongs the term "a touch of tuberculosis" and, improperly applied, "nothing but a little thickened pleura."

No physician needs to be told that "a spot on the lung" is no diagnosis. He realizes that it is evidence, on the one hand, of healed disease which calls neither for treatment nor for alarming its bearer, or, on the other, of active disease in need of treatment. The physician sometimes uses the term in patients in whom he has failed to establish, with a certainty that carries conviction for himself, the difference between active disease and obsolete scar. "A spot on the lung" has a pleasantly innocent sound. It lulls into inertia and indifference whatever doubts or curiosity the patient and, even in some cases, the doctor may have. But still it is, for the physician, a mental reservation. It seems to beckon as a safe place to stand if "a spot on the lung" later turns out to be carcinoma, tuberculosis or bronchiectasis.

Admittedly, this judgment may be harsh. But I dare say that it will be resented only by those who, with the instrumentality of this ambiguous term, neglect their obligation of persevering until "a spot on the lung" has been accurately diagnosed. No person need be told that he has "a spot on the lung." If the condition is as clinically insignificant as the term suggests, the patient should be told that he has a scar from a previous tuberculous infection — one that needs an occasional checkup or one that needs no further observation. Or when the diagnosis is certain, the patient should be told that his lungs are normal. For, while "a spot on the

THE TREATMENT OF BACTERIAL ENDOCARDITIS WITH PENICILLIN

Experiences at the Boston City Hospital During 1944*

MANSON MEADS, M.D.,† H. WILLIAM HARRIS, M.D.,‡ AND MAXWELL FINLAND, M.D.§

WITH THE TECHNICAL ASSISTANCE OF CLARE WILCOX

BOSTON

FLEMING,¹ in his original studies on the antibacterial action of cultures of his strain of *Penicillium*, included some strains of *Streptococcus viridans*, which he found to vary considerably in their susceptibility. Others²⁻³ have since confirmed these findings with more purified preparations of penicillin in vitro, noting the wide differences in susceptibility of single strains and finding some to be relatively resistant. Clinical trials in the treatment of subacute bacterial endocarditis were begun in 1942. The earliest reports were somewhat discouraging,⁹⁻¹⁶ but they did suggest the possibility that larger doses of penicillin given over a longer time might produce better results. Although negative blood cultures were usually obtained for brief periods during the administration of the small doses, bacteremia recurred after the treatment was ended.^{9, 11, 12, 14}

Loewe and his associates,¹⁷ early in 1944, reported favorable results in 7 consecutive cases of subacute bacterial endocarditis with combined heparin and penicillin treatment, but their cases had been followed for only a short time when this report was made. Later in the year, as larger amounts of penicillin became available, additional encouraging reports began to appear.^{18, 19}

In this paper are presented the findings in 9 cases of subacute bacterial endocarditis caused by *Str. viridans* and in 7 proved or probable cases of acute bacterial endocarditis due to other organisms, all of which were treated with sodium penicillin at the Boston City Hospital during 1944. The final evaluation of the results in surviving cases must, of course, depend on observations of a larger number of cases followed for a considerably longer period. The purpose of this presentation is to bring out some of the problems encountered during the treatment and in the immediately ensuing period. For convenience the cases will be considered according to their bacterial etiology, but the features are shown together for all the cases in the accompanying tables, and the relevant findings in single cases appear in the text figures.

CASES OF SUBACUTE BACTERIAL ENDOCARDITIS

Patients and methods. The 9 patients included in this study represent consecutive, unselected but typical cases of subacute bacterial endocarditis admitted to the medical wards of the Boston City Hospital between February and October, 1944. The diagnosis was based on the finding of multiple positive blood cultures, embolic manifestations and evidence of valvular heart disease. The patients ranged in age between nineteen and fifty-seven years; 5 were under thirty and 4 were over forty. Five were females and 4 were males. All had received courses of one or more of the sulfonamides without benefit before penicillin was started, but sulfonamides were not used during the penicillin treatment. They were sometimes given later for special indications.

CASES OF SUBACUTE BACTERIAL ENDOCARDITIS

Penicillin treatment was begun only after multiple positive blood cultures had been obtained. It was usually given by repeated intramuscular injections and only occasionally by constant intravenous infusion in either 0.85 per cent sodium chloride or 5 per cent glucose solution in water, using a total of 1500 to 2000 cc. per day. A predetermined dosage was used to start the treatment, usually 25,000 units every two hours intramuscularly, but this was altered later according to the clinical response or the serum concentrations obtained.

Acute pyelonephritis as a cause of death was far higher in the diabetic series (7.3 per cent) than in the nondiabetic series (1.6 per cent). The incidence was only 1.7 per cent in our clinical series, but I am sure that the autopsied series is more accurate in this respect. With increasing apprehension we behold such cases after observing uncontrolled diabetes of about fifteen years' duration in young people, and I am positive that the danger of its occurrence should be emphasized. One would like to know the sex of the patients. At one time we thought there was a predominance of females, but we have no analysis of recent data. I have recently discussed disease of the kidneys in uncontrolled diabetes.

The incidences of tuberculosis were about the same in both autopsied groups, being 5.6 per cent for the diabetic series and 8.0 per cent for the nondiabetic. In our clinical series, tuberculosis was recorded as a cause of death in 3.6 per cent of the cases.

In their conclusions the authors state, "The diabetic patient lives as long as the nondiabetic." I wonder if they would wish to modify this sentence or in some way to reconcile their statement on longevity of the diabetic as compared to the nondiabetic patient. The former do not live so long as the latter. In our latest compilation, the average duration of the disease was 13.7 years, although 18.2 per cent of the patients lived over twenty years. In fact, the life expectancy of our diabetic patients is about two thirds as long as that of nondiabetic patients. The authors seem to have overlooked the facts that the usual figures for the expectation of life relate to the expectation at birth and that in referring to the expectation of life for diabetic patients one should take account of the age at which the diagnosis of diabetes was first made. Thus, Table 45 on page 279 of our book¹ shows the expectation of life for the general population and for diabetic patients according to different age groups. It was prepared with the co-operation of the Statistical Bureau of the Metropolitan Life Insurance Company and is based on death rates of each age subsequent to first observation, regardless of the duration of the diabetes. The table is as follows:

Expectation of Life for the General Population and for Diabetic Patients.

AGE	NORMAL WHITE PERSONS	DIABETIC PATIENTS
10	57	40
20	48	33
30	39	28
40	31	21
50	23	14
60	16	10
65	12	8

From the above table it will be seen that the expectancy of life for the diabetic patient is approximately two thirds that of the general population for each age group.

Among the valuable hints that the article contains is the statement, "The example of a cerebral hemorrhage found at autopsy as a cause of death in a case clinically diagnosed as a diabetic coma is a not infrequent occurrence." Speaking for the group of doctors at the New England Deaconess Hospital, we can confirm that statement. In fact, we are beginning to have almost as many cases sent into the hospital with an erroneous diagnosis of diabetic coma as there are cases of diabetic coma itself. We welcome such cases, because the patients are generally very seriously ill and therefore just the ones to be separated promptly from coma cases by proper laboratory tests. A blood carbon-dioxide combining power of 20 vol. per cent or lower is a good differential standard and serves as the greatest common divisor among the symptoms and signs of diabetic coma. That one sentence in the article will, I believe, do a great deal of good, because it emphasizes the necessity for all hospitals to provide laboratory service for diabetic emergencies.

Dr. Joslin's letter was referred to Dr. Robbins for comment. His reply is as follows:

To the Editor: Dr. Tucker and I greatly appreciate Dr. Elliott Joslin's interest in our article. The point that the life expectancy of diabetic patients is only two thirds as long as that of nondiabetic patients is extremely valuable and well taken.

Two questions that were raised can be answered. The average age at death in the coma group of patients was 46.7 years. In agreement with Dr. Joslin's impression, females outnumbered males by a ratio of 2:1 in our series of patients dying of acute pyelonephritis. The total number of cases involved, however, appeared to be too small to warrant any conclusion regarding sex predominance in this disease.

NEED FOR PHYSICIANS IN VETERANS ADMINISTRATION

To the Editor: I desire to bring to your attention the need of physicians for Rating Board work in the Boston office of the Veterans Administration.

A rating board is an agency of the Veterans Administration composed of a medical member, a claims member (attorney) and an occupational member, who pass on claims for benefits administered by the Administration and evaluate the degree of disability resulting from disease or injury. The medical member of this board reviews physical examinations and medical records from various sources and advises the board on all questions of medicine and resulting disability. The work is sedentary in nature and is quiet and dignified in character.

The hours of employment are forty-eight hours per week. The basic salary is \$3800 which, with the overtime now in effect, totals \$4424 per year, less the necessary deductions for retirement and tax purposes. The work may be considered reasonably permanent in nature, and this office is interested in receiving inquiries from physicians meeting the requirements of Civil Service, which are essential to employment in a federal agency.

It would be appreciated if this need were brought to the attention of your readers, as I am certain, that with the present numerous vacancies for physicians in the Veterans Administration there is work for all who are qualified or interested in this type of employment, particularly that type of man who, with a good medical background, cannot, because of some physical impairment, engage in active general practice.

A. A. DOUCET, Assistant Manager

Veterans Administration
Post Office Building

varied in their sensitivity to penicillin, the M. I. C. (minimum inhibiting concentration) ranging from 0.011 to 0.031 Oxford units per cubic centimeter of

others by constant intravenous infusions and, in some patients who were in congestive failure, by reducing the fluid intake. The actual amounts of penicillin given are shown in Table 3. Treatment was continued for twelve to nineteen days except in Case 9, in which death occurred on the seventh

FIGURE 2. Case 2.

Shortly before penicillin therapy was started the patient developed congestive failure, which increased during the course of the treatment. She subsequently regained compensation and no longer requires digitalis. Adequate blood concentrations were maintained with small doses in this case.

culture containing 1000 to 10,000 streptococci. Some of the organisms were tested several times with results varying twofold in either direction on different occasions.

Penicillin dosage. The dose most often used was 25,000 units intramuscularly every two hours. Variations from this dosage were made either for the purpose of observing the clinical and bacteri-

FIGURE 3. Case 3.

Because bacteriostatic levels were not regularly maintained for two hours after 25,000 units intramuscularly the patient was given penicillin by constant intravenous drip at the rate of 15,000 units per hour for three days. During this time there was a return of fever and the intramuscular method was resumed. The patient was readmitted for further observations because of contaminants grown in the last blood culture obtained before discharge. No evidence of a recurrence of infection was found.

day after almost 2,000,000 units had been given. The total amount used in the remaining cases varied

The organisms varied in their rate of growth in blood cultures and in subcultures. They were characteristic strains of *Str. viridans* that failed to react with serums of the Lancefield Groups A, B, C, D and G.* The organisms were tested for their sensitivity to penicillin by the method of Rammelkamp and Maxon,²⁰ modified in later tests only by the use of 0.5-cc. amounts of broth for making the penicillin dilutions. The concentrations of penicillin in the serum were determined by the serial dilution method of Rammelkamp.²¹ From three to seventeen positive blood cultures, with an average of seven, were obtained in each case before penicillin treatment was begun.

Blood cultures were also taken at frequent intervals early in the course of the penicillin treatment and then twice weekly until discharge. Further blood cultures were taken during follow-up examinations. In the latter part of the study, penicillinase† was added to the culture medium when blood was obtained for culture during penicillin therapy.

Heparin was given to 3 of the patients by continuous intravenous infusion. The amount was adjusted in an attempt to keep the blood clotting time at about 60 minutes (range, 30 to 120 minutes).‡ This usually required about 200 to 250 mg. daily. Heparin was discontinued when hemorrhages or other untoward reactions occurred.

Some of the highlights of the clinical course, the treatment and the laboratory findings in the individual cases are shown in Figures 1 to 9.

FIGURE 1. Case 1.

The patient began to improve soon after treatment with heparin and penicillin was started. The marked rise in temperature after a week of treatment was accompanied by malaise, anorexia, nausea and abdominal discomfort. Fever and symptoms subsided within a few hours after heparin was stopped. During each of two subsequent admissions she had a short course of penicillin; the first was given before and after femoral-vein ligations for thrombophlebitis, and the second was given before and after extraction of infected teeth.

Duration before treatment. Some of the relevant dates in each of the cases are listed in Table 1. The

*1943 (all others 1944).
†Patient readmitted for a recurrence.
‡Two admissions, indicated as (a) and (b).
§Patient died during a readmission for cardiac failure.

The patients were examined daily during treatment and at frequent intervals thereafter for evidence of embolic phenomena, changes in cardiac murmurs and other complications.

*We are indebted to Miss Ruth M. Drew of the Department of Bacteriology and Immunology, Harvard Medical School, for the streptococcus groupings and typings.

‡The heparin administration and blood studies in these cases were carried out by Drs. C. S. Davidson and John H. Freed.

time of onset of symptoms as given by the patient is necessarily only approximate, and there is reason to believe that the disease was active in most cases for a longer period. The duration of symptoms of active infection at the time of admission to the hospital was five weeks or less in 6 of the cases, about two months in 2 cases and almost one and a half years in Case 6. Treatment with penicillin was started within ten days after entry of 7 of the cases,

wise varied. In each of the recovered cases, however, these findings were normal before the patient left the hospital. The hemoglobin and red-cell counts likewise returned to normal except in Case 6, which will be referred to later.

Enlargement of the spleen was noted before treatment was begun in 4 cases (Cases 1, 2, 5 and 6), and

FIGURE 6. Case 6.

The patient had symptoms of active infection for about one and a half years before admission to the hospital. He improved rapidly after penicillin was started, although adequate blood levels were not maintained in his blood. Before discharge he had evidence of embolism to the leg, and four weeks later he had a recurrence of symptoms of active infection and a positive blood culture. He was readmitted and again improved on penicillin but more slowly than previously.

there was tenderness over the spleen in 2 of them. The spleen remained palpable throughout most of

FIGURE 7. Case 7.

In this case it was not possible to maintain adequate levels with 25,000 units every two hours and the dosage was changed to 15,000 units every hour. There was a recurrence of symptoms, and a single positive blood culture was obtained after four and a half months. A second course of penicillin was then given in spite of the fact that other blood cultures were negative. The patient again showed a good clinical response to the treatment.

the course of treatment in these 4 cases, but receded later and was no longer palpable at the time of the last examination in any of the living patients. In no case was enlargement of the spleen seen for the first time after the treatment was started.

Effect on bacteremia. Data indicating the effect of penicillin treatment on the results of blood cultures are shown in Table 2. The numbers of positive cultures obtained in each case before treatment was

FIGURE 8. Case 8.

Adequate levels were readily maintained in this case, and the patient improved soon after treatment with heparin and penicillin was started. On the fifth day of treatment the patient became comatose and developed hemiparesis. The cerebrospinal fluid was bloody and showed organisms on smear that could not be cultured. Heparin was discontinued, and three intraspinal injections of penicillin were given. The patient recovered from this episode and improved steadily but continued to have poor cardiac function. He died three and a half months later in what seemed to be so-called "forward failure." At autopsy there was healing of the remnants of vegetations on the aortic valve; occasional organisms were seen in the smears of the ground-up vegetations, but cultures yielded no growth. There was a large splenic abscess, from which *Streptococcus viridans* was grown.

begun are also listed. The last positive culture was obtained before the first dose in Case 2 and from two to seventy-two hours after treatment was begun in the remaining cases except Case 9, in which the cardiac blood obtained at autopsy was positive in

FIGURE 9. Case 9.

The patient had had symptoms for only three weeks and had developed severe congestive failure before treatment with penicillin was started. Although high blood concentrations were readily maintained, the patient died after seven days of the treatment, and *Streptococcus viridans* was grown from the cardiac blood and vegetations.

spite of more than six days of treatment. Subsequent blood cultures in the living cases were all

from 3,000,000 to 6,000,000 units except in Cases 6 and 7, in both of which a total of more than 9,000,000 units was given in two separate courses.

Heparin. This drug was used in Cases 1, 4 and 8. In Cases 1 and 4 it was discontinued after eight and twelve days; respectively, because of the occurrence of a rising temperature and pulse rate associated

Notes:

Case 2. Levels on 3-hourly dosage adequate during congestive failure.
Case 3. Levels were inadequate during intravenous therapy and symptoms recurred.

Case 4. Patient given 20,000 units every 2 hours for 3 days after a splenic infarct, which occurred 16 days after the main course of penicillin.

Case 5. Patient weighed 90 lb.; blood levels were adequate on lower doses.

Case 6. Best clinical response; bacteriostatic levels only for 1 hour after injection.

Case 7. Recurrence (positive blood culture and chills) after 5½ months.

Case 8. Penicillin given intrathecally for 3 days because of pleocytosis and organisms seen (cultures negative) in spinal fluid during hemiparesis.

Case 11. Intrathecal doses for 6 days for meningitis.

Case 12. Intrathecal doses last 4 days for meningitis.

Case 16. Intrathecal doses during first 10 days for meningitis.

*All injections were given intramuscularly in the order noted, with two exceptions, the second series in Case 3 and the first in Case 13 (in each, the figure is the daily intravenous dose, which was continued for 3 days).

with malaise, sweating, anorexia, nausea, drowsiness and irritability. All these symptoms completely subsided within twelve hours after the heparin was stopped. It was therefore assumed that these findings represented an untoward reaction or sensitization to heparin similar to drug fever or serum sickness. In Case 8, the heparin administration was stopped on the fifth day, after the sudden occurrence of hemiparesis associated with grossly bloody cerebrospinal fluid.

Effect of penicillin on the symptoms and signs of infection. The clinical course in those who did not have serious complications was marked by an increase in appetite, a decrease in irritability and sweat-

FIGURE 4. Case 4.

In this case, small doses of penicillin were used during the first five days but they were later increased. The marked rise in temperature lasting about four days was accompanied by vague discomforts, all of which subsided, together with the fever, promptly after the heparin was discontinued. A second course of penicillin was given for three days following the occurrence of a splenic infarct and fever eleven days after the first course was completed.

ing and a general feeling of well-being, which began twenty-four to forty-eight hours after the penicillin was started. In 4 of the cases, the fever subsided, with the oral temperature dropping and remaining below 100°F., within forty-eight hours, whereas in the other 4, excluding Case 9, some fever continued during nine to fourteen days of treatment (Table 1). There was an occasional rise in temperature later in some of the cases, either associated with embolic manifestations or arising from causes not related to the major illness.

FIGURE 5. Case 5.

The patient weighed only about 90 pounds, and high levels were maintained on doses of 20,000 units every two hours.

The white-cell counts were only slightly elevated in most cases, and the effect of treatment was variable. The erythrocyte sedimentation rates like-

Recurrences or possible reinfections. Thus far there has been a recurrence of symptoms and of bacteremia in 2 cases. Case 7 was one in which, because of the failure to maintain bacteriostatic levels throughout the two-hour period after an intramuscular dose of 25,000 units, the patient was given 15,000 units every hour; he seemed to improve following this change. Four months after the treatment was stopped the patient had a recurrence of the original symptoms, and a single positive blood culture was obtained four weeks later. Other blood cultures both before and after this positive one were negative. The patient was nevertheless given another course of penicillin, with rapid alleviation of the symptoms. Interestingly enough, the organism obtained during the recurrence grew more

Complications. There were no untoward reactions to the penicillin except for the temporary local discomfort of the injections. Besides the embolic manifestations the only significant complication was the occurrence of thrombophlebitis of the legs in 2 patients. Interestingly enough, one of these patients received heparin through an arm vein, and in both cases the penicillin was given entirely by intramuscular injection. In Case 1, swelling and pain in one leg began before the patient left the hospital. She was readmitted and had a bilateral femoral ligation because of increasing edema and discomfort, and was given a few doses of penicillin before and after the operation. She was subsequently readmitted for extraction of teeth and was again given penicillin before and for twenty-four hours after

*In 3 cases with no history of rheumatic infection, the figures represent the number of years that the patient had been aware of having a cardiac murmur.

slowly, had a somewhat different colony morphology and, in parallel tests, was more sensitive to penicillin than the one obtained originally (Table 2). No peripheral embolic manifestations were seen during this recurrence.

Another patient (Case 6) was recently readmitted. One week after his discharge from the hospital, he developed a cold with coryza and headache and a few days later again had chills, fever and sweats. New crops of petechiae appeared on the trunk, and there were several tender nodular lesions on the fingers and toes. Several positive blood cultures were obtained, but in this case the organisms had about the same sensitivity to penicillin as those obtained originally, although they too grew somewhat more slowly and in smaller colonies. The symptomatic response to the second course of penicillin was not nearly so striking as that to the initial course. The patient became bacteria-free after fifteen hours and improved symptomatically after three days of treatment.

this procedure. The other patient (Case 7) developed pain and tenderness in the popliteal region with a rise in fever before the completion of the second course of penicillin. This all cleared without special treatment. In Case 6, there was a thrombophlebitis at the site of the constant intravenous infusion during the second course of treatment.

Fatal cases. Two of the 9 patients died, one (Case 9) after only six days of treatment and the other (Case 8) three months after the treatment was completed (Table 6). The former had marked congestive failure, which remained unaffected by treatment with penicillin and digitalis. In this case it was possible to maintain high levels, well above the M. I. C. for the patient's own strain, throughout the two-hour interval between doses. Blood cultures taken after the second day of penicillin were negative, but a culture of the cardiac blood at autopsy was positive, and the organisms were seen in smears and grown in cultures of the large vegetation that was found on the aortic valve.

negative except during the recurrences in Cases 6 and 7. In 3 of the cases the blood cultures were negative in four to eight hours and in a fourth case within 18 hours after the initial dose of penicillin. The heart blood obtained at autopsy in Case 8 was sterile in spite of the fact that no penicillin had been given for the preceding three months.

Embolic manifestations. Signs and symptoms interpreted as evidence of embolic phenomena of one form or another were noted in each of the nine patients with *Str. viridans* endocarditis before treatment with penicillin was begun (Table 4). In most

*Embolic manifestations occurred during treatment with heparin.

†Positive blood culture obtained at the time when the embolic manifestations were observed (in the remaining cases, all blood cultures taken when emboli occurred during or after penicillin treatment showed no growth)

‡Embolus phenomena occurred after heparin had been discontinued

of the cases there were multiple manifestations. Lesions of the extremities, including the joints, were noted in 7 cases, splenic infarction in 4, hematuria in 3, crops of petechiae in 3, occlusion of the central retinal artery in 1, and a pulmonary infarct in 1.

In each of the 3 patients who were treated with heparin, similar occurrences were noted during its administration. In Case 1, crops of petechiae appeared for the first time and chest pain occurred on the day after the heparin was started. A blood culture taken at the time was positive. In Case 4, several crops of petechiae were noted during the heparin administration, and again after it was discontinued but while the penicillin was still being given. In this case many blood cultures taken when these petechiae were noted all showed no growth. In Case 8, a few petechiae were noted for the first time during the heparin treatment, and on the fifth day of this therapy the patient became comatose and developed a hemiparesis. A lumbar puncture done at that time yielded cerebrospinal fluid that was grossly bloody and showed typical short chains of gram-positive cocci in the smear, but culture of the fluid gave no growth. Penicillin was nevertheless given intrathecally in 10,000-unit doses after each of three lumbar punctures.

At first it was thought that these phenomena were associated with the heparin administration, but similar ones occurred in 4 other patients during treatment with penicillin alone. Crops of petechiae were noted during the penicillin therapy in Cases 2 and 6, splenic infarcts, with pain and tenderness in the left upper quadrant, in Cases 2, 3 and 5 and lesions of the joints and extremities in Cases 3, 5 and 6. All the blood cultures taken when these occurred were negative.

In 3 of the cases, lesions occurred in seven to fourteen days after the completion of the penicillin therapy. These involved a finger joint in Case 1, the left foreleg in Case 6 and the spleen in Case 4. In these cases also, all the blood cultures taken at the time were negative. Slight fever, anorexia and malaise were associated with these manifestations. The splenic infarct in Case 4 occurred after a large splenic abscess was discovered at autopsy in Case 8, and for this reason the patient was given a course of penicillin for three days—20,000 units every two hours.

Cardiac findings. A history of previous rheumatic fever was obtained in 6 cases (Table 5). The other 3 patients were aware of having cardiac murmurs for six to twenty-three years, although they had had no previous rheumatic manifestations. Clinically, the mitral valve alone was considered to be involved in 4 cases and both the mitral and aortic valves in the other 5. In 2 of the former, there was no evidence of stenosis, that is, only a systolic murmur was heard, — whereas in 1 of the latter (Case 8), only the aortic valve was found to be involved at autopsy.

Two of the patients were apparently well compensated throughout the period of observation. The other 7 had some degree of failure, which was classified, according to *Nomenclature and Criteria for Diagnosis of Diseases of the Heart*,²² as Grade II in 4 cases, Grade III in 1 case, and Grade IV in 2 cases. One of the patients (Case 8) had been taking digitalis for a long time, and in 2 other cases it had been given for only two days before penicillin treatment was begun. In Cases 2 and 9, congestive failure was increasing progressively just prior to the penicillin therapy, and in the former case this was apparently precipitated by a blood transfusion.

In this group of cases of *Str. viridans* endocarditis the development of congestive failure during or soon after the course of penicillin did not occur. Failure was aggravated in some cases, but the cardiac status remained essentially unchanged in most cases. In Case 2, there was decided improvement during convalescence, and the patient since leaving the hospital has been able to carry on considerable activity without dyspnea or edema. One patient (Case 8) who had marked aortic insufficiency died three months after the penicillin treatment with marked failure but without any evidence of pulmonary or peripheral congestion.

enlargement of the spleen. He was treated with heparin intravenously and with 15,000 units of penicillin intramuscularly every two hours. Blood cultures taken four hours after the first dose and

FIGURE 10. Case 10.

This patient had rheumatic heart disease with mitral insufficiency but was well compensated. Following typical lobar pneumonia he had a persistent bacteremia in spite of sulfadiazine therapy and then developed enlargement of the spleen. A few petechiae appeared before and soon after treatment with heparin and penicillin was started, but he improved rapidly thereafter. He was readmitted and treated with sulfadiazine for an attack of pharyngitis and has been well since then.

many taken later showed no growth. The lungs cleared rapidly. The spleen has receded and is no longer palpable, the heart has remained fully compensated, and the patient has remained well and able to carry on his usual work.

The second patient (Case 11, Fig. 11) had Type 5 pneumococcus pneumonia with bacteremia. This

FIGURE 11. Case 11.

The patient was originally admitted to the hospital for lobar pneumonia with bacteremia, which apparently responded favorably to sulfonamide therapy. Soon after discharge he had chills and fever and was readmitted. Signs of pneumonia were still present, and the patient did not improve with further sulfonamide therapy. Bacteremia then recurred and persisted in spite of chemotherapy, and he developed purulent pneumococcal meningitis. Treatment with penicillin was followed by complete clinical and bacteriologic recovery.

apparently responded to treatment with sulfadiazine, and he was discharged after two weeks.

He returned ten days later with fever, sweats, leukocytosis and persistent signs in the lungs and was again treated with sulfonamides. Bacteremia nevertheless recurred, and the patient developed purulent meningitis with Type 5 pneumococci in the spinal fluid while still on full doses of sulfadiazine. He was then given 15,000 units of penicillin intramuscularly every two hours for six days and also intrathecal injections of 10,000 units after each lumbar puncture. The bacteremia and meningitis cleared rapidly, and the patient has remained well. In this case there were no signs or symptoms pointing directly to cardiac involvement.

In Case 12 (Fig. 12), there was a persistent Type 6 pneumococcus bacteremia without any known focus or antecedent infection. The patient denied any history of rheumatic infections but had an aortic stenosis and regurgitation and was in cardiac failure. Treatment with heparin intravenously and penicillin intramuscularly was begun on what was apparently the eleventh day after the onset of

FIGURE 12. Case 12.

In this case there was persistent bacteremia with aortic endocarditis and no other demonstrable focus of infection when treatment with penicillin and heparin was started. The patient became comatose, and purulent meningitis was found on the third day of treatment; the latter improved with intrathecal penicillin. Congestive failure was present before treatment, but this increased suddenly and changes in the cardiac murmurs were heard shortly before death.

symptoms. The patient was given 15,000 units of penicillin every two hours for three days and then 25,000 units every two hours. Blood cultures taken eight hours after the first dose and several times thereafter showed no growth. On the fourth day of treatment the patient developed signs of meningitis. A lumbar puncture yielded cloudy fluid with a polymorphonuclear pleocytosis and with gram-positive diplococci in moderate numbers in the smears. Cultures of the first and subsequent cerebrospinal fluid specimens yielded no growth. Penicillin was given intrathecally after each of the lumbar punctures, which were done at twelve to eighteen-hour intervals. On the seventh day, after he seemed to be improving, the patient suddenly developed extreme dyspnea, followed by Cheyne-

In Case 8, infection was apparently controlled, but the patient did not regain compensation and continued to be weak and drowsy. He died a few days after re-entry to the hospital. A markedly hypertrophied and dilated heart was found at autopsy with small healing stumps of vegetations on the aortic valve. Smears of these vegetations showed rare organisms, but cultures were negative. There was a large abscess in the spleen, and a culture of pus from it yielded *Str. viridans*. The sensitivity of this strain to penicillin was the same as of that originally obtained from the blood.

One additional fatal case should be briefly mentioned. In this case the data are not shown in the tables. The patient was a man of fifty-three who

negative, was also treated with penicillin, with seemingly good results. The patient was a woman of thirty-eight who had severe rheumatic heart disease with mitral and aortic valvular disease but no congestive failure. She had persistent fever and some emboli before treatment, and after one of them she became comatose and developed a hemiplegia. In spite of repeatedly negative blood cultures, the patient was treated with penicillin—20,000 units intramuscularly every two hours for two weeks. She showed rapid and marked improvement, became afebrile and regained all functions, but has had repeated epileptiform seizures, probably the result of cerebral damage from the previous embolism. The patient had a splenic infarct during

TABLE 6. Autopsy Findings

CASE NO	RELEVANT FINDINGS	BACTERIOLOGY
8	Small, healing vegetations on aortic valve; large splenic abscess; brain and meninges normal.	Cardiac blood and vegetations,* no growth, splenic abscess; <i>Str. viridans</i> .
9	Large vegetations on aortic valve.	Cardiac blood, vegetations and spleen, <i>Str. viridans</i> .

15	Vegetations on aortic and mitral valves; ruptured aortic cusp.	Cardiac blood, no growth; vegetations, gonococci
16	Vegetations on mitral valve; leptomeninges appeared normal	Cardiac blood and meninges, no growth; vegetations, nonhemolytic coagulase-negative <i>Staph. aureus</i> .

*A few organisms were seen in direct smears.

had had symptoms of infection with changing murmurs but no embolic phenomena for two months before penicillin was begun. He had received sulfonamides without benefit and had three positive blood cultures for *Str. viridans* after this treatment was stopped. He had a systolic murmur at entry and developed a mitral diastolic murmur and enlargement of the spleen while under observation. Blood cultures taken eight hours after the first dose of penicillin and many later ones were all negative. He developed marked congestive failure and severe cerebral symptoms on the second day of penicillin therapy after showing considerable improvement. Thereafter his condition grew steadily worse, and he died of a cerebral embolus on the fifteenth day of treatment after receiving 4,500,000 units of penicillin. At autopsy there were the remains of a vegetative endocarditis of the mitral valve with erosion of most of the chordae tendineae, the stubs of which were hanging loosely. The lower third of the spleen was completely infarcted and necrotic, and there were other infarcts in the rest of the spleen and in the kidneys. Cultures of the heart blood showed no growth, but *Str. viridans* was grown from the vegetation and from the necrotic material in the spleen. The sensitivity of these organisms to penicillin was the same as that of the original blood-culture strain.

Endocarditis with negative cultures. An additional case that was probably one of subacute bacterial endocarditis, in which severe embolic phenomena occurred but all the blood cultures were

the third week after treatment ended but for three months has had no evidence of active infection.

CASES OF ACUTE BACTERIAL ENDOCARDITIS

A few apparent cures in cases of acute bacterial endocarditis treated with penicillin have been reported, but in most cases the treatment was unsuccessful.^{13-16, 23-26} The diagnosis is difficult to make with certainty during life. It is strongly suspected, however, in cases in which there is persistent bacteremia without an obvious focus or after apparent improvement following a bacterial infection, when there are embolic phenomena and when cardiac murmurs appear for the first time and persist or change rapidly in character under observation. Brief résumés of 4 proved and 3 suspected cases are presented here. The significant data are shown in Tables 1 through 6. The cases will be considered, for convenience, according to their bacterial etiology.

Pneumococcal endocarditis. There were 2 cases in which pneumococcal bacteremia persisted following pneumonia in spite of sulfonamide therapy. In these cases the possibility of pulmonary thrombophlebitis must be considered in the differential diagnosis. The first of these (Case 10, Fig. 10) was that of a thirty-five-year-old man who had rheumatic heart disease with mitral insufficiency and was apparently well compensated. He had persistent Type 7 pneumococcus bacteremia following temporary improvement under sulfadiazine and then developed petechiae in the conjunctivas and

least a few days. In most cases in which the treatment was carried out for a long enough period, it has not been possible to culture the bacteria from the blood for variable periods after the treatment was discontinued. The proper dosage and duration of treatment have not yet been determined, but the present findings and those of many other writers suggest that in cases of *Str. viridans* endocarditis and probably also in cases due to other organisms it is necessary to give large doses for a fairly long period in order to obtain the most beneficial results.

The bacteria-free and symptom-free interval in each of the surviving cases is shown in Table 1. The results in Cases 6 and 7, in which there seemed to be a favorable response to the recurrent infection, suggest that these patients might have obtained a better result had the first course of treatment been continued with full doses for a longer period. On the other hand, the bacteriologic findings raise the question whether these recurrences represent new infections or relapses of the original infection. In Case 16, the differences in the characteristics of the staphylococcus originally obtained from the blood culture and of the one grown from the vegetation are also of interest in this regard, particularly since the latter was somewhat more susceptible to penicillin than the former and the patient had been treated for sixteen days. The findings in this case likewise suggest the possibility that earlier and more intensive treatment might have been more effective.

The significance of the penicillin concentrations in the blood and their relation to the susceptibility of the organisms are not entirely clear from the limited studies in the present cases. In some cases the clinical response seemed to be accelerated when the dosage was adjusted to maintain continuously a concentration higher than that necessary to inhibit the growth of the patient's organism. In others, however, similar or even better clinical results were apparently obtained in spite of the fact that adequate concentrations were maintained only during part of the interval between injections. The crudeness of the methods used may account in part for these discrepancies. It is interesting to note that while the patients were in congestive failure and on a limited fluid intake, somewhat smaller doses were usually required to maintain adequate blood concentrations.

Many factors probably influence the outlook for successful treatment with penicillin in cases of bacterial endocarditis. The susceptibility of the organism is only one of them. The amount of damage already done to valves and other structures has an important influence. Congestive failure developing or progressing rapidly, either before or during the course of treatment, is another significant factor. Obviously if valve cusps, chordae tendineae or septal structures have already been eroded, the elimination of further infection will not necessarily

result in any functional repair. The amount of damage already sustained by other vital organs is also a factor. All these points demonstrate the need for early diagnosis and early intensive treatment. Because of the more rapid course in cases of acute bacterial endocarditis, once this condition is established, it is particularly important to treat all patients who have persistent bacteremia as though they had potential cases of endocarditis.

Careful management of convalescence in so-called "arrested" or "cured" cases of subacute bacterial endocarditis is also necessary, and this is probably equally true in cases of endocarditis due to other bacteria. Embolic phenomena may occur for some time after the blood becomes bacteria-free. Each such occurrence carries with it the threat of further damage to valves or other underlying structures in the heart from which the emboli are released, as well as possible injuries where they become lodged. Severe cardiac failure may follow these occurrences. Reasonable treatment should therefore include a regime similar to that used in the care of cases of acute coronary thrombosis. This regime comprises an adequate period of inactivity to permit repair, followed by a very gradual increase in activity well within the limits of the cardiac reserve. The length of the convalescent period depends on an estimation of the cardiac status before and after treatment, the return of the white-cell count and sedimentation rate to normal and the possible occurrence of complications and embolic phenomena.

Infected foci in abscessed teeth, diseased tonsils and so forth should be eliminated. It is suggested that a course of treatment with penicillin or sulfonamides or both be begun just before tonsillectomy or tooth extractions and continued for a brief period thereafter, it being assumed that the original site remains vulnerable to reinfection with bacteria that may be released at the time. The finding at autopsy of infected abscesses at the site of splenic infarcts further suggests that a similar course of therapy would be advantageous immediately after any embolic manifestations in spite of the finding of negative blood cultures at such times. There may still be viable organisms in the embolus and at the site from which it was released.

Details of the autopsy findings are to be reported separately. Evidence of some healing was found in every case in which penicillin was given for a few days. In these cases, however, the amount of damage in the heart was usually sufficient to account for the cardiac failure.

Heparin was used in 5 cases of the present series. At first it was thought that the heparin was responsible for the occurrence of petechiae and emboli soon after the treatment was begun. The possible value of effectively eliminating the vegetation at the time when the antibacterial therapy was being carried out was considered as an advantage of the heparin. Subsequent observations in other cases of this series

Stokes respirations. At that time new and louder to-and-fro murmurs were heard, and the patient died a few hours later. At autopsy there were remnants of an acute vegetative endocarditis of the aortic valve, with rupture of one of the cusps where the vegetations had eroded the endocardium before they broke off. There was no gross evidence of meningitis. Cultures of the vegetations, cardiac blood and meninges showed no growth.

Hemolytic streptococcus endocarditis. Two patients with beta-hemolytic streptococcus endocarditis were treated with penicillin. One of them (Case 14) died after only two intramuscular injections. Cultures of the blood taken before treatment as well as those of the cardiac blood and vegetations at autopsy yielded a Group A streptococcus that did not react with available typing serums.

The other patient (Case 13, Fig. 13) was found to have a Group A, Type 28, hemolytic streptococcus bacteremia three weeks after what was probably

FIGURE 13. Case 13.

Persistent bacteremia followed what was probably a septic abortion and persisted during a short course of sulfamerazine. The patient developed congestive failure, which increased soon after penicillin treatment was started, and later a diastolic murmur appeared and persisted. The patient is now fully compensated and does not require digitalis.

a septic abortion. The bacteremia persisted under treatment with full doses of sulfamerazine. The patient had no known antecedent heart disease, but she developed congestive failure before penicillin was started, and this became steadily worse during three days of treatment given by constant intravenous infusion. Treatment was therefore changed to intramuscular injections, 15,000 units every three hours being sufficient to maintain bacteriostatic levels for the patient's organism. Blood cultures taken twenty-four hours after penicillin treatment was begun and all subsequent ones showed no growth. A loud aortic diastolic murmur was heard for the first time on the fifth day of penicillin treatment and persisted thereafter. The patient improved steadily, however, and the heart has gradually become fully compensated so that she is now able to carry on her usual activities without digitalis.

Gonococcal endocarditis. One patient (Case 15) was treated briefly and without success. She was a twenty-year-old woman in the sixth month of pregnancy who had an acute gonorrheal infection treated with sulfonamides five months before admission to the hospital. For four weeks she had had symptoms of a systemic infection. She developed petechiae, joint involvement and positive blood cultures for gonococcus and was then treated with sulfamerazine. Subsequent blood cultures were negative but fever persisted, and after two days of sulfonamides she was started on penicillin — 15,000 units intramuscularly every three hours. Shortly thereafter, however, she developed marked congestive failure and died after only three days on penicillin therapy. At autopsy there were vegetations on the mitral and aortic valves and one of the cusps of the latter had ruptured. Cultures of the cardiac blood yielded no growth, but gonococci were obtained from cultures of the vegetations.

Staphylococcal endocarditis. A fifty-two-year-old man (Case 16) was admitted to the hospital on the third day of an acute febrile illness during which he developed signs and symptoms of meningitis. At the time of entry he also had a generalized petechial and purpuric rash resembling that of meningococcemia, but these lesions later became pustular. A single dose of 5 gm. of sodium sulfadiazine was given on entry, and he was then treated with penicillin intramuscularly in the doses shown in Table 3. He was also given intrathecal injections of 15,000 units of penicillin twice the first day and then once daily for a total of nine injections. Spinal-fluid cultures were sterile on the third day, and blood cultures were negative on the fifth day. The symptoms of meningitis cleared slowly, and the patient became rational on the fifth day. He then developed gradually increasing congestive heart failure, which did not respond to the usual therapeutic measures, and a mitral systolic murmur was heard for the first time. He died after sixteen days of penicillin therapy. At autopsy the meninges appeared to be grossly normal, but there was a vegetative endocarditis of the mitral valve. Cultures of the cardiac blood and meninges gave no growth. Cultures of the vegetations yielded *Staphylococcus aureus* that was nonhemolytic, coagulase-negative and somewhat more sensitive to penicillin than the original blood-culture strain.

COMMENT

The results of the observations presented, when viewed in the light of the data already known and many that have not yet been published, indicate that penicillin is by far the most effective agent now available for the treatment of subacute bacterial endocarditis and for endocarditis caused by other susceptible organisms. It has rendered the blood stream free of bacteria in almost all such cases in which it has been given in adequate doses for at

CLINICAL NOTE

A NEW POCKET PRISMATIC MICROSCOPE

DANIEL J. O'BRIEN, M.D.

WINTHROP, MASSACHUSETTS

A NEW compact microscope is shown in Figure 1. This pocket microscope weighs 1 pound and 6 ounces, and measures $4\frac{1}{2}$ inches in length, $2\frac{1}{2}$ inches in width and $5\frac{1}{4}$ inches in height. Conventional eyepieces and objectives (low-dry, high-dry and oil immersion) are used, giving a magnification and size of field comparable to the ordinary laboratory microscope. The action of a large microscope is made possible in this diminutive model by bending the light rays through four right-angle prisms in line. A focal length of 175 mm. is maintained, and this allows the use of regular objectives and eyepieces. There is no appreciable loss of magnification or clarity.

This workshop model possesses only a coarse focal adjustment, but a fine adjustment can be added to the precision-built, factory instrument. There is some inevitable reflectionary loss of light as the rays pass through the prisms, but a similar loss of light occurs in the large binocular microscopes. The substage condensing of light, normally done with an Abbé condensing lens, has been practically accomplished by using a mirror of short focal length

(5-cm. radius and $+10,-10$ curve) that reflects a completely satisfactory cone of light on the slide. The occasional desire for the reduction of light

FIGURE 1.

usually accomplished with a diaphragm is performed by a mirror adjustment by means of a small knoblike button at the side of the base.

This prismatic microscope is presented as a small, light, powerful instrument for bedside use.

MEDICAL PROGRESS

THE CLINICAL IMPORTANCE OF THE RH BLOOD TYPE (Concluded)*

LOUIS K. DIAMOND, M.D.†

BOSTON

RH INCOMPATIBILITY IN PREGNANCY

In contrast to the type of mild or only moderate transfusion reactions described above in men and in nongravid women, it has been recognized for several years that during pregnancy, or shortly thereafter, women may have severe transfusion reactions when given presumably compatible blood during a first transfusion. In 1939, Levine and Stetson¹⁰ reported a case of intragroup agglutination in a pregnant woman in which they demonstrated an abnormal agglutinin; they suggested that this had resulted from sensitization of the mother to some agent present in the fetus, inherited

from the father. They did not give this antigen a name, and only later recognized it as similar to the Rh factor described by Landsteiner and Wiener.

A typical instance of this sort is illustrated in the following case.

CASE 4. *Hemolytic reaction to first transfusion of Rh+ blood.* A 26-year-old woman at term in her third pregnancy gave the following history. The first pregnancy had resulted in a normal child, and the second, in an infant with moderate jaundice shortly after birth and anemia lasting 6 weeks. Recovery occurred without transfusion. Shortly before admission, fetal activity ceased, and a few hours later a still-born infant was delivered. At necropsy the diagnosis of erythroblastosis fetalis was substantiated.

There was considerable post-partum bleeding; this was uncontrolled by vaginal packing so that transfusion was necessary. The husband, being Group O and apparently compatible, was used. After 300 cc. of blood had been infused the patient showed signs of shock and passed a small amount of bloody urine. Thereafter her condition was precarious, with the development of anuria and jaundice. No further transfusions were given, and the patient recovered in about 3 weeks. Impaired renal function persisted, however.

*From the Department of Pediatrics, Harvard Medical School, the Infants' and Children's Hospital, and the Blood Grouping Laboratory, Boston

and those made by other workers have shown a similar course under treatment with penicillin alone. No advantage has therefore been found to justify the additional effort and risks of heparin treatment. A true evaluation of the relative merits of the combined treatment is extremely difficult and requires a considerably greater experience than is represented in the present series.

SUMMARY AND CONCLUSIONS

The relevant data are presented in 9 cases of subacute bacterial endocarditis that were treated with sodium penicillin at the Boston City Hospital during 1944. The dose generally used was 25,000 units intramuscularly every two hours for two weeks. Seven of the patients are alive and have been free of evidences of active infection for one to eleven months.

Two patients had recurrence of infection, one after four months and the other after only one month. It is not certain whether these recurrences represent reactivation of the original infection or reinfection.

An additional fatal case of *Streptococcus viridans* endocarditis was treated. Another extremely severe case with a characteristic clinical course of subacute bacterial endocarditis with multiple emboli improved, and the patient was living three months after treatment, but no bacteria could be grown from the blood before penicillin was started.

All the fatal cases had severe heart failure resulting from extensive damage to cardiac structures.

The findings in 7 cases of acute bacterial endocarditis treated during the same period are also presented. Small doses were generally used in these cases because of the greater susceptibility of the organisms. In 3 of these cases, — one caused by a Type 7 pneumococcus, the second by a Type 5 pneumococcus and the third by a Group A, Type 28, hemolytic streptococcus, — the patients are living and well. The diagnosis in all the fatal cases was confirmed at autopsy but in those who survived is only highly probable.

Heparin was used together with penicillin in 3 of the *Str. viridans* cases and in 2 of those due to pneumococcus. There appeared to be no benefit from this therapy to justify the additional effort and risk.

The present findings suggest that early and intensive treatment with penicillin maintained for an

adequate period offers the best hope for recovery or arrest of infection in cases of subacute and acute bacterial endocarditis. The optimum dosage and duration of treatment are yet to be determined.

The importance of early diagnosis and treatment, as well as the careful and intelligent management of the convalescent phase, are stressed.

We are indebted to the members of the visiting and resident staff of the hospital, who co-operated generously in the study of these cases. The routine bacteriologic studies were done by Miss Marion E. Lamb and her associates at the Mallory Institute of Pathology.

though Rh+, because the pregnancy initiates the stimulation of the mother's antibody production. In this case, previous transfusion caused antibody development, and even the first child suffered from severe erythroblastosis fetalis. Succeeding pregnancies with Rh+ infants resulted in similar catastrophes.

Erythroblastosis fetalis resulting from sensitization produced by the transfusion of an Rh- woman with Rh+ blood is always the worst form of this disease. Thus, in the 25 women in our series, 18 had two or more infants with erythroblastosis fetalis. Of 32 of these fetuses or babies, 28 died in utero, and 4 lived for less than twenty-four hours. Three women each had a single normal infant, and each of the latter was Rh-. In such cases, the sensitization may be established long before pregnancy begins, so that the Rh+ fetus begins to suffer harm early in gestation, probably from about the eighth to tenth week, when its red cells first develop Rh agglutinogens. Such infants are prone to die in utero, usually in the seventh to eighth month of gestation, and even those that are born alive, usually before the end of term, succumb within a day or two. Although this complication of pregnancy may occur relatively infrequently, it represents a major catastrophe in the life of such women and in their child-bearing potentialities. Only women married to heterozygous Rh+ men will succeed in having living children, and these will be Rh-. Since 38 per cent of the population is R+ homozygous, sensitization of the Rh- woman of child-bearing age by transfusion of Rh+ blood remains a serious hazard.

Because of the increasing use of stored blood and the frequency of transfusion as a therapeutic measure, the danger of immunization of women of child-bearing age is an increasing one. A recent development that makes this danger even greater is the use of resuspended red cells from which the plasma has been removed for the production of plasma. Since these cells have been made readily available in many large cities, especially on the public wards of hospitals, transfusion of resuspended cells has been liberally used. Since many women of child-bearing age have been given such blood without preliminary typing of the recipient for the Rh factor, the danger of sensitization with Rh+ cells has increased and the successful termination of future pregnancies has thereby been jeopardized, and needlessly so. Rh typing is therefore an important preliminary to the transfusion of blood, particularly those in the child-bearing age.

ERYTHROBLASTOSIS FETALIS

This disease has already been mentioned as a sequel to sensitization of the Rh- mother to Rh+ red cells, with the development in the mother's serum of anti-Rh agglutinins. These can readily pass the placental barrier and affect the Rh+ infant

just as soon as a sufficiently high titer has developed in the mother's blood. This important discovery, the outstanding contribution to our understanding of erythroblastosis fetalis, was first made by Levine, Katzin, and Burnham⁴¹ in 1941. It was proved conclusively in numerous subsequent studies by Levine and his co-workers,⁴²⁻⁴⁵ and this has been confirmed by many others.⁴⁶⁻⁵⁰ The disease usually develops in the second or subsequent Rh+ infant, since it usually requires at least one pregnancy to initiate sensitization of the Rh- mother, when a second or subsequent pregnancy restimulates her to the development of stronger agglutinins. Sometimes the first child to be so affected develops relatively mild symptoms of jaundice and anemia and recovers spontaneously.

The classic symptoms and signs of this disease are jaundice within twenty-four to forty-eight hours and the development of anemia, often at birth but more regularly by the third or fourth day, becoming most profound by the end of the seventh or the eighth day if the disease is not of the fulminating type. Death due to anemia and anoxia, however, may occur within the first twenty-four to forty-eight hours. Splenomegaly and hepatomegaly are quite frequently present. Edema and even universal hydrops may be noted in the most severely affected infants immediately after birth or within the first day. A large number of nucleated erythrocytes often occur in the peripheral blood, but this finding is not necessarily a criterion of the disease. Finally, erythroblastosis may develop in infants who do not have hemolytic anemia due to Rh incompatibility, especially those with infection, with congenital malformations of the heart, with anoxia due to atelectasis of the lungs and with intracranial hemorrhage, and even extremely premature infants. In the usual case, the final laboratory confirmation of the diagnosis is the demonstration of an Rh- mother, an Rh+ father, an Rh+ infant and anti-Rh agglutinins in the mother's serum.

In the severe forms, the jaundice often increases rapidly and is then augmented by an obstructive jaundice, owing to blockage of the bile capillaries in the liver and a disturbance of function of the hepatic cells. This obstruction may be so intense, with all the signs and symptoms so overshadowing the anemia and other signs of erythroblastosis fetalis, that the patient is thought to be suffering from congenital obliteration of the bile ducts. In fact some patients with hemolytic anemia have been subjected to exploratory operation for such a congenital defect before the diagnosis of hemolytic anemia was made.^{51, 52} Hemolytic anemia of the newborn tends to become severer in succeeding pregnancies, with greater degrees of jaundice and earlier intrauterine death of the infant, with universal hydrops and anemia.

Treatment of the condition consists chiefly of the early recognition of the disease and the use of trans-

Blood typing revealed that the patient was 'Group 0, Rh—; her husband, Group 0, Rh+; and the two living children, Group 0, Rh+. The patient's serum showed a large amount of anti-Rh agglutinin.

In contrast to the forewarning that usually occurs in transfusion reactions due to Rh incompatibility in men or in nongravid women, in whom the first transfusion is uneventful and only the second may produce signs of a hemolytic reaction, in pregnancy the first transfusion given to the Rh— woman who has had an infant with jaundice, anemia or other signs of hemolytic anemia or erythroblastosis fetalis may result in a serious if not fatal reaction. In such cases it is found that the husband and the child are Rh+, that the mother is Rh— and that her serum contains anti-Rh agglutinins. As has been pointed out by Levine, a modified compatibility test will occasionally give warning of such an incompatible transfusion, in that the donor's cells may be agglutinated by the recipient's serum after incubation for half an hour at 37°C. This test when negative, however, cannot be relied on as evidence of no danger of a transfusion reaction, since, as has been pointed out, the test-tube agglutination method fails in more than 50 per cent of the persons in whom such antibodies are present.

A carefully taken history of the previous pregnancies, with the result of each, may occasionally forewarn of the danger of an intragroup transfusion reaction in women who have borne one or more children. In such cases a story of jaundice or anemia in a child or of a late stillbirth should always be regarded as significant, and the danger of a transfusion reaction should be avoided by careful grouping, Rh typing and cross-matching.

In contrast to the statistics for hemolytic transfusion reactions in men and nongravid women, severe reactions due to Rh incompatibility occur when immunization is the result of pregnancy. Thus, in 32 cases, 21 patients had moderately severe reactions and 6 had severe reactions, 5 of the latter dying. Such evidence alone is sufficient proof of the danger of transfusion in obstetric patients who are Rh—.

Another and even more serious type of reaction in pregnancy is illustrated below.

CASE 5. Hemolytic reaction to second transfusion of Rh+ blood. A 36-year-old patient had had four pregnancies, the first three children being alive and well and the fourth having died of prematurity and pulmonary atelectasis after 7 months of gestation. The fifth pregnancy was terminated by cesarean section at 7 months on account of a complete placenta previa, and the infant succumbed to atelectasis. The mother required a transfusion, the blood being obtained from the husband, a presumably compatible donor, later proved to be Rh+; no reaction followed. A sixth pregnancy four years later resulted in the precipitate delivery at 8 months of an infant with erythroblastosis fetalis, who died in 12 hours. The placenta was large, and there was considerable hydramnios.

Immediately after delivery continued bleeding from a hole in the uterus necessitated hysterectomy. Because of a hemorrhage, 500 cc. of presumably compatible blood (Donor 1) was given while the patient was still anesthetized. This was followed by a hematemesis and symptoms of shock. In the

following 3 hours three more transfusions (Donors 2, 3 and 4) were administered, with increasing shock, anuria and jaundice. Finally, transfusions from Donors 5, 6 and 7, especially chosen for their Rh type, were given with no untoward reaction. Anuria continued, however, and the patient became uremic and died in about 2 weeks.

Blood typing proved the patient was Group 0, Rh—; the husband, Group 0, Rh+, the children, Group 0, Rh+, Donors 1, 2, 3 and 4, Group 0, Rh+; and Donors 5, 6 and 7, Group 0, Rh—. The patient's serum contained a high titer of anti-Rh agglutinins when tested after the later transfusions. This Rh— woman, married to an Rh+ man, had three normal Rh+ infants. No sensitization occurred due to these pregnancies, as proved by the necropsy examination of the fourth and fifth infants and the uneventful transfusion of Rh+ blood following the fifth pregnancy. This transfusion, however, produced sensitization to the Rh factor, with the development of agglutinins. The sixth pregnancy probably increased the sensitization. The fetus was severely damaged by the agglutinins present in the mother's circulation and died of erythroblastosis. The several transfusions that were required produced serious hemolytic reactions, even though they were from homologous donors. Later typing proved that the reactions were due to the interaction of the infused Rh+ cells with the high-titered anti-Rh agglutinins in the patient's serum. Despite three compatible transfusions of Rh— blood, taken without reaction, the patient succumbed. Thus, although the pregnancies had produced no sensitization, a single transfusion of Rh+ blood sensitized the patient, with resulting harm to the next Rh+ fetus and to herself after transfusion of Rh+ blood.

Since some of the earliest symptoms of incompatible blood transfusion are subjective, it is generally advisable to avoid the use of whole blood in anesthetized patients.

In Rh— women sensitized by previous transfusion and in whom this sensitivity has been increased by pregnancy with an Rh+ fetus, transfusion reactions are almost invariably fatal, with, in addition, erythroblastosis producing death of the fetus before term. This was true in all 3 such cases in our series.

The last important complication of Rh incompatibility in pregnancy is the development of erythroblastosis in the fetus as the result of sensitization of an Rh— woman by transfusion of Rh+ blood. The following case is illustrative.

CASE 6. Erythroblastosis fetalis resulting from incompatible transfusions. A 23-year-old white woman gave the following history. At the age of 16 she had had a major operation for removal of a tumor and, because of subsequent bleeding, had required six blood transfusions, which were given without reaction. Two years later the recurrence of bleeding following surgery required four further transfusions. These produced no serious reactions, but the patient apparently felt uncomfortable and subsequently failed to show the expected rise in hemoglobin level. One year later, her first pregnancy ended at term in a stillborn infant with the congenital hydrops type of erythroblastosis fetalis.

Blood typing proved the patient to be Group 0, Rh—, and the husband, Group 0, Rh+. Two of the donors previously used were Rh+. The patient's serum contained a high titer of anti-Rh agglutinins. The following year, and again two years later, pregnancies resulted in stillborn infants with severe erythroblastosis of the fetal hydrops type.

This Rh— woman received multiple transfusions, which caused the development of a high titer of anti-Rh agglutinins. Her Rh+ husband transmitted this factor to his offspring. The usual history obtained in women having infants with erythroblastosis states that the first child is unaffected, even

satisfactory titer of agglutinins, but 4 developed none at all and showed no reaction at the end of a series of injections when given a larger amount of Rh+ blood. It remains for statistical studies, particularly those on men in the armed forces, where large amounts of whole blood have been given, to determine how many persons can develop anti-Rh agglutinins as the result of stimulation by transfusion alone. With the increasing therapeutic use of whole blood and its greater availability in blood banks, the Rh factor has become increasingly important.

Regarding pregnancy, it must first be realized that not every Rh- woman married to an Rh+ man will suffer harm from pregnancy with Rh+ infants. Owing to the occasional newspaper report of the birth of infants with erythroblastosis fetalis and the peculiarities of the mother's blood that produced such disturbances, flurries of excitement have occurred, and many women have been forewarned that, because they have Rh- blood, their pregnancies are sure to suffer forever after. Statistically the marriage of an Rh- woman to an Rh+ man occurs in 12 per cent of all marriages. Erythroblastosis fetalis has been stated to occur about once in two hundred deliveries (Javert⁷³ and Schwartz and Levine⁷⁴), but was found as frequently as once in about one hundred and fifty deliveries in our series. Therefore, only one in about fifteen marriages between an Rh- woman and an Rh+ man will lead to erythroblastosis fetalis in the offspring, and this usually does not occur until the second or later pregnancy. In addition, the factors in isoimmunization by pregnancy alone can be resolved further on the basis of whether the father of the child is homozygous, that is, the offspring of two Rh+ parents, and carrying two Rh+ genes, or heterozygous and carrying only one Rh+ gene in his cells. This is not always detectable by Rh testing of his cells but is of practical importance. In the former case, all the children must be Rh+, although heterozygous; in the latter case, half the children will be Rh- and will thus escape harm by the agglutinins of the mother if such have developed through previous transfusion or pregnancy. In addition, to produce erythroblastosis fetalis, it is assumed that the placental barrier must be faulty and that the fetal Rh+ cells must be able to enter the maternal circulation.

Since the placental barrier is assumed to hold back cellular elements, since some persons do not respond to Rh antigen by anti-Rh production, since 49 per cent of Rh+ men are heterozygous and can father Rh- children and since two or more pregnancies are usually necessary to produce infants suffering from erythroblastosis fetalis, this disease remains a fairly rare complication of Rh differences between mates. It may even be suggested that other incompatibilities between man and wife are more hazardous to married life than differences in the Rh factor.

In attempting a prognosis for further pregnancies in any given family, it is of value not only to test the mother's blood for anti-Rh agglutinins in the second and subsequent pregnancies, but also to try to determine whether the father is homozygous or heterozygous. Should he be homozygous and one infant with erythroblastosis has been born, all subsequent infants will be similarly affected and further pregnancies may be contraindicated.

An additional laboratory measurement of prognostic value is the determination of the increase in anti-Rh titer during pregnancy in women who have had a previous infant with erythroblastosis fetalis or who have been sensitized by an Rh+ transfusion. In such cases, the agglutinin titer tends to increase relatively late in pregnancy, usually by the seventh or eighth month. Earlier in pregnancy, the presence of anti-Rh agglutinins has not been proved harmful to the fetus, since even a high titer of antibodies does not usually cause abortion at the second or third month of gestation. Possibly this is related to the relatively late appearance in the fetus of red cells carrying the Rh agglutigen. They have been found by us in a three-month fetus on four separate occasions, by Stratton⁷⁵ in a 48-mm. embryo and by Bornstein and Israel⁷⁶ in a 17-cm. fetus.

If the titer does suddenly rise, the delivery of an infant who seems large enough to be viable at about eight to eight and a half months of gestation results in a milder degree of erythroblastosis than if the infant had been permitted to remain in utero and thus subjected to a high titer of agglutinins until term. The following case is illustrative.

CASE 7. Increase in anti-Rh titer during pregnancy. A 30-year-old woman had had a normal first-born child and a second child who died of erythroblastosis on the 3rd day of life. The husband proved to be Rh+; the wife, Rh-; and the two children, Rh+.

During the third gestation, tests on the mother's serum for anti-Rh agglutinins were as follows: at 6 months, negative; at 7 months, negative; at 7½ months, low agglutinin titer; at 8 months, moderate agglutinin titer; and at 8½ months, high agglutinin titer. Because of the sudden increase in antibodies against the Rh factor late in pregnancy, delivery was induced at 8½ months, and a 5-pound, Rh+ infant was obtained. Within 24 hours, jaundice and anemia were noted, but after three transfusions the infant recovered and remained well.

In this case, although a second child had died at term of erythroblastosis, a third pregnancy resulted in a child surviving after several transfusions.

This is one of the two methods of proved value in assisting the previously sensitized Rh- mother to have a living Rh+ infant. In 41 cases of early induction of delivery on account of a rising titer of anti-Rh agglutinin, there have been 32 living and 9 dead children. The other method, particularly applicable in the mating of a homozygous Rh+ man to a sensitized Rh- woman, is artificial insemination using an Rh- donor. This has been uniformly successful in 6 cases. Potter and Willson⁷⁷ have recently reported a similar experience. The

fusions of compatible blood, which for the first ten to fourteen days of life should be Rh—. For this, the mother's washed cells or, still better, whole blood from an Rh— donor may be used.^{42, 53-57} The rationale for the use of Rh— blood is that many of these infants still have in their circulation anti-Rh agglutinins that are not combined with their own Rh+ cells and are therefore potentially active against other Rh+ cells infused into the infant's circulation. Rh— cells cannot be affected by such abnormal agglutinins and have been proved to survive in the infant's circulation.^{52, 58}

Infants with erythroblastosis should not be permitted to receive the mother's breast milk, since it has been proved that the agglutinins may be present therein and, after absorption through the stomach, may produce further destruction of the Rh+ cells.^{50, 59, 60}

One of the complications of erythroblastosis fetalis of the severe icteric type (icterus gravis familiaris) is damage to the nuclei of the brain, a condition known as kernicterus. When this occurs, the infant exhibits convulsions, twitching, opisthotonos and respiratory difficulties. Death may occur in the first week. If the baby survives, he is sometimes left with an impaired nervous system, with spastic paraplegia and mental retardation later in life. Fortunately, this complication of the severely icteric type of erythroblastosis occurs in less than 16 per cent of all such patients. The majority of children who recover develop normally in later life and show no damage from the early hemolytic anemia. One late complication in infants who have been severely jaundiced at birth is a deep-green staining of the deciduous teeth. This is directly related to the degree and the time of the jaundice in intrauterine and neonatal life and is the result of pigment deposition in the growing enamel. It does not affect the permanent teeth and can therefore be ignored.

TESTING FOR RH FACTOR AND ANTI-RH AGGLUTININS

There are a few practical considerations regarding laboratory technics involving the Rh factor and anti-Rh agglutinins. In performing tests for the Rh factor, it is important to make certain that the red cells are obtained from freshly drawn blood. The Rh agglutininogen is apparently more fragile than are the A and B agglutininogens and tends to give weaker reactions the longer the red cells remain outside the body, particularly if they are suspended in normal saline solution; thus, false negative tests may result. The details of the technic of Rh testing, including the precautions necessary for accuracy, have been best described by Wiener,³² by Levine⁶¹ and by Taylor.⁶²

The anti-Rh serum used for Rh determinations should be tested frequently against known Rh+ and Rh— cells. Such serum, especially if originally low

in potency, tends to deteriorate on standing, even when stored in the refrigerator. In general, the serum should be of the highest possible potency and of wide specificity. At least four types of serum have already been identified, namely, one that agglutinates only 30 per cent of Rh+ cells (anti-Rh''), one that agglutinates 73 per cent of Rh+ cells (anti-Rh'), one that agglutinates 85 per cent of Rh+ cells (anti-Rh₀) and one that agglutinates 87 per cent of Rh+ cells (anti-Rh). For complete differentiation, more than one of the first three serums may be necessary.

It has been advised that the demonstration of anti-Rh agglutinins be carried out in the test tube with a dilute suspension of Rh+ cells from a known donor and freshly drawn serum from the subject under investigation.^{32, 53, 61-65} This test, however, is not always conclusive, since a new type of antibody, the so-called "blocking antibody" of Wiener,⁶⁶ the "incomplete antibody" of Race⁶⁷ or the "inhibitor substance,"⁶⁸ is present in more than 50 per cent of the serums of women who have been sensitized by transfusion or pregnancy, or both; this inhibits agglutination of a dilute suspension of Rh+ cells by anti-Rh agglutinin in a test tube on incubation at 37°C. Wiener has suggested a test for this blocking antibody. Furthermore, a rapid method for the demonstration of anti-Rh agglutinins that avoids difficulties resulting from the inhibitor substance has been described.⁶⁹ It must therefore be recognized that anti-Rh agglutinins may exist in the serum of sensitized persons without necessarily being demonstrable by the test-tube incubation method of detection and that the so-called "modified compatibility test" cannot be used as the sole safeguard in cross-matching preliminary to transfusion.

PRACTICAL APPLICATIONS

That the determination of the Rh factor has practical value has been briefly presented in the preceding pages. More comprehensive reviews have been written by Potter,⁷⁰ by Davidsohn⁷¹ and by Boyd.⁷² From the accumulated facts, certain conclusions are permissible.

It is of increasing importance that recipients of transfusions, especially of multiple transfusions, be typed for the Rh factor. The Rh— individuals (13 per cent of the white population) who receive Rh+ blood may develop anti-Rh agglutinins, which will interfere in succeeding transfusions with complete benefit from the infused blood. Transfusion reactions of increasing severity will then occur, and in some cases these may cause serious kidney damage, although death does not commonly occur as a result of Rh sensitization from transfusion alone. An attempt to evaluate the frequency with which men or nongravid women can develop anti-Rh agglutinins when given Rh+ cells was made by repeatedly injecting small amounts of such cells into Rh— subjects. Six of 10 men developed a

CASE 31171

PRESENTATION OF CASE

A fifty-two-year-old man was admitted to the hospital because of difficulty in swallowing.

Six weeks before admission, the patient noticed difficulty in swallowing solids for the first time. He had to follow solid food with large amounts of tea and other liquids, otherwise hiccoughs and slight substernal pain ensued. This difficulty progressed, and an uncomfortable "stretching sensation" with each swallow became pronounced about the area of the midsternum. Over a period of four weeks the dysphagia became so marked that he could swallow only liquids and mushy foods. He had no nausea or regurgitation and had lost little or no weight. He felt well and did not become fatigued easily. A barium swallow and chest x-ray in the Out Patient Department two weeks before admission showed the swallowing function to be normal. The esophagus was rather irregularly dilated to a point about 16 cm. above the esophago-gastric junction, where there was a constant narrowing with probable shelf formation extending for a distance of 7 cm. There was no ballooning in this area, and the barium passed through rather rapidly without evidence of obstruction. The mucosal pattern did not appear to be normal in this area, and there was probably a small amount of destruction. The remaining 9 cm. of esophagus appeared to be normal. Two weeks before admission the patient allegedly had one tarry stool. He had had frequent nosebleeds in the past few weeks and thought that he had regurgitated small amounts of blood. The patient believed that he had become quite pale in the past two years.

At twenty-two years he had had pneumonia, and in his early twenties gonorrhea. At twenty-five years of age he had suffered from migratory joint pains, was told that he had rheumatism and remained in the hospital for two months. The following year he had a tonsillectomy. He was seen frequently in the Out Patient Department at the age of forty-eight, four years before admission, because of severe substernal pain on exertion, which was promptly relieved by rest or nitroglycerin. X-ray

films at that time showed the heart to be enlarged across the base, with a prominent left auricle and pulmonary conus. The lung fields and diaphragm were normal. An electrocardiogram was thought to be within normal limits. The blood pressure was 120 systolic, 80 diastolic. The anginal pain improved, but he continued to be moderately dyspneic on exertion.

Physical examination revealed a slightly obese, well-developed man in no distress. The chest was moderately emphysematous, and a few inspiratory rales were heard at the apices. The apex beat was 1 cm. to the left of the midclavicular line. A loud first sound was heard at the apex. There was a questionable early diastolic murmur along the left sternal border in the third interspace. The aortic second sound was greater than the pulmonic. The abdomen was normal. There was no lymphadenopathy. A rectal examination revealed an enlarged, firm, smooth prostate.

The temperature and respirations were normal. The pulse was 75.

Examination of the blood showed a red-cell count of 5,160,000 and a white-cell count of 9200. Examination of the urine was negative. Stools were guaiac negative. The prothrombin time was 23 seconds (normal, 18 to 20 seconds). The serum nonprotein nitrogen, the protein and the chloride values were normal. An electrocardiogram showed normal rhythm at 85, a PR interval of 0.18 second, normal axis, small Q₁, upright T₁, T₂ and T₄ and flat T₃.

X-ray films of the chest showed no evidence of metastatic cancer. There appeared to be some enlargement of the left auricle and perhaps of the left ventricle.

On the sixth hospital day the patient was esophagoscoped. The instrument passed readily to approximately 29 cm. below the teeth, where there was marked narrowing of the lumen to a diameter of approximately 3 mm. There were reddening, slight irregularity and erosion of the anterior wall. Seven hours after esophagoscopy the patient became slightly dizzy and cyanotic, with mild, nonradiating, substernal pain. The blood pressure was 60 systolic, 40 diastolic. The temperature was 100.6°F., and the pulse was irregular and thready, with a rate of about 110. The patient perspired profusely, became unresponsive and developed convulsive twitchings. A few seconds after oxygen was administered he regained consciousness. An electrocardiogram revealed auricular fibrillation, with a rate of 155, normal axis, low upright T₁ and upright T waves in Leads 2, 3, CF₂, CF₄ and CF₆. There were two ventricular premature beats in Lead 1. In some areas the P waves seemed prominent and suggested runs of paroxysmal auricular tachycardia. A repeat electrocardiogram three hours later was unchanged, except that the rate had increased to 175. Two hours after 6 cc. of Cedilanid had been given, the patient

*On leave of absence.

emotional adjustments necessary for this form of treatment do not recommend it for widespread use.

CONCLUSIONS

The Rh blood type, present in about 87 per cent of the white population, is of practical importance almost exclusively to the persons who lack it. In the latter, repeated transfusion of Rh+ blood cells may lead to increasing hemolytic reactions, owing to the interaction of anti-Rh agglutinins initiated by the first Rh+ transfusion with the specific agglutigen of the infused cells.

Rh- women married to Rh+ men may be sensitized by means of one or more pregnancies involving an Rh+ fetus, the Rh factor being inherited as a dominant trait. Although this only occurs in one of about fifteen such matings, once so immunized, the woman cannot safely be given even one transfusion of untyped or Rh+ blood, since it may produce a serious, even fatal, hemolytic reaction.

A single Rh+ transfusion to an Rh- woman, married to an Rh+ man, may initiate the antibody response, and a subsequent pregnancy with an Rh+ fetus may end in the severest form of erythroblastosis fetalis in the infant. Women of child-bearing age must therefore be protected against this potential danger.

Infants who have erythroblastosis fetalis should be treated early and actively with transfusions of Rh- blood. The diagnosis of the usual type of erythroblastosis fetalis is dependent not only on the well-known physical signs but also on the laboratory demonstration of anti-Rh agglutinins in the Rh- mother of an Rh+ infant of an Rh+ father.

The laboratory technics for testing for the Rh factor and anti-Rh agglutinins require certain safeguards and experience.

Finally, Rh typing is necessary for all recipients (male or female) of repeated transfusions, for all women requiring transfusion, to avoid serious reactions in those who have borne an erythroblastic infant and to avoid sensitization of Rh- women of child-bearing age, for the listing of Rh- donors for emergency use and for the procurement of Rh- banked blood to be given to Rh- patients.

An anti-Rh determination is particularly indicated in pregnant women whose histories show that one or more previous pregnancies ended in late stillbirths, infants with severe jaundice or anemia or even infant deaths apparently due to hemorrhage or anoxia, in Rh- women who have received transfusions, especially from their husbands and in Rh- women married to Rh+ men who have had one or two children and may therefore have been sensitized to the Rh factor.

Some practical benefit may be derived from following the anti-Rh agglutinin titer of the serum during the pregnancy of the woman who has had a previous child with erythroblastosis fetalis.

CASE 31171

PRESENTATION OF CASE

A fifty-two-year-old man was admitted to the hospital because of difficulty in swallowing.

Six weeks before admission, the patient noticed difficulty in swallowing solids for the first time. He had to follow solid food with large amounts of tea and other liquids, otherwise hiccoughs and slight substernal pain ensued. This difficulty progressed, and an uncomfortable "stretching sensation" with each swallow became pronounced about the area of the midsternum. Over a period of four weeks the dysphagia became so marked that he could swallow only liquids and mushy foods. He had no nausea or regurgitation and had lost little or no weight. He felt well and did not become fatigued easily. A barium swallow and chest x-ray in the Out Patient Department two weeks before admission showed the swallowing function to be normal. The esophagus was rather irregularly dilated to a point about 16 cm. above the esophago-gastric junction, where there was a constant narrowing with probable shelf formation extending for a distance of 7 cm. There was no ballooning in this area, and the barium passed through rather rapidly without evidence of obstruction. The mucosal pattern did not appear to be normal in this area, and there was probably a small amount of destruction. The remaining 9 cm. of esophagus appeared to be normal. Two weeks before admission the patient allegedly had one tarry stool. He had had frequent nosebleeds in the past few weeks and thought that he had regurgitated small amounts of blood. The patient believed that he had become quite pale in the past two years.

At twenty-two years he had had pneumonia, and in his early twenties gonorrhea. At twenty-five years of age he had suffered from migratory joint pains, was told that he had rheumatism and remained in the hospital for two months. The following year he had a tonsillectomy. He was seen frequently in the Out Patient Department at the age of forty-eight, four years before admission, because of severe substernal pain on exertion, which was promptly relieved by rest or nitroglycerin. X-ray

*On leave of absence.

films at that time showed the heart to be enlarged across the base, with a prominent left auricle and pulmonary conus. The lung fields and diaphragm were normal. An electrocardiogram was thought to be within normal limits. The blood pressure was 120 systolic, 80 diastolic. The anginal pain improved, but he continued to be moderately dyspneic on exertion.

Physical examination revealed a slightly obese, well-developed man in no distress. The chest was moderately emphysematous, and a few inspiratory rales were heard at the apices. The apex beat was 1 cm. to the left of the midclavicular line. A loud first sound was heard at the apex. There was a questionable early diastolic murmur along the left sternal border in the third interspace. The aortic second sound was greater than the pulmonic. The abdomen was normal. There was no lymphadenopathy. A rectal examination revealed an enlarged, firm, smooth prostate.

The temperature and respirations were normal. The pulse was 75.

Examination of the blood showed a red-cell count of 5,160,000 and a white-cell count of 9200. Examination of the urine was negative. Stools were guaiac negative. The prothrombin time was 23 seconds (normal, 18 to 20 seconds). The serum nonprotein nitrogen, the protein and the chloride values were normal. An electrocardiogram showed normal rhythm at 85, a PR interval of 0.18 second, normal axis, small Q₁, upright T₁, T₂ and T₄ and flat T₃.

X-ray films of the chest showed no evidence of metastatic cancer. There appeared to be some enlargement of the left auricle and perhaps of the left ventricle.

On the sixth hospital day the patient was esophagoscoped. The instrument passed readily to approximately 29 cm. below the teeth, where there was marked narrowing of the lumen to a diameter of approximately 3 mm. There were reddening, slight irregularity and erosion of the anterior wall. Seven hours after esophagoscopy the patient became slightly dizzy and cyanotic, with mild, nonradiating, substernal pain. The blood pressure was 60 systolic, 40 diastolic. The temperature was 100.6°F., and the pulse was irregular and thready, with a rate of about 110. The patient perspired profusely, became unresponsive and developed convulsive twitchings. A few seconds after oxygen was administered he regained consciousness. An electrocardiogram revealed auricular fibrillation, with a rate of 155, normal axis, low upright T₁ and upright T waves in Leads 2, 3, CF₂, CF₄ and CF₆. There were two ventricular premature beats in Lead 1. In some areas the P waves seemed prominent and suggested runs of paroxysmal auricular tachycardia. A repeat electrocardiogram three hours later was unchanged, except that the rate had increased to 175. Two hours after 6 cc. of Cedilanid had been given, the patient

was comfortable and oriented, with a strong, regular pulse, at a rate of 90, and a blood pressure of 105 systolic, 65 diastolic.

On the following day he passed about 300 cc. of dark blood by rectum. He became pale, and the red-cell count dropped to 3,300,000, and the blood pressure to 90 systolic, 60 diastolic, with a pulse of 90. He had mild substernal pain and coughed up a small amount of blood. He developed purpuric spots over his arms and legs (similar spots had allegedly been appearing and disappearing during the previous month).

X-ray films of the chest showed clear lung fields, with no air in the mediastinum. A repeat film on the eighth hospital day showed linear areas of increased density opposite the fourth rib anteriorly that were not present previously. Two subsequent films showed no change. On the eleventh hospital day the stools were tarry. The red-cell count had dropped to 2,600,000. A repeat prothrombin time was 23 seconds (normal, 18 to 20 seconds). A blood smear showed 84 per cent neutrophils, 10 per cent lymphocytes and 4 per cent monocytes, with almost no platelets and no abnormal red or white cells. A diagnosis of thrombocytopenic purpura was made. Several blood transfusions were given and a splenectomy was performed on the fifteenth hospital day. The patient was kept digitalized and made a prompt recovery. After several transfusions the red-cell count rose to 4,300,000. The bleeding tendency ceased, but the platelet count did not rise.

During the third hospital week the patient became hoarse. The hoarseness increased, and on the twenty-ninth hospital day the left vocal cord was found to be completely paralyzed. The temperature following splenectomy had had daily swings from normal to 100 or 101°F.

On the thirtieth hospital day, the temperature spiked to 104°F. and he began to have paroxysms of cough, during which he brought up bloody sputum. There was no pain; the blood pressure was 110 systolic, 60 diastolic, and the respiratory rate was 22. Dullness and diminished breath sounds developed in both lung bases. X-ray examination of the chest showed an extensive area of increased density close to the right side of the dorsal spine, as well as areas of increased density extending into both lung fields, more marked on the left than on the right. This had not been seen on the films taken two days previously. One swallow of barium was given and, before fluoroscopic observation was possible, the patient experienced a coughing spell, following which barium was seen to outline the previously described irregular mass in the esophagus and also the lower end of the trachea and both stem bronchi. A large amount of barium collected in an irregular cavity that was apparently connected with the esophageal mass and not with the bronchus (Fig. 1). The temperature and respirations remained elevated, and the cough became ineffective. On the

thirty-sixth hospital day he became semiconscious, coughed and vomited gross blood and finally went into shock and expired.

DIFFERENTIAL DIAGNOSIS

DR. EARLE M. CHAPMAN: May we see the x-ray films?

DR. GEORGE W. HOLMES: In this set of films there is nothing definite in the lungs or in the appearance of the heart. The esophagus shows no

FIGURE 1.

obstruction but has a peculiar appearance in the midportion. I do not know when these spot films were taken, but obviously there is a lesion at this point. There is no evidence of disease in the lungs or heart. To go back to the esophagus, there is an extensive filling defect in it, with some dilatation. It is not the annular infiltrating type of lesion that one ordinarily sees but has the appearance that one sees when there is something inside the esophagus, either a lobulated tumor mass or a foreign body, or both. Later on something happened that allowed the barium to pass from the esophagus into the bronchial tree (Fig. 1) and there is quite a different picture, which is now that of a fistula between the esophagus and the bronchial tree.

DR. CHAPMAN: The bronchial tree at the bifurcation lies on the anterior wall of the esophagus. What is the relation of the aorta at this level to these two structures?

DR. HOLMES: They are close to the ascending aorta.

DR. CHAPMAN: It seems to me that this patient died because of a lesion that was located in an area at the level of the bifurcation of the trachea and at the portion of the esophagus that we believe was 29 cm. down from the teeth. At the level of this eroding lesion there were several structures. We have to believe that it involved the trachea, the bronchi at the bifurcation and the anterior wall of the esophagus and the heart; the left and right auricle lie anterior to this, and the ascending portion of the aorta lies immediately behind. What sort of process would first cause trouble in swallowing and later lead to definite erosion? I should like to ask Dr. Holmes why there was no ballooning of the esophagus above the lesion.

DR. HOLMES: The esophageal wall was rigid and did not expand. A cancer can do that; of course there are other more unusual lesions.

DR. EDWARD B. BENEDICT: We see cancer frequently without obstruction and without much dilatation.

DR. CHAPMAN: It seems clear that this man had an eroding process in the esophagus. He was esophagoscoped, and from there on his course was an unhappy one; he went into shock and bled into the intestinal tract and also into the bronchial tree. The incident of cardiac disturbance might well have been from irritation of the sinoauricular node, which lies in the auricle at this same level. The disturbance of rhythm was controlled, and I do not believe that it indicates coronary occlusion.

DR. HOLMES: The descending aorta is seen fairly well, and if one can tell anything from examination of the x-ray films, he did not have an aneurysm of the aorta.

DR. CHAPMAN: If one can tell, but of course one cannot always tell.

DR. HOLMES: I thought it might help you.

DR. CHAPMAN: Many points suggest syphilis rather than carcinoma.

DR. HOLMES: I thought that you were working up to a differentiation of tumors and aneurysm and were assuming that there was more in the x-ray films than there is.

DR. CHAPMAN: I should like to know about the Hinton and Wassermann tests. There are many things that favor syphilis and I might as well discuss that diagnosis. The patient had angina four years before entry, and it cleared up considerably; this is unusual for ordinary angina, it is usually progressive. We are told that he had a blowing diastolic murmur along the left border of the heart. If we can accept that as a fact, it is strong evidence of a syphilitic lesion involving the heart and causing

aortic regurgitation. We know that he finally died from a process that eroded through into the bronchus and into the esophagus, so if it were an aneurysm it must have been in the descending aorta, a most unusual place. Is that correct, Dr. Holmes?

DR. HOLMES: Yes.

DR. CHAPMAN: This is likelier, however, to be a tumor. Where, then, did the primary tumor lie? With the x-ray description and the later description that it did not cause obstruction, one wonders if it arose from the heart and penetrated the esophagus, or if it arose at the bifurcation of the trachea or in the bronchial tree and was perhaps growing inward to the anterior wall of the esophagus. A good deal of blood had obviously leaked from the primary tumor into the lungs, and he had pneumonitis when he died. Even the barium, as you see, passed out into the lungs through the eroded area. Primary carcinoma of the esophagus has to be considered.

The appearance of purpura hemorrhagica or thrombocytopenic purpura, I believe, was symptomatic of the other process. Whether the main process was syphilis or carcinoma, it is obvious that splenectomy did not increase the platelets, so probably it was not a true thrombocytopenic purpura, which is followed by a rise in platelets after splenectomy.

What else do we have to consider?

In reading one of the x-ray descriptions I thought of pulmonary infarction because of the linear areas of density, but I do not believe that we have to consider such a diagnosis in this case. The disturbance of cardiac rhythm is interesting. I should guess that this man had a good deal of inflammatory reaction about the heart, which involved the surface of the auricles, and that this irritation set up a disturbance of rhythm.

What types of tumor do we have to consider other than carcinoma? It may be that this man's symptoms four years before entry, interpreted as angina, were mistakenly diagnosed. This assumption is supported by the normal electrocardiogram and by Dr. Holmes's statement that the heart was normal by x-ray. He might have had a benign lesion in the esophagus, such as a polyp, that was causing intermittent obstruction and symptoms simulating angina. The reason he got better is that the trouble was not cardiac or vascular in origin. I wonder if he had some unusual type of tumor, such as a hemangioma. All these are remote, however, and it is up to the pathologist to tell what type of tumor this man actually had. I regret the lack of a blood Hinton test, although I do not believe that the lesion was an aneurysm.

DR. RONALD C. SNIFFEN: There was a negative Hinton test reported in the record, which supports your argument against syphilis.

CLINICAL DIAGNOSIS

Carcinoma of esophagus.

DR. CHAPMAN'S DIAGNOSES

Mediastinal tumor (? type), involving esophagus, bifurcation of trachea and auricles.
 Purpura, symptomatic.

ANATOMICAL DIAGNOSES

Malignant lymphoma (clasmatocytic type) of esophagus and mediastinal and retroperitoneal lymph nodes.
 Esophagobronchial fistula.
 Purpura, symptomatic.
 Coronary sclerosis.
 Operative wound: splenectomy.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: This man had a tumor that surrounded the esophagus, starting at the bifurcation of the trachea and extending downward for 11 cm. The mucosa of the anterior esophageal wall was destroyed over an 11-by-3 cm. area. Tumor also involved the mediastinal lymph nodes and had spread to the right lower lobe, eroding one of the secondary branches of the lower lobe bronchus. In doing this it had produced a fistula between the esophagus and the bronchus, with the result that a 12-cm. abscess had formed in the right lower lobe in its medial part, with satellite abscesses lateral to it. Tumor also involved the retroperitoneal lymph nodes behind the stomach and had ensheathed the arch of the aorta. Microscopic sections of this tumor showed a clasmatocytic lymphoma or, in other words, a reticulum-cell sarcoma.

In addition he had a widespread purpura of the skin, the mucous membranes of the small intestine and kidney pelvis and the pancreas. Two hundred centimeters of bloody fluid were found in each pleural cavity, and 100 cc. in the pericardial sac. The heart was not enlarged, but there were ecchymoses in the epicardium, in the endocardium of both ventricles and throughout the muscle of the septum and left apex. He had quite severe arteriosclerosis of the coronary arteries, but we could find no occlusion. The only indication of rheumatic heart disease was slight interadherence of the cusps of the aortic valve. The bone marrow was not involved by tumor; it was hyperplastic and contained only a few megakaryocytes. We know that purpura does occur in a small percentage of people with malignant lymphoma. I am not sure whether or not one has to have bone-marrow involvement to produce the purpura. We could find nothing abnormal in the resected spleen.

CASE 31172

PRESENTATION OF CASE

A seventy-five-year-old business executive was brought to the hospital after he had collapsed in the street.

He had had frequent medical checkups for the past twenty-five years and until about six months before admission had been active and well, with a blood pressure of 160 systolic, 90 diastolic. At that time he began to notice a feeling of pressure or aching in the upper sternal region during exertion. Four months later the pain was no longer present. During the past few months he had had nocturia (three or four times) and had been treated non-surgically for prostatic hypertrophy. On the evening before admission he noted a dull ache in the lumbar region of the back. Despite moderate discomfort he fell asleep but noticed the ache when he arose to urinate, as usual during the night and when he got up the following morning. He had an unusually small bowel movement that morning and passed urine without difficulty at noon. After breakfast he took a streetcar downtown. After an early noon lunch he walked into the street, whereupon the pain in the back became severe. He felt faint and collapsed, losing consciousness for a period of a few minutes. About ten minutes after he was brought into the hospital he vomited a large amount of gastric content, which contained no gross blood. Approximately half an hour later he vomited again and felt much relieved, although he still complained of slight pain in the back.

Physical examination showed a well-developed, well-nourished man in a state of collapse. The blood pressure was 80 systolic, 60 diastolic. The pulse was 94 and of poor quality. The neck veins were not distended. The apex beat could not be felt, and the heart sounds were very distant. There were no murmurs or gallop rhythm. The lungs were clear, and the abdomen was soft, with slight tenderness in the right lower quadrant; no masses could be felt. The liver and spleen were not palpable. A surgical consultant was impressed by an easily felt pulsation low in the left abdomen. This pulsation lay more laterally than one would expect, unless the aorta were displaced to the left. Good femoral pulsations were felt bilaterally. The dorsalis pedis and posterior tibial arteries could not be felt. The arms and legs were cool.

The oral temperature was 97°F; four hours later the rectal temperature was 100°F. The pulse and respirations did not change significantly.

Examination of the blood four hours after admission showed a white-cell count of 27,600, with 84 per cent neutrophils, 12 per cent lymphocytes and 4 per cent monocytes. Two electrocardiograms taken six hours apart showed no progression of change. Both showed normal rhythm, at a rate of 70 to 80, and marked left-axis deviation. There was slight depression of the ST segments in Leads 2 and 3, and very low T waves in Leads 1 and CF₁, with diphasic T waves in Lead CF₂; QRS was of a low amplitude in CF₂.

The patient lay quietly in bed conversing amiably, in no pain. The pulse was strong. The abdomen

was flaccid, save in the right lower quadrant, where at first he was quite tender. After reassurance there was little spasm and extremely little tenderness. There was a soft, slightly fluctuant, nonpulsating mass, which gave the sensation of mobility that one gets with a large soft cyst or wadded loops of bowel. The easily felt pulsations low in the left abdomen were still present. Peristalsis was normal. He continued to have pain in the back and noted a slight pain down the anterior aspect of the right thigh. Shortly after the examination the patient suddenly sat up in bed, gasped and expired.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: The blood pressure was 160 systolic, 90 diastolic. That sounds like a fairly good blood pressure for a man of this patient's age. What do you think, Dr. Richardson?

DR. WYMAN RICHARDSON: It is an excellent blood pressure.

DR. LINTON: It seems to me that I have to decide why this man went into shock as he walked out into the street and, after a period of relatively few hours, suddenly died. I can think of four conditions that might explain his demise. Certainly something quite dramatic happened, as evidenced by his losing consciousness and the reduction in blood pressure after admission to the hospital. I cannot get much reliable information from the physical examination, and I wonder what this questionable mass was that they thought pulsated in the left side of the abdomen.

Did this man have an aneurysm of the abdominal aorta? From the physical examination described here, I should say that he did not, unless the aneurysm had ruptured, producing a large hematoma in the retroperitoneal tissues. Even if he had that, I think that one would still be able to feel the original abdominal aneurysm. He could have had a slow leak from it and succumbed.

Another possibility is that he had pulmonary embolism. I doubt very much that he died from embolism since he had been walking around until shortly before death. It is most unusual for patients who have been ambulatory to develop a massive fatal pulmonary embolism; they may have minor pulmonary infarcts.

Did he die of coronary heart disease? That is a question which I cannot answer, and I should like someone to interpret the electrocardiograms.

DR. CONGER WILLIAMS: I took both electrocardiograms, so I shall simply say that I found no difference between the two films. I was able to conclude only that the changes were probably of long standing.

DR. LINTON: Are they consistent with coronary heart disease?

DR. WILLIAMS: Consistent with, but not diagnostic of, infarction — that is the way I expressed it.

DR. LINTON: I do not see how we can connect up the heart with the pain in the back and the

abdomen, so far as coronary heart disease or cardiac infarction is concerned. But there is one other condition that ought to be seriously considered. Did he have a dissecting aneurysm of the arch of the aorta? I do not know any positive way of making that diagnosis. If he had had absent pulsations in the arteries to the lower extremities I should more seriously consider such a diagnosis. The patients whom I have seen have had diminution or absence of pulsations in the lower extremities owing to the fact that the blood had dissected down the layers of the aorta and had gradually shut off the arterial flow.

I cannot think of any other possibility that might explain the sudden demise, and I favor the diagnosis of an abdominal aneurysm that had ruptured, with the patient dying as a result.

DR. WILLIAMS: When this patient came in it was obvious that he had some sort of very severe accident, which we thought was vascular. The diagnosis of dissecting aneurysm was considered as time went on. The pulse was almost imperceptible when he came in, but between examinations the pulse gradually increased in strength. The blood pressure nevertheless stayed fairly low, which may have interfered with the pulsation of the mass in the abdomen. As a result of the dilatation in the aorta the cardiac output was very poor. It is interesting that the mass in the abdomen was not visible on the previous evening. The next morning, when we were visiting and stopped outside to discuss the sudden appearance of the mass, the patient died in a period of about thirty seconds.

DR. RICHARDSON: I should like to mention that everything points to the fact that this man had severe hemorrhage. Might it have been within the bowel, an unrecognized ulcer or something else. The mass felt might have been due to a large amount of blood in the bowel that had not been passed. Is that possible?

DR. LINTON: Most patients with massive gastric hemorrhage vomit the blood or pass it by rectum.

DR. RICHARDSON: Most of them do, but I have seen some that did not.

DR. LINTON: Another thing, he vomited but he did not vomit blood. I believe that the vomiting was secondary to vagus stimulation.

DR. RICHARDSON: Owing to blood in the abdominal cavity?

DR. LINTON: Yes; blood in the region of vagal distribution — in the retroperitoneal area.

A PHYSICIAN: How about pain in the back?

DR. LINTON: It seems to fit abdominal aneurysm more than anything else. One might think of acute pancreatitis, but people do not die so suddenly from acute pancreatitis.

DR. RICHARDSON: I was thinking of acute ulcer with hemorrhage.

DR. BENJAMIN CASTLEMAN: A factor against dissecting aneurysm is the fall in blood pressure, which usually remains elevated. With a dissecting aneu-

rysm extending down into the abdominal aorta, dissection almost always extends into the iliac arteries as well and there should be a diminution in the pulse in the legs, as Dr. Linton has intimated.

DR. WILLIAMS: Another point against it is the level of the blood pressure before this happened; it was 160 systolic, 90 diastolic, which is not remarkable. These patients usually have a higher blood pressure, although it has been reported in those with normal blood pressures.

CLINICAL DIAGNOSIS

Mesenteric thrombosis?

DR. LINTON'S DIAGNOSIS

Ruptured abdominal aortic aneurysm.

ANATOMICAL DIAGNOSES

Arteriosclerotic aneurysm of abdominal aorta, with rupture.

Retroperitoneal hematoma, right.

Coronary sclerosis.

Myocardial fibrosis.

Cardiac hypertrophy.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: This man had a large arteriosclerotic aneurysm of the aorta beginning below the origin of the renal artery and extending down to the bifurcation. The aneurysm in places had a circumference of 18 cm. It had ruptured on the right side through a large linear tear 8 cm. in length. This tear was undoubtedly the terminal episode; the first attack was probably a small rupture with a slow leak, which accounts for the huge retroperitoneal hematoma that was felt just before he died. The aneurysm was arteriosclerotic, there being no evidence to suggest syphilis. Both common iliac and right hypogastric arteries were also markedly dilated — the diffuse aneurysmal dilatation not infrequently seen with severe arteriosclerosis. The heart was moderately enlarged, weighing 452 gm. There was evidence of severe coronary sclerosis and myocardial fibrosis.

DR. LINTON: I wonder when he had had his most recent clinical checkup. He was supposed to have had them frequently.

DR. WILLIAMS: He was a rather heavy-set man, and it is quite possible his physician would not have been able to feel the aneurysm.

PENICILLIN IN BACTERIAL ENDOCARDITIS

Prior to the introduction of the sulfonamides, medical science possessed no effective agent for the treatment of bacterial endocarditis. Sulfonamide therapy constituted a tremendous advance in the management of this disease by demonstrating for the first time that bacterial endocarditis could be cured, but its usefulness proved to be disappointingly limited. The various sulfonamide derivatives had little or no effect on cases of acute bacterial endocarditis, and less than 5 per cent of patients with the subacute form of the disease were permanently benefited by their administration; thus, it soon

became clear that an even more effective chemotherapeutic agent was needed. Surgical treatment, although sometimes successful in patients in whom infection is superimposed on a patent ductus arteriosus, unfortunately offers nothing to the majority of patients with bacterial endocarditis.

Good evidence to the effect that penicillin is a potent agent for the treatment of this disease is beginning to accumulate.¹⁻³ Further support for this view is to be found in the work of Meads, Harris and Finland, reported elsewhere in this issue of the *Journal*. Of 10 patients with subacute bacterial endocarditis treated with penicillin during 1944, at the Boston City Hospital, 7 had the infection arrested, at least temporarily; and 3 of 7 patients with acute bacterial endocarditis are likewise reported to be well. The results in this relatively small series are in close agreement with those in a much larger group that have been reported to the Committee on Chemotherapeutics and Other Agents of the National Research Council. These reports indicate that, in cases in which the infecting organism was sensitive to the action of the drug, penicillin therapy arrested the infection in 55 to 60 per cent of cases of subacute bacterial endocarditis and in 25 to 40 per cent of cases of acute bacterial endocarditis caused by pyogenic cocci. To accomplish these results, it was necessary to administer not less than 200,000 units of penicillin daily for two or more weeks. When used alone, penicillin was fully as effective as when given in conjunction with an anticoagulant. Thus, the simultaneous administration of heparin or dicumarol appears to be neither necessary nor desirable.

In cases of either subacute or acute bacterial endocarditis in which the infecting organism was shown to be resistant in vitro to the action of penicillin, even extremely large doses of the drug had no effect. It has been recommended, therefore, that before or at the beginning of therapy the causative organism in each case be tested for its susceptibility to penicillin. This procedure is especially indicated in cases of subacute bacterial endocarditis caused by nonhemolytic streptococci. Although most strains of this type of streptococcus are sensitive to penicillin, occasional ones with a high natural resistance to the drug are encountered.⁴

There can be no question that penicillin is the most effective agent now known for the treatment of bacterial endocarditis. It is still too early to estimate in what percentage of cases actual cure of the disease is obtained. Follow-up observations of a year or even longer are needed before the fact of cure can be established. As indicated by the experience at the Boston City Hospital, relapse or reinfection may occur several months after the apparent successful completion of treatment.

Bacterial endocarditis remains a serious disease, and the search for an even more efficient form of therapy will no doubt continue. It is clear, however, that the physician now has at his command an agent that gives promise of curing upward of half the patients suffering from this disease. The early diagnosis of bacterial endocarditis thus becomes a problem of practical importance, as well as one of academic interest.

MAY DAY AND BIRTH REGISTRATION

THE first day of May has been set aside as Child Health Day in this country since 1923, a new tradition that was officially sanctioned by Congress in 1928. Its observance is now dignified further through the recognition accorded it by the American Child Health Association, state and provincial health authorities and the Children's Bureau of the United States Department of Labor. In our busy cycle of duties, and of observances and performances, we have fittingly set aside one day each year on which to give thought to the onrushing generations.

It has been customary, in this observance of Child Health Day, to feature some particular point deserving emphasis — the health of young workers in 1943 and immunization against diphtheria and smallpox in 1942. This year, when masses of persons

in other, less fortunate, countries have lost their social security and practically their personal identities, the importance of birth registration has been selected as the May Day feature story.

The significance to everyone of birth registration and the birth certificate is so obvious as hardly to need elaboration. Suffice it to say that it furnishes incontrovertible evidence of one's identity, and on it may depend the right to an education and the right to work, to vote, to marry or to enter civil service. Various other civil rights may hinge on this proof of age and of citizenship — obtaining an automobile license or a pilot's license, Social Security benefits and the settlement of pensions. On this evidence of birth may also depend the proof of parentage and of legal dependency, the inheritance of property and the settlement of insurance.

The registration of births is an obligation that falls almost entirely on the attendant at the birth, which, in this state, ordinarily means the physician. Massachusetts stands well in its record of birth registrations, ranking, with its total percentage of 98.9, high among the twenty-eight states and the District of Columbia with registrations of 95 per cent and over. In this it is surpassed, in fact, only by Connecticut, New Jersey and Minnesota. Among the less adequately registered southern states, Arkansas trails, with a percentage of 75.9.

A registration percentage of 98.9 is good, although it can and should be better. When we realize that, in the Nation, since the attack on Pearl Harbor about 700,000 babies have been born who are still unregistered, we become aware of a figure that we can face less complacently.

MASSACHUSETTS MEDICAL SOCIETY

TREASURER'S REPORT COVERING DISTRIBUTION OF REFUND

The Treasurer of the Massachusetts Medical Society makes the following report regarding the refund to district societies for 1944:

The Council voted to distribute the sum of \$4000 to district societies. The total number of payments of annual dues received by the Treasurer by March 1, to be counted for the refund, was 3297. The refund to the district societies for each paid fellow is therefore \$1.213.

The following table gives the number of payments, as of March 1, and the refund to each district as of April 5:

DISTRICT	NUMBER REPORTED PAID	REFUND
Barnstable	32	\$38 87
Berkshire	88	106 78
Bristol North	45	54 63
Bristol South	139	168 64
Essex North	128	155 30
Essex South	191	231 72
Franklin	31	37 65
Hampden	210	254 76
Hampshire	49	59 48
Middlesex East	83	100 74
Middlesex North	80	97 08
Middlesex South	661	801 83
Norfolk	587	712 06
Norfolk South	93	112 86
Plymouth	98	118 92
Suffolk	442	536 18
Worcester	275	333 61
Worcester North	65	78 89
	- 3297	\$4000 00

In 1944, for comparison, the total number of payments for the refund was 3060.

ELIOT HUBBARD, JR., M.D., *Treasurer*

DEATH

KNOWLTON — Charles D. Knowlton, M.D., of Rockport, died January 5. He was in his seventy-eighth year.
Dr. Knowlton received his degree from Tufts College Medical School in 1894. He later studied at the University of Pennsylvania School of Medicine and at the University of Berlin. He was formerly assistant professor of theory and practice of medicine at Tufts College Medical School and instructor in laryngology at Harvard Medical School. He was a consulting surgeon at the Massachusetts Eye and Ear Infirmary and was formerly president of the Norfolk District Medical Society. He was an affiliate fellow of the American Medical Association.

NEW HAMPSHIRE
MEDICAL SOCIETY

DEATH

FLANDERS — Louis W. Flanders, M.D., of Dover, died January 16. He was in his eighty-first year.
Dr. Flanders received his degree from the University of Vermont College of Medicine in 1885. He was a member of the Strafford County Medical Society and the New Hampshire Medical Society. He was a past president of the New Hampshire Medical Society.
His widow, a son, two sisters and a brother survive.

WESTON — Arthur F. Weston, of Keene, died March 25. He was in his seventy-third year.
Dr. Weston received his degree from Boston University School of Medicine in 1903.
His widow, a daughter and a sister survive.

MISCELLANY

ANNUAL PRIZE SUBSCRIPTION

The annual prize subscription offered by the *New England Journal of Medicine* for the best undergraduate contribution to the *Tufts Medical Journal* has been awarded to A. Harvey Salans, '46, for his paper "Rheumatic Fever: A major public-health problem," which appeared in the June, 1944, issue. The paper "Penicillin: A review," by Henry H. Banks, '46, received honorable mention; it appeared in the April, 1944, issue. According to custom, these students will be given a two-year and a one-year subscription to the *Journal*, respectively.

CORRESPONDENCE

SCHOOL PHYSICIANS

To the Editor: When any medical journal prints an editorial in which the school physician is even mentioned, that event becomes front-page news.

The editorial in the March 15 issue of the *Journal*, concerning the Strayer survey, had some pertinent things to say about school health programs in general. Every experienced school physician will agree with the statement that health service "suffers from overdetalled legal prescriptions and inferior physical equipment." One of the reasons, perhaps the greatest one, for this situation is the attitude of organized medicine. The position of school physician is a legitimate specialty in medicine, but it has never been recognized as such by the Massachusetts Medical Society. The school physician is the only member of the school staff whose basic training qualifies him to head up the school health program. If organized medicine fails to give public recognition and professional support to this work, how can we expect city and town officials to provide adequate financial support for it?

WHITMAN G. STICKNEY, M.D.

13 Thorndike Street
Beverly, Massachusetts

DIAGNOSTIC TEST DOSE OF NEOSTIGMINE

On page 289 of the March 8 issue of the *Journal* mention is made, in the discussion of one of the case records of the Massachusetts General Hospital, of the neostigmine (Prostigmin) test for myasthenia gravis. The dose used for this test is given as 0.5 mg. of neostigmine methylsulfate by intramuscular injection. This is not sufficient when the drug is to be used as a diagnostic test in an adult. The matter of dosage was pointed out by Schwab and myself (Schwab, R. S., and Viets, H. R. Prostigmin test in myasthenia gravis. *New Eng. J. Med.* 219:226-228, 1938), 1.5 mg. of neostigmine methylsulfate being advised. Since that time, a special diagnostic ampule has been put on the market; this contains 1.5 mg. of neostigmine methylsulfate and 0.6 mg. of atropine sulfate. In order to avoid a false, negative or incomplete report, the dosage contained in the diagnostic ampule is recommended.

A PLEA FOR MIDDLESEX

To the Editor: The editorial "Standards of Medical Education" in the February 1 issue of the *Journal* was quite interesting. I, too, am one of those whose photograph is represented by the historic picture taken when Governor James M. Curley signed that bill. Let us be fair and reasonable. So long as the Commonwealth of Massachusetts has chartered a medical school and recognized the graduates, is it logical to recognize graduates from other states when those states refuse to recognize all graduates from Massachusetts? There are several states which refuse to recognize graduates from other states because the latter discriminate by failing to give recognition to graduates of the former, for example, Ohio, New York and Connecticut. Why does not Massachusetts protect its own graduates?

There are a few hundred graduates from Middlesex University School of Medicine who are fellows of the Medical Society; there are many commissioned officers in the armed forces from Middlesex; there is a graduate from Middlesex who is medical examiner appointed by former Governor Saltonstall; a graduate from Middlesex was appointed to the United States Public Health Service; there is a health officer in one of the neighboring cities of Boston who is a Middlesex graduate; many Middlesex graduates completed their internships in some of the finest hospitals; many Middlesex graduates are in active practice; several Middlesex graduates are on the staffs in a few hospitals in the Commonwealth; and there are several Middlesex graduates practicing in other states. Yet, in spite of all this, graduates from Middlesex are discriminated against in hospitals, in appointments and even at the present time in the armed forces. When they entered on the study of medicine, they had all the necessary requirements; they completed the prescribed courses, as per law; they received their M.D. degrees; they underwent their required internships; and they passed the medical licensing examinations. Still, they are not given the

same opportunity as other graduates. It is a shame to penalize such qualified graduates.

Middlesex is showing that she is willing to do everything that is humanly possible to improve the medical school in order to get recognition. Why does not the Massachusetts Medical Society, which is playing such a vital part, and the Approving Authority and the American Medical Association do everything possible to help Middlesex? I can name medical schools which were not given full recognition by the New York State Board of Regents but which, with the proper help, did receive recognition. Unless complete co-operation is shown to help Middlesex become as good a medical school as any other, I firmly feel that the General Court should pass legislation to eliminate the Approving Authority and should also pass laws forbidding recognition to graduates from other states that refuse to recognize all graduates from our medical schools. If full recognition in all hospitals were given to its graduates, other states would follow suit.

BERNARD ZUCKERMAN, M.D.

1804 North Avenue,
Bridgeport 4, Connecticut.

NOTICES

BOSTON DISPENSARY

A clinical staff meeting of the Boston Dispensary will be held at the Pratt Hospital Auditorium on Friday, May 4, at 12:30 p.m. Dr. Daniel L. Lynch will speak on the subject "Rehabilitation Problems in Industry." Luncheon will be served at 12 noon.

SUFFOLK DISTRICT MEDICAL SOCIETY

A dinner meeting of the Suffolk District Medical Society will take place on Saturday, April 28, at 7 p.m., at the Harvard Club of Boston. Surgeon-General Thomas Parran, of the United States Public Health Service, will speak on the subject "Place of the Hospital in Postwar Medical Care." Tickets \$3.75.

TUFTS ALPHA OMEGA ALPHA

The Tufts chapter of the Alpha Omega Alpha will meet in the Auditorium of the Beth Israel Hospital, Boston, on Wednesday, May 9, at 8:15 p.m. Dr. Fuller Albright will speak on the subject "Action of Vitamin D."

JOSEPH H. PRATT

DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM*

Wednesday, May 2 — The Spleen, the Bone Marrow, and Thrombopenic Purpura. Dr. William Dameshek.

Friday, May 4 — The Heart in Hypertension since the Days of Richard Bright. Dr. Paul D. White.

Wednesday, May 9 — Cardiac Clinic. Dr. Heinz Magendanz.

Friday, May 11 — Carcinoma of the Prostate. Dr. William C. Quimby.

Tuesday, May 15 — Clinicopathological conference. Drs. Chester S. Keefer and H. E. MacMahon.

Wednesday, May 16 — Endocrine Problems in Childhood. Dr. Richard Wagner.

Friday, May 18 — Thyroid Disease. Dr. Frank H. Lahey.

Wednesday, May 23 — Common Duct Stone: A review of cases. Dr. William T. Roberts.

Friday, May 25 — Peri-Arteritis Nodosa and Acute Disseminated Lupus from the X-ray Viewpoint. Dr. Merrill Sosman.

On Monday mornings (except May 7) clinics will be given by Dr. Samuel Proger. On Tuesday and Thursday mornings Dr. S. J. Thannhauser will give medical clinics on hospital cases. On Saturday mornings clinics will be given by Dr. William Dameshek.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, May 3, in the classroom of the nurses' residence.

PROGRAM

Laryngotracheobronchitis: Brief summary of six cases having penicillin treatment. Drs. Helen N. Perry and Clara Waldinger.

Bacteriological Observations and Local Use of Penicillin.

Miss Anita B. Mangiaracine.

Discussion of nasal drops.

Dr. Margaret Noyes Kleinert will be chairman.

EDWARD K. DUNHAM LECTURES

The Faculty of Medicine of Harvard University has announced that the following lectures on the general topic "The Insect as a Medium for the Study of Physiology" will be delivered by Dr. Vincent B. Wigglesworth under the Edward K. Dunham Lectureship for the Promotion of the Medical Sciences:

Monday, May 7. The Insect Cuticle as a Living System.

Wednesday, May 9. Hormones and the Regulation of Insect Growth.

Friday, May 11. Integration in the Epidermis of Insects.

These lectures are scheduled for 5 p.m. at the Harvard Medical School, Building C Amphitheater.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MAY 3

FRIDAY, MAY 4

THE CARDINAL MANIFESTATIONS OF PAROXYSMAL TACHYCARDIA*

I. Anginal Pain

LOUIS WOLFF, M.D.†

BOSTON

THE symptoms accompanying paroxysmal tachycardia are numerous and varied. Most of them are not caused directly by the tachycardia, nor are they directly or specifically related to the underlying heart condition. Inquiry into the circumstances under which they arise throws no light on their meaning or on the underlying cardiovascular status. A few of the symptoms, however, arise under such constant conditions that they create a uniform clinical pattern. Because these symptoms — palpitation, pulmonary congestion, anginal pain, congestive failure, vascular collapse, central-nervous-system manifestations and embolism — may be correlated with significant variables, such as the type of patient, the heart lesion, the functional status of the heart and circulation, the ventricular rate and the presence or absence of embolism, it is proper to designate them as the cardinal manifestations of paroxysmal tachycardia. A detailed clinical analysis of 125 cases served as the basis for these and other conclusions, which were reported in a previous publication.¹ The present series of papers is devoted to a consideration, in greater detail, of some of the cardinal manifestations previously discussed. To the first group of 125 cases have been added 128 unselected new ones, making a total of 253. All cases had an electrocardiogram, confirming the presence of an abnormal rhythm and providing the ventricular rate during the paroxysm.

NONANGINAL CHEST PAIN

Chest pain is usually mentioned as one of the symptoms associated with paroxysmal tachycardia, but its incidence, character and significance are variously estimated or entirely disregarded by different authors. In 1888, in a paper containing the first clear description of paroxysmal tachycardia, Bristowe² stated that 1 of his 9 patients had anginal-like attacks during the paroxysms of rapid heart

action; similar observations have been reported by other authors³⁻⁶ in single case reports. Barnes and Willius⁷ noted the occurrence of anginal pain in 19 of 380 cases of paroxysmal tachycardia; the pain was usually described as a precordial ache; in no case did angina pectoris occur between the paroxysms. In 4 cases reported by White and Camp⁸ and in some of those previously reported by me^{1, 9} there was angina pectoris on effort; the former authors considered the induction of anginal pain by paroxysmal tachycardia a rare disorder. Campbell and Elliott¹⁰ stated that tightness in the chest was present in most attacks of paroxysmal tachycardia and was of no special significance; in 12 of their 100 cases there was anginal pain, which was considered benign because induced by paroxysmal tachycardia. Williams and Ellis¹¹ recorded the occurrence of severe substernal pain in 2 patients during paroxysmal ventricular tachycardia; both patients had large hearts but were free of angina pectoris between paroxysms. The first study in which the induction of anginal pain by paroxysmal tachycardia was correlated with specific cardiovascular conditions was reported from this clinic in the paper referred to above.¹

Analysis of the present larger series of cases shows that anginal pain was present during paroxysms of tachycardia in 40 cases, or 16 per cent of the series; these will be discussed in detail below. An almost equal number of patients had pain that was not anginal in character. In view of the significance of anginal pain in paroxysmal tachycardia, it is necessary to make a clear distinction between it and other types of pain. Nonanginal pain is frequently described as a precordial ache or distress, during or following the cessation of paroxysms of tachycardia. This is particularly frequent in patients with mitral stenosis, but is not limited to this group. Other patients are conscious of a tired or weak feeling in the region of the heart. Occasionally the cause of pain is the palpitation itself. This painful palpitation is usually seen in sensitive persons; consciousness of the heart action is interpreted by them as pain and is extremely disturbing; as the

†Instructor, Courses for Graduates, Harvard Medical School; associate visiting physician, and chief of Cardiac Clinic and Electrocardiographic Laboratory, Beth Israel Hospital.

paroxysm ends there may be a severe, sharp, momentary exacerbation of the pain. Another type of non-anginal pain associated with tachycardia is sharp, pleuritic-like pain, often of great severity, over the precordium and left shoulder, occurring with inspiration. Upper abdominal pain due to acute congestion of the liver from an exacerbation of congestive failure secondary to paroxysmal rapid heart action may suggest anginal pain but should be differentiated without difficulty. Some patients complain of momentary twinges of precordial pain during paroxysms of tachycardia, and as a rule, similar pains are experienced between paroxysms; in other patients, vague, unexplained chest pain is noted during tachycardia. There is little to suggest anginal pain in these cases. In patients with neurocirculatory asthenia, pain is frequent with paroxysms of tachycardia, as it is during the normal cardiac mechanism. Another type of pain is so-called "imitation angina," occurring in those familiar with the syndrome of angina pectoris, such as physicians or nurses.

The remaining examples of nonanginal pain associated with paroxysmal tachycardia have no relation to heart disease or are not at all related to the tachycardia. The most important of these are pulmonary embolism and pericarditis.¹² In this series other causes of pain simulating angina pectoris and associated with paroxysmal tachycardia were peptic ulcer, gall-bladder disease, chest trauma or fractured ribs, neoplastic disease in the chest, post-operative pain in the upper abdomen or lower chest, splenic infarct and spontaneous pneumothorax. Pain, at times simulating angina pectoris, may occur in all these conditions, which may be complicated by paroxysmal tachycardia; the pain is due to the underlying condition and not to the tachycardia.

CASE 1. S. S., a 25-year-old man, had painless paroxysmal auricular fibrillation, but careful study revealed no evidence of organic heart disease. After exercising in a gymnasium, he was seized with severe, constricting precordial pain. An electrocardiogram showed auricular fibrillation with a ventricular rate of 120. Investigation revealed that the pain was due to spontaneous pneumothorax.

ANGINAL PAIN

Pain with the features characteristic of angina pectoris was classified as anginal pain regardless of duration. Since the pain in these cases was induced by tachycardia, the ordinary inciting causes of effort and emotion were absent. Most of these patients also had angina pectoris with effort or emotion; the similarity of the pain induced by paroxysmal tachycardia to that occurring at other times facilitated its interpretation. The duration of the pain depended on the duration of the tachycardia and the coincidental occurrence of acute myocardial infarction. With very short paroxysms the pain was identical with an ordinary attack of angina pectoris, but with prolonged tachycardia the pain was intermittent (status anginosus) or continuous, simulating acute myocardial infarction. The latter term

is used in its widely-accepted clinical sense, but includes major coronary attacks with evidence of heart-tissue necrosis. A diagnosis of acute myocardial infarction was made in 10 of the 40 cases having anginal pain.

Pain in the Absence of Acute Myocardial Infarction

Anginal pain in the absence of myocardial infarction was induced by paroxysmal tachycardia in 30 cases. The ages of the patients in this group ranged from twenty-eight to eighty-five years; there were 5 cases in the fifth decade, 9 each in the sixth and seventh, 5 in the eighth and 1 in the ninth. The single 28-year-old patient had rheumatic heart disease and free aortic insufficiency. There were 15 cases of paroxysmal auricular fibrillation (50 per cent), 9 of paroxysmal auricular tachycardia (30 per cent), 4 of paroxysmal auricular flutter (13 per cent) and 2 of paroxysmal ventricular tachycardia (7 per cent). The ventricular rate was 150 per minute or more in 26 cases, 140 in 3 and 120 in 1. Twenty-two patients gave a clear history of angina pectoris on effort, but no such history could be elicited in the remaining 8 cases. Of the latter, 3 developed acute myocardial infarction one to seven days after paroxysmal tachycardia had induced anginal pain. One patient had free aortic insufficiency; another had had an acute myocardial infarct six years previously, but no angina pectoris for a year preceding the induction of anginal pain by paroxysmal ventricular tachycardia. One patient in this group was a seventy-five-year-old woman with hypertensive heart disease and crippling arthritis. Only 2 patients had apparently normal hearts. Thus, of the 30 patients in whom paroxysmal tachycardia induced anginal pain, 73 per cent had exertional angina, 10 per cent did not have angina pectoris but developed acute myocardial infarction within a few days after paroxysmal tachycardia-induced anginal pain, 10 per cent had organic heart disease, and 7 per cent had normal hearts.

The following 4 cases are typical examples of the induction of anginal pain by paroxysmal tachycardia.

CASE 2. I. O., a 65-year-old man, had had angina pectoris on effort for 3 or 4 years, always relieved by nitroglycerin. While in the hospital he had repeated attacks at rest, always associated with paroxysmal auricular tachycardia with a ventricular rate of 170. The pain lasted continuously during the tachycardia and was not relieved by nitroglycerin, but ended at once when the abnormal rhythm was terminated.

CASE 3. S. W., a 58-year-old man, had a history of old myocardial infarction, paroxysmal dyspnea and angina pectoris on effort. During a routine examination he had repeated attacks of angina pectoris, weakness and faintness. It was noted that the episodes of pain coincided with extremely rapid heart action, and that when the heart rate suddenly slowed spontaneously or as the result of gentle stimulation of the right carotid sinus, the pain immediately disappeared. An electrocardiogram showed paroxysmal auricular tachycardia with an auricular rate of 214 and intermittent 2:1 auriculoventricular block, with a resulting ventricular rate of either 214 or 107.

CASE 4. S. G., a 66-year-old woman, had had paroxysmal tachycardia for 50 years, associated with vascular collapse. Ever since the menopause 13 years previously, she had had hot flashes and the attacks of paroxysmal rapid heart action had increased in frequency. For several years effort provoked substernal, squeezing pain radiating into the back. Similar pain was induced during the same period by the paroxysms of tachycardia. When seen during an attack of pain the patient was in collapse, with a pale, moist skin, absent radial pulsations and a blood pressure of 76/70. The clinical picture was that of acute myocardial infarction. The heart rate, however, was very rapid, and an electrocardiogram showed paroxysmal auricular tachycardia with a ventricular rate of 200. Stimulation of the right carotid sinus interrupted the abnormal rhythm, with immediate cessation of the pain and return of a normal pulse and blood pressure. The patient was seen in several similar attacks, and at no time was evidence of myocardial infarction obtained. She died suddenly some months later.

CASE 5. M. T., a 62-year-old male with a negative cardiovascular history, had a partial gastrectomy for a penetrating ulcer of the stomach. During convalescence he had a paroxysm of auricular flutter with a ventricular rate of 170; no symptoms were provoked, and he was entirely unaware of the paroxysm. Within 24 hours a second paroxysm with a ventricular rate of 166 occurred, but that time it induced anginal pain; when the paroxysm ended, the pain disappeared. On the following day, he developed severe, prolonged anginal pain, although the heart rhythm was normal. This was followed by elevation of the temperature and white-cell count and serial electrocardiographic changes indicating the presence of acute myocardial infarction.

Pain Associated with Acute Myocardial Infarction

The ages of the 10 patients in this group ranged from fifty-five to eighty-five; there were 2 cases in the sixth decade, 5 in the seventh, 2 in the eighth and 1 in the ninth. There were 4 cases of paroxysmal auricular fibrillation, 3 of paroxysmal auricular tachycardia, 2 of paroxysmal ventricular tachycardia and 1 of paroxysmal auricular flutter. The ventricular rate was 150 per minute in 5 cases and 154, 166, 170, 180 and 200, respectively, in the others. The onset of the arrhythmia and acute myocardial infarction appeared to be simultaneous in 4 cases; the tachycardia in 2 of these ended spontaneously after some hours, but the pain persisted, whereas in another the pain disappeared several hours after the attack began despite the continuance of paroxysmal auricular tachycardia for another twenty-four hours. Paroxysmal ventricular tachycardia with a ventricular rate of 170 occurred in 1 case on the third day of acute myocardial infarction, but did not appear to increase the pain, which was still present; two weeks later, after there had been no pain for over a week, paroxysmal ventricular tachycardia, with a ventricular rate of 170 to 180 recurred, but did not induce pain. Paroxysmal tachycardia in 3 cases occurred on the second to fourth days of acute infarction, while pain was still present but apparently without influencing it. On the sixth day after the onset of acute infarction in another case, intermittent anginal pain was still occurring, and was also induced by a paroxysm of auricular tachycardia with a ventricular rate of 150. The tenth patient continued to have spontaneous angina pectoris for

four weeks following acute myocardial infarction, and paroxysmal ventricular tachycardia on the tenth and twenty-fifth days, respectively, induced anginal pain.

CASE 6. J. H., a 70-year-old woman, had a history of diabetes, hypertensive heart disease and a previous cerebral accident. Her first attack of precordial oppression, accompanied by palpitation, a rapid heart rate and dyspnea, necessitated a hypodermic injection of morphine sulfate. On the following day the symptoms were still present and she was admitted to the hospital, where an electrocardiogram showed paroxysmal auricular tachycardia with a ventricular rate of 166. Three hours after the subcutaneous injection of morphine sulfate the pain disappeared, but the paroxysmal auricular tachycardia, without any change in rate, continued for another 24 hours. The data clearly indicated the presence of acute myocardial infarction.

CASE 7. S. A., a 75-year-old woman with an apparently normal heart, had had for 5 years prolonged attacks of paroxysmal auricular tachycardia in which the only symptom was palpitation. She then had an attack of pressure in the chest, quickly went into shock and developed pulmonary edema. Examination showed paroxysmal auricular tachycardia with a ventricular rate of 200. The tachycardia stopped after 4 hours, but pain and shock continued for 4 to 5 days. The electrocardiographic and other evidence indicated the presence of acute myocardial infarction. Following recovery she had angina pectoris, both on effort and with paroxysmal auricular tachycardia.

FAILURE OF PAROXYSMAL TACHYCARDIA TO INDUCE ANGINAL PAIN IN CORONARY HEART DISEASE

Paroxysmal tachycardia failed to induce anginal pain in 48 cases of coronary heart disease. All the patients in this group had a past or present history of angina pectoris or myocardial infarction or post-mortem evidence of significant coronary-artery disease. There was 1 patient in the fourth decade, three in the fifth, 12 in the sixth, 17 in the seventh, fourteen in the eighth and 1 in the ninth. Twenty-four (50 per cent) had paroxysmal auricular fibrillation, 12 (25 per cent) paroxysmal ventricular tachycardia, 9 (19 per cent) paroxysmal auricular flutter and 3 (6 per cent) paroxysmal auricular tachycardia. The ventricular rate was 150 or more in 32 cases and less than 150 in 16 cases.

Ventricular Rate Less Than 150

Of the 16 cases in this group, paroxysmal tachycardia complicated acute or recent myocardial infarction in 9. Paroxysmal auricular fibrillation with a ventricular rate of 120 per minute failed to induce anginal pain in a patient who was still having intermittent pain following a recent infarct. In 5 patients with a past history of angina pectoris on effort, paroxysmal tachycardia on the sixth, fourth, tenth, fourteenth and fifth days, respectively, following the onset of acute myocardial infarction failed to induce anginal pain, nor was pain occurring otherwise in these patients. The 3 remaining patients with acute infarction were asymptomatic (without pain) when paroxysmal tachycardia on the third, fourth and seventh days, respectively, failed to induce anginal pain.

Three patients with angina pectoris on effort had no pain during tachycardia with ventricular rates less than 150. The remaining 4 patients did not have exertional angina and pain was not induced by tachycardia; 2 had a previous history of myocardial infarction, and in the other 2 post-mortem examination disclosed the presence of significant coronary disease.

Ventricular Rate 150 or More

Thirty-two patients with coronary heart disease did not have anginal pain during paroxysmal tachycardia with a ventricular rate of 150 or more. Acute or recent myocardial infarction was present in 18 cases, in each one of which the tachycardia occurred when the illness had become painless. The tachycardia occurred on the following days after the onset of acute infarction: in 1 case on the third day, in 3 on the fifth, in 1 on the sixth, in 1 on the eighth, in 4 on the tenth, in 1 at the end of two weeks, in 2 at the end of three weeks and in the remaining 5 after five to eight weeks. Seven patients had had angina on effort for variable lengths of time preceding the onset of acute infarction.

There remain in this group 14 patients in whom paroxysmal tachycardia with ventricular rates of 150 or more did not induce anginal pain. Only 3 of these patients had a history of effort angina, which, however, had disappeared many months before the onset of paroxysmal tachycardia; post-mortem examination disclosed significant coronary disease in 2 of these. Five patients had a history of old myocardial infarction but not of angina pectoris, and autopsy confirmed the diagnosis in the 1 patient who died. In the remaining 6 cases, angina pectoris or myocardial infarction had never been observed during life, but at autopsy significant coronary disease was found in all of them.

DISCUSSION

The present study of anginal pain in relation to paroxysmal rapid heart action has confirmed many of the conclusions stated in the previous report¹ and has revealed other facts of practical interest. The critical ventricular rate for the induction of anginal pain is about 150; pain is not provoked below this level. Paroxysmal tachycardia invariably induces anginal pain in patients with angina on effort, provided the ventricular rate is 150 or more; the ventricular rate, not the type of rhythm, is the significant factor. With few exceptions, patients in whom tachycardia induces anginal pain have organic heart disease, mostly coronary heart disease and angina pectoris and occasionally aortic valvular disease; such patients rarely have normal hearts. When anginal pain is induced by paroxysmal tachycardia in patients who do not have effort angina, it suggests acute myocardial infarction, or it may be a premonitory symptom of infarction. It may also indicate disease of an entirely different

nature, such as pulmonary embolism or pericarditis, in which the tachycardia bears no relation to the pain but is merely a complication of the underlying disease, which itself is responsible for the pain. These and other possibilities must be considered particularly when pain is present during tachycardia with rates well under 150 or when pain is associated with tachycardia for the first time with a history of preceding painless paroxysms. When the ventricular rate is less than 150, pain is generally not due to the tachycardia.

Pain was present in only 10 of the 37 cases of acute or recent myocardial infarction in this series. Of greater significance than the ventricular rate in these cases is the time of occurrence of the tachycardia in relation to the onset of infarction, or, more precisely, the fact that pain of infarction or intermittent, spontaneous anginal pain is or is not still occurring when the tachycardia begins. When tachycardia occurs early in the course of infarction, while continuous pain is present, it may or may not enhance the pain, which may even disappear while the tachycardia continues; but if, following infarction, spontaneous intermittent pain is occurring, the tachycardia invariably induces anginal pain, provided the ventricular rate is 150 or more. Once the constant or intermittent pain associated with infarction has disappeared, paroxysmal tachycardia, regardless of the ventricular rate, does not induce anginal pain.

In cases of asymptomatic coronary heart disease, paroxysmal tachycardia does not induce anginal pain. This group comprises those who never had angina on effort, those with a past history of myocardial infarction or angina pectoris and those with acute and recent myocardial infarction in the painless stage. It is obvious that failure of paroxysmal tachycardia to induce anginal pain does not exclude the presence of coronary heart disease.

SUMMARY

The clinical data of 253 cases of paroxysmal tachycardia are analyzed with reference to the occurrence of chest pain.

Chest pain, anginal and otherwise, is a frequent symptom in association with paroxysmal tachycardia. Anginal pain occurs under constant conditions and is therefore one of the cardinal manifestations of paroxysmal tachycardia. It occurred in 16 per cent of the cases in this series.

Anginal pain is invariably provoked by paroxysms of rapid heart action in patients with angina pectoris, provided the ventricular rate is 150 (the critical level) or more.

In the great majority of cases in which paroxysmal tachycardia induces anginal pain, coronary heart disease, usually with angina pectoris, is present.

The association of anginal pain and paroxysmal tachycardia, with ventricular rates under 150 or regardless of the rate, in patients without a history of

angina pectoris suggests various diagnostic possibilities, both cardiac and noncardiac.

Paroxysmal tachycardia does not always enhance the pain of acute myocardial infarction.

The failure of paroxysmal tachycardia to induce pain does not exclude the presence of coronary heart disease, acute, recent or old myocardial infarction or angina pectoris in the past.

A MODIFICATION OF AN OLD AND SIMPLE METHOD OF TREATING RECTAL PROLAPSE*

GEORGE VAN S. SMITH, M.D.†

BROOKLINE, MASSACHUSETTS

UNFAMILIAR at the time with the literature on rectal prolapse, yet with a distinct impression that the various treatments employed were not consistently satisfactory, I tried in October, 1939, a method that I humorously named the "garden-hose" technic. I had a feeling of originality that I soon learned was only partially justified. As will become apparent, this method may hardly be classified under the heading of the art of surgery, but the results thus far, in view of the simplicity of the procedure, have been fairly good.

CASE 1. M. C., a 71-year-old, married woman, had a 12.5-cm. procidentia of the rectum. A section of ordinary garden hose 15 cm. long, with an external diameter of approximately 2.5 cm. and an internal diameter of about 1.8 cm., was chosen because of its noncompressibility. In it a circular groove 1.5 cm. wide was cut deeply 4.0 cm. from the end to be inserted into the bowel. The patient was narcotized with morphine and scopolamine. The rectal sleeve was dragged out its full length and carefully palpated for the presence of small intestine in the herniated pouch of Douglas. With the aid of lubricating jelly, the hose was inserted so that its groove came just distal to the anal margin. Compression of the bowel against the groove was accomplished by ligatures of doubled No. 2 chromic catgut and strong, narrow rubber hands. As a further precaution against too early expulsion of the hose, the end of the prolapse was clamped to its outer end. The operation was performed in 13 minutes.

The postoperative course was reasonably comfortable, although the patient was alarmingly febrile. On the 13th day, the hose and slough came away. She was discharged on the 23rd day. There have been no rectal complaints, and repeated examinations have revealed no abnormalities during the 4 years and 11 months that have elapsed.

CASE 2. S. T., a 67-year-old, married woman, had a 5-cm. prolapse. In November, 1940, an operation similar to that described in Case 1 was done, with short anesthesia by ether. Convalescence was short and uneventful. The hose was removed on the 6th postoperative day and the patient was discharged on the 12th day. After 1 year there was a recurrence

4 cm. long, and in September, 1942, the same operation was performed, along with a small plastic for exertional urinary incontinence, but at that time constriction was made by twisting copper wire of 1.5-mm. diameter around the mass with electrician's pliers. Succinylsulfathiazole was given preoperatively and postoperatively, and ether was the anesthetic. Convalescence was uneventful. The hose was expelled on the 11th postoperative day and the patient was discharged on the 15th day. She remained cured for 1 year and 6 months. Symptoms recurred in March, 1944, and there is now a recurrence that starts 3 cm. above the anus and protrudes for 3 cm. on straining. Eighteen centimeters of bowel has already been removed, and 12 cm. more soon will be. Perhaps one of the newer procedures by the abdominal route would be more effective,^{1,2} but in view of the patient's age the risk of another recurrence in 1 or 2 years is preferable.

CASE 3. A. M. P., a 64-year-old, unmarried woman, had a 6-cm. prolapse of the rectum. In May, 1941, an operation similar to that in Case 1 was performed, with anesthesia by ether. Convalescence was uneventful, and the patient was discharged on the 19th postoperative day. A stenosis formed that required repeated dilatation during the following 4 months and has for the last 3 years given occasional slight trouble. The patient is satisfied with the result, and there has been no recurrence of prolapse.

CASE 4. E. C., a 69-year-old, married woman, had an 8-cm. procidentia of the rectum. She received succinylsulfathiazole preoperatively and postoperatively. In September, 1942, under short anesthesia by Pentothal Sodium, the same technic as that described above was employed, compression being accomplished by wire and pliers. The postoperative course was smooth. On the 11th day most remaining slough was removed by cutting against the hose, which was then withdrawn. The patient was discharged on the 15th day. During the last 2 years she has not admitted a complaint, but she has had a stricture 4 cm. above the anus. This was twice dilated in the fall of 1943. It now has a lumen 1.7 cm. in diameter.

CASE 5. M. J., a 51-year-old, married woman, had a 9-cm. procidentia of the rectum, 7 cm. in diameter. Disturbed by the strictures in the previous 2 patients, even though they were of minor inconvenience, I reasoned that they had occurred because of too short a diameter of the hose at the groove of compression. Therefore, instead of cutting a groove, I built up a circular trough as follows. First, the external diameter of the hose was increased to 3 cm. by winding broad adhesive plaster around it. On each side 4 cm. from the end to be inserted into the rectum 2-cm. adhesive

*From the Free Hospital for Women.

Presented at the annual meeting of the New England Surgical Society, Boston, September 20, 1944.

†William H. Baker Professor of Gynecology, Harvard Medical School; visiting surgeon and director of the Fearing Research Laboratory, Free Hospital for Women.

plaster was wound, leaving a trough 1.5 cm. wide and 0.5 cm. deep.

The patient received succinylsulfathiazole preoperatively and postoperatively. A plastic operation for a lacerated perineum and a large rectocele with enterocele was performed in December, 1942, ether being the anesthetic, before proceeding with the "garden-hose" maneuver. Constriction was made with copper wire, the ends of which were left long and hooked into the outer lumen of the hose. On the 6th postoperative day most of the slough was cut away. Fecal obstruction of the large intestine was easily cleared by enemas given through the hose, which was removed on the 8th day. Convalescence was excellent, and the patient was discharged on the 14th day. She has been well for 1 year and 9 months, and there has been no narrowing of the rectal lumen or recurrent prolapse.

Four of these patients were elderly and frail and had cardiovascular disease; the fifth was obese. Until two years ago, catharsis and enemas were given as part of the preoperative preparation and defecation was inhibited by tincture of opium for ten days postoperatively. Succinylsulfathiazole has made this regime unnecessary and has apparently been the chief factor in achieving practically afebrile convalescences. The daily use of soap and water, boric acid powder and dry dressings was adequate for the care of the local area. All the patients had stretched, relaxed anal sphincters before treatment, and in all cases good muscular tone returned afterward. If one is not sure that the herniated pouch of Douglas is empty, there is no stringent contraindication to incising the anterior side of the rectal procidentia well below the anal margin and exploring before proceeding with constriction. I have not yet considered it necessary to do this.

DISCUSSION

Older methods of achieving constriction amputation involved ligatures or elastic bands, and rubber tubing. The only original features of the present method are the cutting of a circular groove in garden hose or building up a trough around it and drastic compression by twisting strong malleable copper wire around the protrusion. Emerson,⁵ in 1938, stated, "Generally a piece of garden hose . . . is used." Yet he is the only author to be found who specifically mentions garden hose.

Removal of rectal prolapses by constriction has been done for years, but not often, since any one surgeon's experience with this entity is usually limited to less than 10 cases. References to the early literature on removal by constriction are covered in papers by Moschcowitz,⁶ Reid,^{7, 8} and Eliason and Erb.⁹ Reid stimulated renewed interest in this type of procedure, although he limited it to cases with irreducible prolapse. The ones I have treated were all reducible, as were the ones reported in the more recent literature. According to Eliason and Erb, only 1 death from this type of operation had been recorded — in 1900. They treated 3 cases in this manner with good results at four to fifteen months. Wangersteen¹⁰ reported 1 case satisfactorily man-

aged in this way with a good outcome two months later. Reid's 2 patients were cured between three and four years afterward. Anderson and Borland¹¹ had 1 case treated by the Reid technic with a good immediate result. In 1938, Emerson⁵ recorded 2 deaths following treatment by elastic ligature and severe morbidity in 5 others, with ensuing stenosis. Thus, from the literature one would conclude that amputation of rectal procidentias by constriction is not a good procedure, since in the last twenty years there have been 2 operative deaths among 14 reported cases. There has also been considerable morbidity, as well as rectal stenosis, and the period of observation has been for the most part too short to decide about the permanency of cure.

A fairly complete review of the literature of the last fourteen years leads one to the same conclusion concerning the various other methods of treatment, both abdominal and perineal. Either the morbidity or the mortality is similar, or there is a high rate of recurrence, or good results are based on insufficient length of observation. This conclusion applies in part to my own cases, which are expected to increase and which will be followed for significantly longer periods.

The largest series of cases with apparently the best results is that of Miles.^{12, 13} He performed surgical amputation of the protruded bowel on 34 patients, with 1 operative death and 1 recurrence at five years. Lockhart-Mummery¹⁴ wrote, "For very large prolapses the best operation is amputation." Yet in 1932, Rankin, Barger and Buie¹⁵ stated, "Procedures directed toward the cure of the prolapse by resection have little to recommend them."

The objective of all methods of treatment is the formation of scar tissue between the rectum and the surrounding structures. This seems to have been well accomplished by surgical amputation and logically should be achieved just as well by compression amputation. The minimal loss of blood and the short time required are in favor of the latter technic, and succinylsulfathiazole has removed its greatest danger — namely, sepsis. The mortality and morbidity with the constriction method appear to have come from technical errors. For example, the hose has been inserted too far above the point of constriction, thus allowing the accumulation of feces between it and the rectum. Peristalsis may have forced some of this material through a weakened area in the tissues. There should not be more than a few centimeters of hose above the point of compression. Furthermore, it is probable that in some cases strangulation has not been complete, thus permitting much greater septic and toxic absorption. A slight increase in the diameter of the hose might have reduced or eliminated an undesirable amount of stenosis. From my experiences with uterine procidentias and vaginal relaxations, I am convinced that some patients have tissues so constituted as to be incapable of permanent anatomic

reposition, and that just as 15 per cent of gynecologic patients have more or less recurrence, so will there continue to be an unavoidable percentage of recurrent rectal prolapse.

SUMMARY

Some modifications of an old method of removing rectal prolapses by compression amputation have been presented. In 5 cases of reducible rectal prolapse in women the procedure has been safe, and the results in 4 cases have thus far been good for periods varying from one year and nine months to four years and eleven months. In the fifth case, prolapse has twice recurred after twelve and eighteen months, respectively, of temporary cure.

A brief evaluation of the literature is included, with evidence that surgical amputation has yielded the best results. It is suggested that compression amputation should be just as effective, and it has the advantage of being a much simpler procedure.

DISCUSSION

DR. JAMES B. WOODMAN, Franklin, N. H.: Some years ago on looking up the Whitehead operation, which was in vogue at that time, I found that there was no apparatus described to put in the rectum as a form around which to do this operation, so I secured a champagne cork and fitted a heavy loop of wire in one end for a handle, introduced it and tied on heavy braided silk,—thus doing away with the necessity of putting tape there,—with excellent results. I have used this method three or four times since then.

DR. ALLEN G. RICE, Springfield, Mass.: I cannot lay claim to the invention of any ingenious gadget, but five years ago next December an engineer presented himself in the office and demonstrated with the greatest ease what his trouble was. With hardly any exertion he could extrude about 20 cm. of his rectum. He told me that he had previously had three operations, one from below and two from inside the abdomen, and that all had been failures. He wanted to know if there was anything I could do. I asked for a day or two to think it over, and when he came back I proposed the following procedure, which he accepted. I opened the abdomen and pulled up all the sigmoid until it was taut, and then did a Mikulicz type of colostomy. Later I cut the spur and closed the incision. The patient has been perfectly well ever since.

DR. E. PARKER HAYDEN, Boston: Reid several years ago described 3 cases in which he carried out this procedure, but Dr. George Smith is the only person with whom I have discussed it firsthand. I am going to ask him if he had examined the slough to see whether by any chance it included the uterus, but he mentioned in the latter part of his paper that one could palpate and explore the cul de sac, if one desired.

I have had 1 case in which the uterus was palpable in the anterior wall of the prolapse—the entire uterus. When I inspected the abdomen I was unable to see the uterus in the pelvis until I reached down with my hand and pulled it up from the depths of the cul-de-sac herniation.

I looked these cases up at the Massachusetts General Hospital several years ago and found that we had had about 1 case a year. In a period of twenty-one years there were 20 cases, operated on by many surgeons and by a variety of methods, consisting principally of the Moschowitz obliteration of the cul de sac. The mucous membrane, in some cases, had to be excised afterward because it persisted in prolapsing, and in several cases a plastic was done on the atonic sphincter. For example, one patient had had a complete prolapse for twenty years, and one year after doing both a Moschowitz and a Lockhart-Mummery procedure, because of relaxed sphincter, I trimmed the mucosa away and did a plastic on the sphincter. Compression ligature is a simple method, and I do not see why it is not a successful way of handling this condition.

Dr. Reginald H. Smithwick has done several Delorme operations with considerable success. The mucous membrane is excised in a cuff around the prolapse, after which sutures are taken in the submucosa vertically, thereby reducing the length of the prolapse until the mucous membrane edges come together, these edges are then sutured.

One can apparently treat this condition successfully by a number of different procedures, of which the method described by Dr. Smith is undoubtedly the simplest technically.

plaster was wound, leaving a trough 1.5 cm. wide and 0.5 cm. deep.

The patient received succinylsulfathiazole preoperatively and postoperatively. A plastic operation for a lacerated perineum and a large rectocoele with enterocele was performed in December, 1942, ether being the anesthetic, before proceeding with the "garden-hose" maneuver. Constriction was made with copper wire, the ends of which were left long and hooked into the outer lumen of the hose. On the 6th postoperative day most of the slough was cut away. Fecal obstruction of the large intestine was easily cleared by enemas given through the hose, which was removed on the 8th day. Convalescence was excellent, and the patient was discharged on the 14th day. She has been well for 1 year and 9 months, and there has been no narrowing of the rectal lumen or recurrent prolapse.

Four of these patients were elderly and frail and had cardiovascular disease; the fifth was obese. Until two years ago, catharsis and enemas were given as part of the preoperative preparation and defecation was inhibited by tincture of opium for ten days postoperatively. Succinylsulfathiazole has made this regime unnecessary and has apparently been the chief factor in achieving practically afebrile convalescences. The daily use of soap and water, boric acid powder and dry dressings was adequate for the care of the local area. All the patients had stretched, relaxed anal sphincters before treatment, and in all cases good muscular tone returned afterward. If one is not sure that the herniated pouch of Douglas is empty, there is no stringent contraindication to incising the anterior side of the rectal procidentia well below the anal margin and exploring before proceeding with constriction. I have not yet considered it necessary to do this.

Lockhart-Mummery¹⁴ wrote, "For very large prolapses the best operation is amputation." Yet in 1932, Rankin, Barga and Buie¹⁵ stated, "Procedures directed toward the cure of the prolapse by resection have little to recommend them."

The objective of all methods of treatment is the formation of scar tissue between the rectum and the surrounding structures. This seems to have been well accomplished by surgical amputation and logically should be achieved just as well by compression amputation. The minimal loss of blood and the short time required are in favor of the latter technic, and succinylsulfathiazole has removed its greatest danger—namely, sepsis. The mortality and morbidity with the constriction method appear to have come from technical errors. For example, the hose has been inserted too far above the point of constriction, thus allowing the accumulation of feces between it and the rectum. Peristalsis may have forced some of this material through a weakened area in the tissues. There should not be more than a few centimeters of hose above the point of compression. Furthermore, it is probable that in some cases strangulation has not been complete, thus permitting much greater septic and toxic absorption. A slight increase in the diameter of the hose might have reduced or eliminated an undesirable amount of stenosis. From my experiences with uterine procidentias and vaginal relaxations, I am convinced that some patients have tissues so constituted as to be incapable of permanent anatomic

made to remove all the bony fragments and pieces of periosteum that lay between the forearm bones and to suture the torn soft tissues. Complete repair, however, was impossible because of the severe trauma.

The second incision, small in size, was made over the site of the ulnar fracture. It was found that the ulnar fragments

growth between the radius and ulna. It was impossible to separate the muscles without carrying away some of the periosteum. The bridge of bone between the radius and ulna was next removed, thereby restoring the rotary motion of the forearm. The muscles on each side of the interosseous space were sutured in such a manner as to cover the raw

FIGURE 2. Roentgenograms Taken Over Three Years after Resection of the Synostosis and Showing No Evidence of Renewed Proliferation.

had fallen into position on the reduction of the radial fracture, and it was necessary only to secure them with chromic catgut, which was drawn through two drill holes.

An uneventful convalescence ensued. Roentgenograms taken on January 15 showed the fragments in good alignment (Fig. 1B). The vitallium plate was removed in April.

The first definite evidence of cross-union between the radius and ulna was noted in a roentgenogram taken on March 7 (Fig. 1C). In subsequent roentgenograms the bridging between the bones became increasingly dense (Fig. 1D). Clinically, rotation of the forearm was impossible. Operative excision of the synostosis was advised.

On October 11, the surgical treatment was carried out as follows. Under general anesthesia, an incision was made along the inner side of the ulna in the line of the synostosis. The muscles were split down to the interosseous space and, with a great deal of difficulty, were separated from the bony

bony surfaces. The forearm was supinated as much as possible, and a compression dressing was applied.

The patient made a good recovery. Complete range of flexion and extension at the elbow was obtained early.

When the patient was examined on January 17, 1945, three years and three months after the removal of the bony bridge, he had recovered 75 per cent of the normal rotary motion at the elbow. There was slight limitation in the motion at the wrist, owing to the presence of arthritic changes. The hand had a complete grip. A roentgenogram taken on that date showed good integrity of the interosseous space (Fig. 2).

SUMMARY

A case of radioulnar synostosis, with complete recovery following operative excision, is reported.

412 Beacon Street

RADIOULNAR SYNOSTEOSIS OF TRAUMATIC ORIGIN*

Report of a Case

HAROLD G. LEE, M.D.†

BOSTON

AN EXTENSIVE review of the medical literature reveals that there are few recorded cases of synostosis of the forearm bones, although this is always mentioned as a possible complication in discussions of radial and ulnar fractures. The purpose of this report is to present a case of radioulnar

at the time of the accident revealed comminuted fractures of the radius and ulna, semioblique in type and situated 12 cm. above the wrist (Fig. 1A). The fractures were at slightly different levels, and the fragments were completely displaced.

In view of the severity of the trauma, it was realized at the outset of treatment that the soft tissues had undoubtedly been extensively damaged; hence, the possibility of the

FIGURE 1. Roentgenograms of Forearm.

A — This film shows the original semioblique fractures of the radius and ulna at different levels; B — this film, taken four days after open reduction, indicates that the fragments were in good alignment; C — this film, taken approximately two months after reduction, shows evidence of cross-union between the radius and ulna; and D — this film, taken about four and a half months after reduction, shows definite synostosis.

cross-union that occurred as a sequela to comminuted fractures of the forearm bones, which were accompanied by a great deal of damage to the soft tissues.

CASE REPORT

A large, muscular 44-year-old man, while at work in a factory on January 7, 1941, caught his forearm in a moving belt, sustaining an extremely severe injury. The radius and ulna were fractured, and the distal fragments with the hand were carried beyond a right angle by the force of the belt. Only by exerting great force was the patient able to prevent the forearm's being drawn into the pulley. Roentgenograms taken

development of synostosis was considered. The danger of circulatory disturbance was also considered, because of the sclerosis of the vessels that was revealed in the roentgenograms. To permit observation and ensure circulatory stabilization, the forearm was maintained in suspension in a molded-plaster cast for 4 days.

Reduction by a closed method was not considered feasible because of the obliquity of the fragments. On January 11, I carried out an operative reduction, taking great care to prevent further traumatization. Two incisions were used for exposure. First, a longitudinal incision was made over the site of the radial fracture. The fragments were easily placed in normal anatomic alignment and made secure by applying a three-screw plate of vitallium. The membrane and periosteum were found to be badly lacerated, and small chips of bone were displaced into the interosseous space. An attempt was

than would have been expected from the usual scarlet-fever attack rate. By the time the directions on the package were modified the reputation of the Dick toxin in pediatric practice was bad, and its use has been continued only in the hands of a few practitioners.

The immunization of pupil nurses has been so satisfactory from the standpoint of economy that the procedure is carried out in most hospital training schools. Where this procedure has been carried out with the care and scrutiny due an erythrogenic toxin derived from streptococci, the discomfort has been at a minimum. With permission of the patent holders a formalized toxin was made by the Massachusetts Department of Public Health. This did away with the discomforts, but the immunity gained was not so good as that achieved with the straight toxin. Permission to continue this investigation in Minnesota was refused.⁹⁻¹⁰ As far back as 1925, several hospitals were giving eight or ten doses instead of three or five, and thereby reducing to the minimum the incidence of sore arms and febrile reactions. A general hostility toward the patent prompted some institutions to make their own toxin for this purpose. Needless to say, their methods were not published, and an unknown amount of investigative work was stifled because of the difficulty of getting permission to perform it.

Toomey¹¹ has given an excellent review of scarlet-fever immunization. The attack rate of pupil nurses varied in different years in different hospitals from 8.6 to 17.7 per cent. Among the immunized nurses the attack rate in these hospitals was 0.6 per cent. Reactions were noted in 10.2 per cent. Pupil nurses are continuously and heavily exposed on the scarlet-fever wards. Prior to immunization it was usual to have several nurses constantly sick with scarlet fever throughout the winter months. It is now rare to have one nurse lost from duty from this cause. This economic gain to the hospitals for contagious diseases over the past twenty years has been enormous.

The question is raised whether this immunity is more apparent than real. In other words, it is argued that only an immunity against the toxin is achieved, and that these immunized nurses probably act as dangerous streptococcal carriers. On the other hand, it has been asserted that there is apparently somewhat less streptococcal disease among the immunized nurses as a result of this immunization. There is no substantial evidence to support either contention. In short, immunization against scarlet fever gives rise to a specific immunity against the toxin similar to that achieved by an attack of scarlet fever, probably no more and no less. It is distinctly worth while for pupil nurses whose training includes duty on scarlet-fever wards. Beyond this, there is room for debate owing to the low morbidity and low mortality of scarlet fever.

Recently scarlet-fever immunization has been instituted in the 25 per cent of men of the Royal Canadian Air Force¹² found to be Dick positive. The advantages and disadvantages of this procedure remain to be seen.

One disadvantage of immunization is that in those who harbor chronic streptococcal infections or who have had rheumatic infections in the past there is a sensitiveness to the hemolytic streptococcus toxin as manifested by polyarthritides, erythema nodosum and even heart disease.¹³ Such persons, however, would show much the same symptoms if they came down with scarlet fever. Consequently, it is better for them not to be immunized and to avoid exposure to streptococcal diseases — if such a thing is possible. Therefore, in selecting those who are to be immunized, one should eliminate not only those who are Dick negative but those whose past histories offer contraindications.

Passive immunization has been used successfully in the last twenty-five years. Immediately after exposure a dose of pooled convalescent serum or Dick antitoxin is administered intramuscularly. The protection lasts only about fourteen days.

FORMS OF SCARLET FEVER

It is necessary to keep in mind that the usual form of scarlet fever is the result of streptococcal infection of the upper respiratory tract. As such it is spread by direct and indirect contact, and it may also be air-borne. The dust in scarlet-fever wards is apt to be heavily laden with hemolytic streptococci, and the air is especially full of these bacteria after bedmaking and sweeping.¹⁴ On the other hand, so-called "puerperal scarlet fever" results from a pelvic infection, and "surgical scarlet fever" from wound infection. Of course, the streptococci in these infections must be capable of producing erythrogenic toxin. "Burn scarlet fever" may come on at any time during the healing of an extensive burn when these hemolytic streptococci get onto the wound and elaborate their scarlet-fever-producing toxin. To these well-known forms of scarlet fever must now be added so-called "intestinal scarlet fever," which is due to the absorption of the toxin from the intestine in cases showing much gastrointestinal disturbance. The Dicks¹⁵ showed that enteric-coated tablets of the toxin could give rise to vomiting and diarrhea, along with the rash. In this activity of the streptococcus in the gastrointestinal tract it may also give off an enterotoxin¹⁶ that is quite apart from the toxin that produces the rash. The term "septic scarlet fever" is used when the pyogenic properties of the streptococcus are in evidence.

The Dicks¹⁷ resurrected the term "*scarlatinae sine eruptione*" because in their inoculation experiments certain subjects became sick without the rash. The modern concept no longer grants any

MEDICAL PROGRESS

SCARLET FEVER*

CONRAD WESSELHOEFT, M.D.,† AND LOUIS WEINSTEIN, M.D.‡

BOSTON

WHEN Sydenham¹ coined the term "scarlet fever" in 1676, he remarked that this was a disease in name only. The truth of this statement becomes more and more apparent with the progress of knowledge of streptococcal infections. When the Dicks isolated their so-called "*Streptococcus scarlatinae*" and patented the toxin and antitoxin derived from it, the idea of a disease entity seemed to become more fixed. This patent has now expired. With the advance in the knowledge of streptococcal diseases many ideas regarding this eruptive fever have changed. Scarlet fever is not so much a disease entity as it is a manifestation in susceptible persons of a toxic substance elaborated by some strains of beta-hemolytic streptococci. Nor are the toxins elaborated from these types identical.² Not only can many different types of streptococcus produce a scarlet-fever toxin, but from the work of Aranow and Wood³ it appears that certain strains of hemolytic *Staphylococcus aureus* can produce a typical scarlatiniform rash, and that they elaborate an erythrogenic toxin that is antigenically related to that produced by the streptococcus.

The sore throat of scarlet fever cannot be differentiated from any other streptococcal sore throat except that there is apt to be a bright-red enanthem on the soft palate. The eruption is much less likely to be on the face than is the case in measles and German measles. It is essentially an erythema due to engorgement of the superficial capillaries of the skin. Engorgement of the capillary tufts in the papillae gives rise to the punctate character of the rash. In a severe rash the capillaries tend to rupture, especially in the folds of the skin — the so-called "bleeding lines." The engorgement of the capillaries in the papillae of the tongue gives its strawberry or raspberry appearance. Except for the inflammation of the fauces, all these manifestations of scarlet fever are due to the action of the erythrogenic toxin on the superficial capillaries. This toxin is also responsible for the fever and the not infrequent nausea and vomiting and occasional diarrhea.

IMMUNITY

The Dick test is the measure of susceptibility to scarlet fever. It consists of an intradermal injection of 0.1 cc. of a standardized dilution of the toxin, with recording of the result twenty-four hours later.

*From the Haynes Memorial and Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†Clinical professor of infectious diseases, Harvard Medical School; professor of clinical medicine, Boston University School of Medicine; physician, Haynes Memorial, Massachusetts Memorial Hospitals.

‡Resident physician, Haynes Memorial, and fellow in medicine, Evans Memorial, Massachusetts Memorial Hospitals; instructor in medicine, Boston University School of Medicine; assistant in infectious diseases, Harvard Medical School.

Those who are susceptible show a localized erythema and are recorded as Dick positive, whereas those who show no reaction are recorded as Dick negative. The Dick reaction is almost always negative at birth. Thus, an infant is born with immunity to scarlet fever but loses it rapidly as it approaches the second year of life.⁴ From this age the percentage of Dick positives drops from nearly 80 per cent through the grammar-school period to somewhere between 40 and 20 per cent at the military age, according to the opportunity for exposure. This age curve of immunity as measured by the Dick test⁴ is similar to the incidence curve of scarlet fever according to age.⁵ Powers and Boisvert⁶ have studied the factor of age in relation to the type of infection in streptococcosis. The incidence of other manifestations of streptococcal infections follows different patterns as regards age.

Generally speaking, the erythrogenic toxin of the many strains of streptococcus is antigenically much the same, and in the long run confers a lasting immunity. The immunologic response may be monovalent during convalescence and become polyvalent only well after recovery. In other words, the scarlet-fever patient sometimes reacts specifically to the type of organism with which he is infected. In this case, if he is exposed to another type during convalescence, he may have a relapse with a return of the sore throat, fever and rash.⁷ On the other hand, given sufficient time, the immunity conferred by one attack usually affords protection against the toxin of a variety of strains — hence the relatively permanent immunity conferred by one attack of scarlet fever. Although the immunity conferred by a single attack of scarlet fever is primarily against the toxin, this does not of necessity include protection from subsequent bacterial invasion by the original type or any other type of streptococcus. Kuttner and Lenert⁸ have shown that bacteriostatic properties develop in the blood of patients recovering from pharyngitis due to a single type of Group A streptococcus, and that these properties may persist for many months.

By injecting the erythrogenic toxin in repeated doses a relative immunity to scarlet fever can be achieved. This method of immunizing was begun in 1925. Unfortunately, the early dosage as printed on the preparations licensed through the Dick patent was too large and resulted in the very thing that the patent aimed to avoid, namely, bad effects from the toxin. Most pediatricians promptly discarded this procedure because it caused more illness

especially in the cervical region. The lymph nodes in the neck become swollen and tender, but if they are soft and not particularly painful no chemotherapy is indicated even though fever is present; nor are any local applications necessary. This situation represents a late reaction to the streptococcal infection, is manifested also in the axillas and groins, and subsides of itself. A hard, firm, extremely tender cervical node is quite another matter and may represent a pyogenic invasion. Here the question of chemotherapy is debatable. Chemotherapy undoubtedly controls the pus formation, but the induration remains for a long time. Sometimes it remains longer than if the sulfonamides had not been used and the node had been allowed to suppurate and point to the surface and had then been incised. The application of heat or cold has no apparent influence on the course of such suppuration, since pointing takes place under an ice bag as it does under a hot poultice. Either heat or cold may afford a definite degree of comfort.

In addition to the suppurative complications following scarlet fever, there are several others that are the result of some altered response to the causative streptococci or their products, namely, acute diffuse glomerulonephritis, erythema multiforme and rheumatic fever, the tissue changes of which are discussed by Mallory and Keefer.²⁷

Nephritis in scarlet fever is of varying degrees of seriousness. During and following the eruptive phase an increased Addis count²⁸ is found even in the mildest cases. A mild transient albuminuria may also take place. These are both due to the irritant action of the toxin. When red cells or casts begin to show in an ordinary centrifuged specimen of urine, one must be on guard. The explosive nature of acute hemorrhagic glomerulonephritis suggests a violent antigen-antibody reaction in the glomeruli. This is apt to occur some time between the ninth and twenty-first days of convalescence. The urine on the previous day may have been quite normal. The situation is the same as that in glomerulonephritis in diseases other than scarlet fever and calls for the same treatment.^{29, 30} Glomerulonephritis cannot be prevented by dietary regulations.

Erythema nodosum, erythema marginata and urticaria of nonserum origin are not infrequent on any large scarlet-fever service. These also are looked on as antigen-antibody reactions.

Scarlet fever has long been considered to be the origin of endocarditis. The toxin of scarlet fever does not in itself do any permanent damage to the endocardium, and only in the severest toxic cases is the myocardium injured in the eruptive phase. Scarlet fever, however, as a streptococcal disease may initiate rheumatic fever, and that is where the greatest danger of scarlet fever lies today. The exact relation of streptococcosis to rheumatic fever is not yet known, but that streptococcal infections do usher in rheumatic fever is beyond all doubt.

It was formerly thought that transient murmurs in the course of scarlet fever were of no significance.³¹ Subsequent experience has shown that the "will-of-the-wisp" murmurs that appear in the second and third weeks are sometimes followed within four weeks by electrocardiographic indications of myocardial damage, marked murmurs and even sudden cardiac failure. These are clearly of rheumatic-fever origin. It is of great interest that rheumatic fever is apparently likelier to occur after the more superficial infections than after the deeper invasions of the streptococcus, such as erysipelas and abscess formation. Ordinary scarlet fever itself is one of the most superficial of streptococcal infections, and as such it is a dangerous instigator of that far more serious condition, rheumatic fever. It is in this capacity that scarlet fever may lead to subsequent damage of the heart valves. Furthermore, streptococcal tonsillitis is just as dangerous. Thus, the superficial infective process rather than the rash appears to be the factor involved in the instigation of rheumatic fever.

ETIOLOGY

The concept of the etiology of scarlet fever has undergone remarkable changes in the last twenty years. In 1924, the Dicks³² incriminated a hemolytic streptococcus as the causative agent in this disease. Their work helped greatly to clear the confusion concerning the specific agent, but their term "*Streptococcus scarlatinae*," tended to oversimplify the situation. With the development of methods for the identification of streptococci according to their antigenic make-up and for the classification of these organisms according to the group-specific carbohydrate material³³ and type-specific nucleoproteins,³⁴ a more exact basis was furnished for the study of the organisms that produce scarlet fever. It is now known that strains that produce scarlet fever in some patients may produce only localized diseases without a rash in others, and that in various communities of a single country and in the various countries of the world the streptococci that are responsible for the production of scarlet fever may be widely different antigenically, varying to a slight degree in the type of group-specific carbohydrate that they contain, and in a much greater degree in the nature of the type-specific nucleoprotein.

All the strains of streptococcus isolated from the pharynges or other local sites of infection in cases of scarlet fever belong to the group that produce beta hemolysis, as seen by a fairly wide, well-defined, clear ring of hemolysis about the colony in blood agar media. Analyses according to the method of Lancefield³⁵ of many strains for the type of carbohydrate that they contain have shown that more than 95 per cent of them belong to her Group A, the group that is known to be by far the most prevalent in all infections in man due

such term. Without the rash there is no scarlet fever, even though the patient is infected with a streptococcus that is causing a rash in others. Furthermore, such a patient who does not have scarlet fever is capable of giving it to those who are susceptible. To include all infections of the toxin-producing streptococci as scarlet fever is a misuse of the term, since the resistance of the host is an equally important factor. Thus, as pointed out by Gordon,¹⁸ scarlet fever is not just a problem of identifying a rash. From the clinical and epidemiologic standpoint, much depends on where the infection is situated, on the type of streptococcus and on the resistance of the host.

It is obvious that dissemination of these streptococci is greatest in those cases in which the infection is in the upper respiratory tract. In the puerperal form the infected discharge is fairly well confined by the pads over the vagina, especially when these are disposed of by the proper technic and bedpans are sterilized. The dressings of wounds and burns permit the least possible dissemination of infected material. Thus, with good modern surgical technic, a case of scarlet fever originating on a maternity or surgical ward rarely gives rise to a second case. Prompt isolation of the patient makes it unnecessary to quarantine the ward. On the other hand, when upper respiratory scarlet fever breaks out on a maternity or surgical ward, there is much more opportunity for the dissemination of the streptococci.

TREATMENT

Scarlet-fever antitoxin is the specific measure to combat the eruptive manifestation of this disease in that it neutralizes the erythrogenic toxin. Thus, the degree of toxicity manifested in the patient is the indication for this antitoxin, which may be administered intramuscularly or, in a severe case, intravenously, in the form of a polyvalent horse serum (Dick). In moderate cases, a patient under 50 pounds in weight should receive 8000 units, and in severe cases 16,000 units. In those over 50 pounds one should give 16,000 units in moderate cases and 32,000 units in severe ones. Pooled convalescent serum given intramuscularly or intravenously is also efficacious. Here a patient under 50 pounds gets 20 cc. in mild cases and 40 to 60 cc. in severe cases, whereas for those over 50 pounds the dose is 40 cc. in moderate cases and 60 to 100 cc. in severe ones. If given in the first forty-eight hours both these serums show a prompt and beneficial action. The temperature usually drops abruptly, the rash fades, and the sore throat subsides. Occasionally one sees no appreciable effect even with early treatment; in other cases dramatic response may be achieved as late as the fourth day. Serum therapy is unnecessary in mild cases, and is of no value in late septic complications.^{19,20} The concentrated gamma globulin fraction from pooled normal plasma has been used in the eruptive phase, but judging from our observations the results in its present form are inconstant.

Sulfonamide therapy does not neutralize the toxin and therefore has no effect on the eruptive phase.¹⁹⁻²¹ The temperature is not materially lowered, and the duration of the rash is not shortened. The sulfonamides do tend to control the further invasion of the streptococcus, and they definitely control the pyogenic activity of the streptococci if and when such activity is in evidence. In mild and moderate uncomplicated cases, when sulfonamides are given for the duration of the fever only, no appreciable benefit has been noted by most observers when adequate controls have been instituted.²² In severe cases with evidence of deep invasion of the throat, serum therapy should be given along with sulfonamides.

If sulfonamide therapy is instituted at the start in adequate dosage to give a level of approximately 6 mg. for the first four days, and a maintenance dose of half that daily dose is continued for another four days and halved again for the next eleven days, the pyogenic complications are reduced. Nevertheless, one must not be surprised if suppurative otitis media and suppurative cervical adenitis develop in spite of this treatment.* Furthermore, drug rashes and drug fevers occur in certain patients to baffle the clinician, and in rare cases severe anemia develops rather suddenly and requires blood transfusions. In any event, the nonpyogenic complications are not avoided.

COMPLICATIONS

The complications of scarlet fever constitute the manifold expressions of streptococcosis. From the upper respiratory tract may develop sinusitis, especially ethmoiditis, which may be particularly prominent in certain epidemics. This, like suppurative otitis media, represents bacterial invasion with pus formation. The accepted therapy of all pyogenic manifestations is full dosage of sulfadiazine or sulfamerazine. If, after withdrawal of the drug, a discharge from the ear returns, it is well to consider the possibility of a mastoiditis. Here one must keep in mind that sulfonamide therapy may hold back a leukocytosis and mask the x-ray findings.²³ The postponement of surgery may delay recovery. Surgical mastoiditis has been greatly simplified by the local use of sulfonamide drugs, and more recently by the use of penicillin.²⁴ Severe tonsillitis, pharyngitis, laryngitis, pneumonia, empyema, meningitis and bacteremia call for intensive sulfonamide or penicillin therapy. In the presence of rheumatic fever, penicillin is to be preferred for the treatment of the suppurative complications.^{25,26}

A generalized lymphadenitis is a frequent accompaniment of scarlet fever. This occurs early in the disease as a result of the circulating toxin. Later on, between the tenth and the twenty-first day, there may be a recrudescence of lymphadenopathy,

*The widespread use of sulfonamide therapy and prophylaxis may be responsible for the development of sulfonamide-resistant strains of streptococci during an epidemic of scarlet fever.

type of toxin have been described. Some of them have been isolated from other cases of osteomyelitis, and one from the pharynx of a patient who had a typical case of scarlet fever. Thus the present concept of the etiology of scarlet fever extends even beyond the Group A streptococci.

A rational concept of the etiology of scarlet fever appears to be one in which it is recognized that with certain rare exceptions the beta-hemolytic streptococcus is the agent that is responsible for the disease. It is usually Group A organisms that are responsible, however, and practically any of the forty-six serologic types of the Group A streptococci that have been identified may produce the disease, the predominant type varying with the year, the community and the country.

All the serologic types of the Group A streptococcus that produce scarlet fever have one property in common, namely, the ability to produce erythrogenic toxin. Lack of this toxin renders a strain incapable of producing the rash that characterizes scarlet fever. The mere ability of a strain to produce this toxin, however, does not necessarily imply that it will produce scarlet fever in every person in whom it gains a foothold. The immune state of the infected subject against erythrogenic toxin is the other determining factor. Thus, people who have an antitoxic immunity (Dick negative) develop only localized streptococcal infections without a rash, whereas those who have no antitoxic immunity (Dick positive) develop a scarlatinal rash. It is a well-established fact that many of the strains that produce only localized infections without a rash in certain people are capable in the test tube of producing erythrogenic toxin, which when injected into a susceptible (Dick-positive) person produces the typical reaction. Thus, a Dick-negative person with a localized infection — without a rash — can infect a Dick-positive one, who breaks out with scarlet fever.

Although the production of erythrogenic toxin appears on the surface to be the one property that all the streptococci that produce scarlet fever have in common, this point requires qualification, since it has been shown by Hooker and Follensby² that strains of streptococcus isolated from scarlet fever may produce two different types of erythrogenic toxin, A and B, which are distinguishable on the basis of both chemical and immunologic criteria. They have shown that a single toxigenic strain may produce A or B, both or neither. This difference in the quality of erythrogenic toxin produced by different strains of the hemolytic streptococcus is thought by these authors to be a possible explanation of the fact that some persons do not become Dick negative after having had scarlet fever, and that occasionally even the early administration of potent

antitoxin does not appear to alter the toxic manifestations of scarlet fever in certain patients.

(To be concluded)

to the streptococcus. Although this evidence points to a marked degree of similarity between all the strains of streptococci that are isolated from cases of scarlet fever, such a generalization cannot be made because other groups — namely, Group C³⁵ and Group G³⁶ — have been shown to be capable of producing the same disease, although much less frequently than Group A. In any event, as pointed out by Brown and Schaub,³⁷ *Str. scarlatinae* is not the streptococcus of scarlet fever but is a streptococcus of scarlet fever.

That no single strain of streptococcus is involved in the production of scarlet fever becomes evident from the studies on the type-specific nucleoprotein present in strains of streptococci isolated from different cases of scarlet fever. Keefer and his co-workers³⁸ analyzed the literature on the distribution of the various types of streptococci demonstrable in scarlet fever and studied a large group of cases that came under their own observation. Their conclusions were that scarlet fever may be due to a wide variety of streptococci and that the predominant types may vary from one country to another, from one community to another and from year to year in the same community or country. They found that during an epidemic in a community one type predominated or two types thrived simultaneously. They also found that as an epidemic of scarlet fever progressed in the same community, one type might be replaced later by another. This same fact was noted last year at the Haynes Memorial Hospital, where early in the winter the predominant type isolated from cases of scarlet fever was Type 1, although there were six or seven other types present. In the spring and late winter, Type 2 became the organism most frequently isolated, although some cases were still due to Type 1. Keefer and his co-workers also point out that in sporadic cases of scarlet fever the infections are oftener due to types that are not concerned with the types causing the epidemic and that there is often wide scattering. They also state that the same type of streptococcus may be responsible for different clinical diseases — that is, scarlet fever in one person, tonsillitis in another, erysipelas in a third and rhinitis in a fourth — and that when one or more types are predominant in any community, the same types are usually isolated from persons with various diseases, such as scarlet fever, tonsillitis and otitis media. All the studies made during the last two or three years in various Army and Navy establishments have borne out the same fact; in other words, in any large group of men scarlet fever may be due to a number of different types of streptococci, although one or two types are usually found to predominate.³⁹

In view of the ample evidence that the causative streptococcus in scarlet fever may differ not only in the type of group-specific carbohydrate content but much more frequently in the qualitative character of the nucleoprotein content, it appears that

the concept of a single species of organism is hardly tenable. Furthermore, the facts that the organisms isolated from cases of scarlet fever are beta hemolytic streptococci and that they all produce erythrogenic toxin and may show similar fermentative ability do not constitute enough evidence to class them as a single species, particularly since it has been well demonstrated that they differ antigenically. The situation is somewhat analogous to that which prevails in the *Salmonella* groups. Although several strains of this group may cause acute enteritis, may be isolated from the feces of various persons and may show closely similar activity against carbohydrates, they are not classified as a single species. Indeed, they are separated into different species on the basis of an analysis of their antigenic constituents. Whereas in the case of the *Salmonella* group a specific name is usually attached to organisms that resemble each other closely in their invasive, cultural and biochemical activities, such a procedure is not necessary with the Group A beta-hemolytic streptococci, the type number sufficing to identify the organism.

The whole problem of the etiology of scarlet fever is further confused in view of the fact that organisms other than beta-hemolytic streptococci at times produce the same symptom picture. Many drugs, notably quinine and the sulfonamides, are capable of producing fever and a typical scarlatiniform rash in hypersensitive persons, followed by desquamation. These drug rashes, however, do not represent the invasion by an infectious agent, and therefore do not come under the concept of scarlet fever. Moreover, Aranow and Wood³ point out that some strains of hemolytic *Staph. aureus* are capable of producing a symptom picture that is indistinguishable from clinical scarlet fever. They have described a case of osteomyelitis due to a strain of *Staph. aureus* in which a diagnosis of scarlet fever was made on admission to the hospital because the patient had a typical scarlatiniform rash and a raspberry tongue. No beta-hemolytic streptococci were cultured from the pharynx, but convalescent scarlet-fever antiserum was administered, and this blanched the rash. It was subsequently shown that the patient had osteomyelitis of the femur due to a strain of *Staph. aureus*, which was also cultured from the blood stream. Later the patient showed desquamation typical of the convalescent stage of scarlet fever. A study of this staphylococcus showed that it produced erythrogenic toxin that was closely related immunologically to that produced by some strains of beta-hemolytic streptococci. That this is not an isolated case of production of erythrogenic toxin by *Staph. aureus* is shown by a review of the literature on this subject by these same authors, who cite several other investigators who have demonstrated the production of a rash-producing toxin by a staphylococcus; at least forty-three strains that produce this

it should be considered negligence not to take x-ray films of the chest in a man with a story such as this, just as it is considered negligence to make a negative diagnosis of fracture following injury without x-ray examination.

In carcinoma of the bronchus by far the most frequent early signs are pain in the chest, blood spitting and cough; the cough is usually brassy and unproductive. This man did not have pain in the chest and did not have any blood spitting, and the cough was said to be loose. All these facts are against

have had an extensive suppurative process in the lungs. He had a low blood pressure on two occasions. I shall come back to that later.

The examination of the blood — the hemoglobin level, white-cell count and so forth — was within the limits of normal.

It is surprising how little the anteroposterior film (Fig. 1) shows, and one wonders why there were such definite signs on percussion over the left side of the chest. If you look at the lateral view you can see there is dullness in the posterior part of the

FIGURE 1. Anteroposterior (left) and Lateral (right) Roentgenograms of Chest.

carcinoma of the bronchus and in favor of some other cause, possibly tuberculosis.

The story was always one of weakness and malaise, which are not unusual complaints for carcinoma of the bronchus. In the family history they mention locomotor ataxia. He was married and had three children and later on had a negative Hinton test. I do not think we have to pay much attention to syphilis.

What do we get out of the physical examination? He was emaciated and had a cough and limited chest expansion. The statement about the percussion note is interesting. I wonder whether that interpretation would be a help or a hindrance to a clinical man. What do you think about it, Dr. Cass?

DR. JOHN W. CASS: I should say that it was simply a sign of bronchial obstruction.

DR. HOLMES: He had an expiratory wheeze. That is the most significant of all the physical findings. Expiratory wheeze means bronchial obstruction. He had no pain, and no elevation of temperature, pulse or respiration. It seems unlikely that he could

chest in the region of the lower lobe. Then, if you look carefully at the left lung in the anteroposterior film you notice that it is brighter than the other side and that the number of markings in the lung are less than those on the other side. In other words, there is evidence of collapse of the left lower lobe. The lobe is hidden behind the heart shadow. It would be helpful if films had been taken with more exposure and, perhaps, a grid film, to determine the outline of the diaphragm. If the lung is collapsed the outline of the diaphragm is obscured. It would also be helpful to know if there were any cavities in that portion of the lung. In addition, there are these massive shadows at the left lung root. They are probably due to enlarged hilar nodes and are of considerable importance in the diagnosis and also when considering the question of operability. There is no evidence of calcium deposits in any of these nodes, and no calcified masses anywhere in the lung, which is some evidence against tuberculosis.

In a patient with a long story of bronchial obstruction one always has to think of an adenoma, a benign tumor of the bronchus, but this patient's

CASE 31181

PRESENTATION OF CASE

A fifty-six-year-old railroad fireman was admitted to the hospital because of malaise, weight loss and cough.

About twenty months before admission he had lobar pneumonia, which kept him in bed for two weeks. After three months he had recovered and felt quite well, but he never regained his full strength or weight. He returned to work despite the fact that his physician told him there was something wrong with his left chest. Eleven months before admission he suddenly developed malaise, loss of energy and ambition. At that time he was found to have a systolic blood pressure of "about 80" and he was given some medicine. After three weeks he improved and returned to work. He remained active until two months before admission, when he again experienced acute malaise and weakness of a severer nature than that of nine months before. This lasted three weeks. A third attack of weakness and malaise began one month before admission, and the patient remained in bed most of the time for about two weeks. Ever since the episode of pneumonia he had had a chronic "residual" cough which, especially in the morning after arising, was productive of white and gray-brown sputum, which was not malodorous and contained no blood. The cough was worse when he lay on his left side. One week before admission he began to wheeze on exertion. During the two years before admission he had lost about 35 pounds.

In the past he had had mumps, influenza and an infrequent cold. He was a moderate smoker and drank only an occasional glass of beer. His mother had died of diabetes, and his father of "locomotor ataxia." His wife and three children were living and well.

Physical examination revealed a rather emaciated man with an occasional loose cough. The heart sounds were faint and regular. There was slightly limited chest expansion on the left. The percussion note over the left base, both anteriorly and posteriorly, was duller than that on the right. There were diminished to absent tactile fremitus, breath sounds

and voice sounds in the left chest anteriorly and posteriorly, extending from the mid-upper chest to the base. Expiratory wheezes were heard over the entire chest. The throat was normal. Abdominal and rectal examinations were negative.

The temperature, pulse and respirations were normal. The blood pressure was 100 systolic, 74 diastolic.

Examination of the blood showed a red-cell count of 5,250,000, with 15.1 gm. of hemoglobin, and a white-cell count of 12,300, with 85 per cent neutrophils. The serum protein was 6.6 gm. per 100 cc., and the nonprotein nitrogen 21 mg. A Hinton test was negative. An x-ray examination of the chest revealed the left hilus to be markedly increased in size. There was an area of increased density extending downward and posteriorly into the lower lobe. Within this area several rounded masses were seen (Fig. 1). The motion of the diaphragm was paradoxical, and the mediastinum shifted to the left on inspiration. The right lung appeared normal.

On the second hospital day a bronchoscopy was performed.

DIFFERENTIAL DIAGNOSIS

DR. GEORGE W. HOLMES: This story and the x-rays are typical of bronchial obstruction. In fact I think at the start that we can assume that this condition existed, and we must try to analyze the causes of bronchial obstruction. The most frequent cause is bronchiectasis, the next is tuberculosis, and the third, some form of primary neoplasm. In addition, bronchial obstruction is sometimes due to metastatic tumor and also to a foreign body. Let us go over the history with these things in mind and see if it will help us to arrive at a diagnosis.

This man was fifty-six years old, so that he was in the cancer bracket. He worked as a fireman and presumably was exposed to coal dust and other irritants. In the history it says that he was a smoker, but it does not say what he smoked: I think it makes a difference if one smokes cigarettes or a pipe. The record states that he had pneumonia and went to bed, but we are not told any of the details; in fact, we do not know whether he really had pneumonia. A story of pneumonia often follows bronchial obstruction. It really does not help us much in determining the cause of the obstruction. Carcinoma of the bronchus is frequently preceded by a story of pneumonia, and so are various other causes of bronchial obstruction. Following this episode he never regained his former weight, and the doctor warned him that he had something wrong with his chest. One wonders why the doctor did not go farther and find out what he had in the chest. Perhaps he did try, or the patient may have refused further study. Two years had passed before he came into the hospital, and all that time it was known that he had something wrong with his chest. I think that we have reached a period in chest examinations when

*On leave of absence.

After several months' consideration he re-entered the hospital for lobectomy.

DR. SWEET: There are one or two interesting things about this case. I do not believe that he ever had paradoxical motion of the diaphragm, because it seemed to be quite active at operation. Another point is that the x-ray picture shows the anatomic findings with great accuracy. The aerated lung on the left side was the upper lobe, which filled the left chest except for one large bleb about the size of the palm of my hand. Because of Dr. Benedict's bronchoscopic findings, and having been told that the lesion was close to the upper lobe, I was extremely careful in doing the operation to search for tumor and was prepared to do a pneumonectomy. Dr. Evarts Graham* says that it should be done on all these patients, but in this clinic we believe that a lobectomy, if it includes the entire tumor, is sufficient. He believes that the histology indicates that such tumors are potentially malignant.

DR. BENEDICT: All bronchoscopies except the first one showed that most of the tumor was in the lower lobe.

DR. SWEET: Because of that, after removing the lobe, I looked down the bronchus, with the bronchus open, and made sure that there was no tumor.

DR. CASTLEMAN: The shrunken left lower lobe that we received showed no evidence of tumor. In other words all the tumor had been removed bronchoscopically, so far as we could tell grossly, and this was confirmed microscopically. The lobe, however, was irreparably diseased with extensive bronchiectasis. The upper half of the lobe was collapsed, and there was beginning fibrosis. In the lower portion there were cystic bronchiectatic cavities measuring up to 2.5 cm. in diameter. I think that it is a good idea to remove these diseased lobes, even though some of the patients have no symptoms. We had one young boy who had an adenoma almost completely removed. He had ten to fifteen bronchoscopies over a period of years, but the left lung remained collapsed. He went into the Army and died about seven or eight months later of amyloid disease, owing to the chronic infection that he continued to have in the obstructed lobe. It is also interesting that this boy had a metastasis in a bronchial lymph node.

I agree with Dr. Sweet that the large majority of these patients do not develop a malignant tumor, but we have had 2 cases in our series of about 40 in which the regional nodes were involved with the same benign-like adenoma as the primary tumor: in neither of these cases had it gone beyond the regional nodes. Such tumors act much like the argentaffin or carcinoid tumors in the small intestine, which occasionally have metastases to the regional nodes, producing small-bowel obstruction,

but rarely go any farther. The metastasis may remain in that location for years.

DR. HOLMES: The bronchiectasis followed the adenoma?

DR. CASTLEMAN: Yes; it was a secondary bronchiectasis.

DR. HOLMES: Is it not unusual for patients with this type of tumor to be so free from fever?

DR. SWEET: The patient did have several attacks of so-called "pneumonia."

DR. HOLMES: The X-ray Department failed me by observing paradoxical motion of the diaphragm, which he did not have.

DR. SWEET: I tried to point that out.

DR. BENEDICT: Dr. Edward Churchill always believed that this patient had carcinoma, and even after bronchoscopy and after the pathological report of adenoma came back, he was still inclined to believe that it was a carcinoma because of the x-ray findings.

DR. HOLMES: That one statement of paradoxical motion would also have prevented me from accepting the diagnosis of adenoma.

DR. CASTLEMAN: The enlarged hilar lymph nodes were undoubtedly inflammatory. There are later x-ray films that do not show them.

DR. SWEET: At operation they were not particularly significant.

DR. BENEDICT: The sharp, freely movable carina by bronchoscopy at the end of two years was against carcinoma.

DR. CASTLEMAN: The patient probably did not have as much bronchiectasis at the time the first films were taken as was found in the resected lobe; it must have increased during the six years that intervened.

CASE 31182

PRESENTATION OF CASE

First admission. A twenty-four-year-old man was admitted to the hospital complaining of massive hemoptysis.

At eight years of age the patient was acutely ill with joint pains, severe chest pain, fever and malaise. A few weeks later he developed chorea. He was maintained on strict bed rest in a hospital for ten months. He had prolonged elevation of pulse and temperature, but improved gradually with rest and routine care. He was seen in the Cardiac Clinic of the Out Patient Department at the age of twenty years. He worked every day with a prescribed half hour of rest every noon and had no complaints. A physical examination at that time revealed a fairly muscular young man, with a slightly sallow complexion. The lungs were clear. The heart was enlarged, the apex beat being 9 cm. from the midline in the left fifth interspace. A systolic thrill was readily felt to the right of the sternum in the

*Graham, E. A. Problem of so-called adenoma of bronchus. An unpublished paper presented at a meeting of the American Association for Thoracic Surgery, Chicago, May 5, 1944.

history was only two years in duration, which is about the duration for a carcinoma of the bronchus. Adenoma of the bronchus is usually associated with a certain amount of infection, and the patients have a story of raising foul sputum. I cannot rule out an adenoma of the bronchus, but I doubt that that is what he had. I do not believe that we have to consider bronchiectasis seriously, for the same reasons.

Metastatic malignant tumors, including lymphoma, have to be considered. We have had only one case that I know of in which the mass produced compression of the bronchus. As a rule, metastatic tumors of the lung do not cause bronchial obstruction.

That brings it down to whether or not this patient had primary carcinoma of the bronchus or tuberculosis, or both. There is another point in the history that we must consider at this time, that is, the low blood pressure and the story of malaise and weakness coming on at varying intervals and finally bringing him into the hospital. This low blood pressure and a process in the lungs that could be either tuberculosis or cancer makes one think of something involving the adrenal glands. Metastases to the adrenal glands are not rare in carcinoma of the lung, and their involvement is quite frequent in tuberculosis. So again we are left in the same predicament. We do not know whether this was carcinoma or tuberculosis.

Then in the x-ray examination there is something quite significant. He is said to have had paradoxical movement of the diaphragm. That probably means paralysis of the phrenic nerve, which is a fairly frequent occurrence in carcinoma and rarely occurs in other conditions. We have one case reported in which there was paralysis of the phrenic nerve with tuberculosis. This, of course, may be that case. I should like to be absolutely certain about that statement. One would think it would be a hard thing to miss, but it is not. The whole differential diagnosis, or a large part of it, so far as I am concerned, depends on that single statement.

Was any sputum obtained?

DR. BENJAMIN CASTLEMAN: No sputum examination is recorded.

DR. HOLMES: It is an important examination, and we might be able to clinch the diagnosis between carcinoma and tuberculosis on that alone.

Leaving aside the fact that cases selected for this conference are sometimes rare, one must arrive at the conclusion that this patient had a primary carcinoma of the bronchus, with changes of some sort in the adrenal glands.

The record stops at the bronchoscopy. I should like to go a step farther and speculate what should have been done about this man. In the first place I think that he should have had x-ray films taken within a month after the first episode and that he should have had a bronchoscopic examination at

about the same time. On the data that we have here he was inoperable so far as cure is concerned, because the nodes were involved. There is evidence that he may also have had involvement of the adrenal glands. Should he have had x-ray treatment? We do it usually to relieve symptoms rather than with the hope of cure. This man had no symptoms that could be alleviated by radiation.

DR. RICHARD H. SWEET: In regard to the paradoxical motion of the diaphragm, do you think that that would be the case if there had been no evidence on the x-ray films? I assume that the diaphragm was not high on the left side. In other words, I am inclined to doubt the observation.

DR. HOLMES: The fact that the diaphragm was not high makes you doubt the observation?

DR. SWEET: Yes.

DR. EDWARD B. BENEDICT: Bronchoscopy showed the carina to be normal, sharp and not fixed. At a point in the region of the orifice of the left upper lobe there was a smooth, pearly-gray mass, apparently arising from the upper lobe orifice, which partially occluded the left main bronchus.

CLINICAL DIAGNOSIS

Carcinoma of lung.

DR. HOLMES'S DIAGNOSIS

Bronchial obstruction due to primary carcinoma of bronchus.

ANATOMICAL DIAGNOSIS

Bronchial adenoma.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The biopsy specimen showed that this was a benign bronchial adenoma. Dr. Benedict followed the man from then on.

DR. BENEDICT: I followed him at frequent intervals. He had eleven bronchoscopies over a five-year period, and on almost every occasion I found some tumor tissue, which I removed and sent to the laboratory, with a report of "benign adenoma" each time. In the meantime, the bronchial obstruction was relieved and he was symptomatically entirely well, except for a slight morning cough. He gained weight and returned to full-time work. We thought that behind the adenoma in the left lower lobe there were collapse and bronchiectasis. In a younger man we would have advised lobectomy, but in this patient, because of his age and the absence of symptoms, we went ahead observing him bronchoscopically. Each time there was evidence of adenoma. Because of the possibility that there was an extrabronchial adenoma and because some of the cases reported in the literature occasionally show a low-grade malignancy I finally put it up to the patient to have a lobectomy to get rid of the tumor and the irreparably damaged left lower lobe.

week the sedimentation rate was 0.7 mm. per minute and the PR interval was 0.22 second. He had frequent severe hemoptyses. His white-cell count varied from 5000 to 12,000, and the red-cell count rose from 3,600,000 to 5,300,000 on discharge. The urine was negative. The cardiothoracic ratio was 18.2:30.3. X-ray examination of the lungs was consistent with pulmonary edema or congestion. An electrocardiogram showed an inverted T₂ and a

The lungs presented a few fine rales, and the heart almost reached the anterior axillary line. During the first few hours after admission he coughed up 400 cc. of blood, and smaller amounts on the succeeding three days. The red-cell count fell to 3,800,000. Electrocardiographic and x-ray studies showed no heart or lung changes. The temperature, the pulse and the respirations returned to normal on the fourth hospital day, and a slow blood transfusion

FIGURE 1. Roentgenogram of Chest.

Note the fine nodular density throughout the lung fields, as well as diffuse increased density centrally in each field.

tall T₂, with a PR interval of 0.21 to 0.26 second. Physical examination of the heart was unchanged. The lungs cleared fairly well before discharge.

Third admission (ten months later). The patient developed another cold with sore throat and was readmitted to the hospital after several episodes in rapid succession of hemoptysis up to 200 cc. of bright-red blood. The ten-month interim had been almost entirely free from hemoptyses and the lungs had been clear. He had done no work, however.

The temperature was 104.2°F., the pulse 140, and the respirations 30. The blood pressure was 100 systolic, 34 diastolic.

was given. He was discharged on the twentieth day, nearly two weeks after the last hemoptysis.

Final admission (twelve months later). The patient worked for a few months as a painter, then went to Florida to rest. He returned by bus and, while en route to Boston, had the first hemoptysis that he had experienced in twelve months. On the day of admission he coughed up about 500 cc. of bright-red blood.

The temperature, pulse and respirations were normal. The blood pressure was 110 systolic, 50 diastolic.

An electrocardiogram showed partial auriculo-

second interspace. An apical systolic and a mitral diastolic rumble without a presystolic phase were present. A loud, rough aortic systolic murmur associated with a thrill and an aortic diastolic murmur were heard. The pulmonic second sound was prominent, and the aortic was absent. The blood Hinton and Wassermann tests were negative. The temperature and respirations were normal. The blood pressure was 100 systolic, 60 to 40 diastolic. There was a Corrigan pulse, with a regular rate of 80. During the following three years he made frequent visits to the Out Patient Department and showed little change. The heart size increased slightly, and his blood pressure was 118 systolic, 70 diastolic. He was able to climb two or three flights of stairs without dyspnea, and managed to work regularly at jobs that did not require much physical exertion. He smoked one package of cigarettes daily. He came to the Medical Clinic of the Out Patient Department at the age of twenty-three, complaining of expectoration of bright-red blood, unmixed with sputum. The first attack had occurred suddenly at 10:30 p.m., three days before admission. There were no premonitory symptoms, and he had not been exerting himself unduly at the time. The attack consisted of a choking sensation without dyspnea, followed by coughing and expectoration of about one cupful of blood. This episode lasted five minutes, then ceased abruptly, and was not associated with any discomfort. During the month preceding these episodes he had changed from automobile driving to pick-and-shovel work because he could find no other job. Physical examination at that time revealed a slight increase in the size of the heart, which extended by percussion to 11 cm. from the midsternum in the left fifth interspace. A snapping first sound at the apex, which occasionally became weak and muffled without respiratory relation, was preceded by a crescendo presystolic murmur. The systolic murmur at the apex was unchanged. No second sound was heard at the apex or over the aortic area. The diastolic murmur over the aortic area and to the left of the sternum lasted throughout diastole. A loud and extremely rough systolic murmur was present to the right of the sternum in the second, third and fourth interspaces. The rate was regular at 64, except for an occasional premature systole. The blood pressure was 108 systolic, 60 diastolic. The lungs were normal, and there was no clubbing of the fingers, and no edema. The liver could not be felt, and the neck veins were not distended. Careful examination revealed no evidence of oral or nasopharyngeal bleeding. The red-cell count was 3,800,000, and the hemoglobin 55 per cent. X-ray examination of the chest revealed enlargement of the heart in the region of the left ventricle. The aorta and lungs were normal. An electrocardiogram showed a tendency to right-axis deviation; the PR interval was 0.19 second, and T_3 was inverted. Following

this examination the patient did not come to the Out Patient Department for nearly two years when, at the age of twenty-five, he returned. He had had hemoptysis almost every day for the preceding week, producing from half to one cupful of bright-red blood on each occasion. He had a "chest cold," felt weak and experienced dyspnea on exertion and slight orthopnea. He was quite pale, with a red-cell count of 3,980,000 and a hemoglobin of 8.2 gm. A few crackling rales were heard over the lungs anteriorly and posteriorly. Physical examination of the heart was as last described. The blood pressure was 95 systolic, 50 diastolic. There was no venous distention, clubbing of the fingers or enlargement of the liver. There was slight pitting edema of the lower portion of the legs. He was digitalized and given Mercupurin and ferrous sulfate. Fluids and salt were restricted. On this regime the patient improved and returned to work. Seven months later the patient was admitted to the hospital because of recurrent hemoptysis. On the preceding day he had contracted an upper respiratory infection and on the day of admission had had repeated coughing spells with hemoptysis. Shortly before admission he had a shaking chill.

On examination the patient was slightly cyanotic, dyspneic and orthopneic and had slight neck-vein distention. The heart revealed no change. There were crepitant rales over the upper lobes, and loud gurgling rales over both bases anteriorly and posteriorly. The liver could be felt at the costal margin and was slightly tender.

The temperature was 103.6°F., the pulse 84 and the respirations 36.

X-ray examination of the chest revealed a homogeneous area of increased density occupying the middle third of both lung fields from the hila to the lateral chest walls; there was no evidence of fluid (Fig. 1). An electrocardiogram revealed a PR interval of 0.20 second; P_1 and P_2 were prominent, and the axis was borderline. He responded well to intravenous sulfadiazine, as well as Cedilanid and an oxygen tent. The temperature was normal on the third day, and the chest cleared promptly. Several sputum and blood cultures were negative. He was discharged on the tenth hospital day.

Second admission (two months later). Two weeks after discharge he returned to the Out Patient Department after several episodes of hemoptysis, and because he had a "chest cold." The cough was worse when he was recumbent. There was no evidence of right heart failure. More rest, continued digitalis and diuretics were prescribed. He was subsequently readmitted to the hospital because of hemoptysis that was severer than any previous attack of bleeding. This episode again followed the onset of a "cold" and produced "almost a quart of blood."

During a two-month interval in the hospital he was afebrile after the third day. During the first

for a period of several years. Hemoptysis of this degree is not often seen in any sort of intrinsic pulmonary disease, such as tuberculosis, bronchiectasis or new growth. Hemoptysis may occur frequently in these conditions but is rarely so massive. Furthermore, since the lungs were apparently normal, we can rule out the above conditions. Certainly a neoplasm should have manifested itself after a period of four years. Pneumonia, which was suspected once in this patient, was evidently not present.

Other forms of heart disease will occasionally produce bloody sputum. Left ventricular failure due to either hypertension, aortic-valve disease or coronary disease may produce pulmonary congestion and blood-streaked or pinkish sputum but rarely, if ever, does it cause massive hemoptysis of pure blood. There are other less frequent causes of blood spitting, such as aortic aneurysm, which may rupture into a bronchus and produce a massive hemorrhage but does not cause repeated attacks over a period of four years. There is no evidence of aneurysm in the x-ray films.

One diagnosis that I believe should be seriously considered is pulmonary infarction. Pulmonary infarction frequently occurs in patients with rheumatic heart disease, owing either to pulmonary embolism or to pulmonary thrombosis. There is usually, however, only a small quantity of blood coughed up in this condition, and with repeated attacks one would expect to find good x-ray evidence of either recent infarction or scarring from old infarcts. He had none of these.

Patients with mitral stenosis occasionally cough up large amounts of pure blood. The mechanism involved is not that of heart failure, but rather that of an overstrong right ventricle, which tends to flood or overcrowd the pulmonary circulation with blood that has difficulty in getting out of the pulmonary bed because of the tight mitral stenosis. Such a mechanism may lead to pulmonary congestion, to pulmonary edema or, less frequently, to the rupture of small vessels with pulmonary hemorrhage, as observed in this case, a syndrome that has been called "pulmonary apoplexy." Patients with this syndrome do not necessarily have heart failure. This patient showed no evidence of right-sided heart failure in his early attacks of hemoptysis. In fact, the precipitating cause for his attacks is not clear. Hard work is said to precipitate pulmonary apoplexy and did precede his first attacks. Tachycardia is another cause, the rapid heart rate tending to flood the pulmonary circulation, but this was not present in this case. It is interesting to note that he continued to have normal rhythm. Most patients with this syndrome do. I believe, then, that the attacks of hemoptysis were due to the mechanism described above and not to left ventricular failure.

Finally, the question should be raised whether or not this man had active rheumatic fever. He

did have partial auriculoventricular block from time to time, and the sedimentation rate was rapid on the one reading that we have. I therefore suspect that he had active rheumatic fever during his last two or three hospital entries.

DR. CONGER WILLIAMS: I agree with Dr. Wheeler's diagnosis. This man had an interesting collection of symptoms. The most mysterious thing about the syndrome of pulmonary apoplexy is the elevation of temperature, often seen but never adequately explained. We are following such cases in the Out Patient Department. I remember another case with pulmonary edema admitted to a hospital no less than six times with a diagnosis of lobar pneumonia. No one thought it odd that the man should have pneumonia so often and recover so rapidly, that is, within three or four days of the onset. It is often difficult in this disease to restrain the attending physician from giving sulfonamides.

CLINICAL DIAGNOSIS

Rheumatic heart disease, with mitral and aortic stenosis and insufficiency.

DR. WHEELER'S DIAGNOSES

Rheumatic heart disease, with mitral and aortic stenosis and insufficiency.

Syndrome of "pulmonary apoplexy."

Active rheumatic fever and congestive failure.

ANATOMICAL DIAGNOSES

Rheumatic heart disease.

Acute and chronic rheumatic endocarditis of the mitral, aortic and tricuspid valves.

Stenosis of the mitral and tricuspid valves.

Cardiac hypertrophy and auricular dilatation.

Chronic passive congestion of lungs and liver.

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: At the time of death this man was extremely cyanotic. His heart weighed 550 gm., with pronounced auricular dilatation. The mitral valve was stenotic and just admitted the tip of one finger. The aortic valve was not stenotic, but the cusps were somewhat interadherent, thickened and partially calcified. Below the aortic orifice on the posterior ventricular wall, the endocardium was rippled, like the sand on a beach, and three small accessory cusps had formed, indicating aortic regurgitation. The tricuspid valve measured 9 cm. in circumference (normal, 14 cm.), and its leaflets were somewhat thickened. On one cusp of each of these three valves there was a small area of ulceration covered by a fine layer of platelet thrombus. The

ventricular block. The heart was unchanged except for further enlargement. The point of maximum impulse lay in the anterior axillary line in the fifth and sixth interspaces. The lungs were clear. The liver could not be felt, and there was no edema. Examinations of the urine and blood were negative. The serum nonprotein nitrogen and total protein values were normal. The sedimentation rate was normal. A cephalin flocculation test was +++ in twenty-four hours.

The patient coughed up over 600 cc. of blood on all but one of the first five days after admission. After the fourth day, chest examination was difficult because of loud tracheal rales. Dyspnea and cyanosis progressed as the lung fields increased in dullness. On the sixth hospital day he expired quietly, at the age of twenty-seven years.

DIFFERENTIAL DIAGNOSIS

DR. EDWIN O. WHEELER: Obviously this man had severe, prolonged rheumatic fever at the age of eight years. There was no further evidence of rheumatic fever for a period of twelve years.

There is not much question concerning the type of heart disease that this patient had. At the age of twenty years he presented a typical picture of rheumatic heart disease, with mitral and aortic stenosis and insufficiency and cardiac enlargement. He had no evidence of congestive failure, and he had not developed auricular fibrillation. During the next three years the mitral murmur became crescendo in character and the first sound at the apex became snapping, suggesting that the mitral stenosis had increased in severity and was of the typical adult type. The aortic insufficiency was not of marked degree. The electrocardiogram at the same time revealed an axis that was within normal limits, suggesting that the two valvular lesions, aortic and mitral, tended to balance each other so that no ventricular preponderance developed.

It is rather unusual for a patient to cough up so much blood. It was pure blood, apparently, and he had repeated attacks. There was no evidence of pulmonary congestion during the first attack. I wonder how soon after the episode of hemoptysis that observation was made. In a patient who had bled that much one would expect to find rales at the lung bases. We do not know whether he had fever or leukocytosis during the early episodes, though such did occur later on. Evidently the physician doing the examination did not believe that the patient had a chest cold, since it is noted in quotation marks. Pulmonary congestion may well have produced this sensation, for he had had dyspnea on exertion and slight orthopnea. There was little or no evidence of right-sided heart failure during these early attacks except for the slight edema of the legs. There was, however, considerable evidence of pulmonary congestion at the time of his first admission for an episode of hemoptysis,

with no evidence of pulmonary consolidation or of a localized pulmonary lesion.

May we see the x-ray films?

DR. LAURENCE L. ROBBINS: In the first film, taken in the Out Patient Department, there is increased density in the central portion of each lung field. The heart is prominent in the region of the left ventricle, and there is left auricular enlargement. One film shows prominence of the pulmonary artery. I do not see any calcification in either the mediastinum or the aortic valve, but that cannot be determined without fluoroscopy.

This film was taken three years later. The heart has increased in size. In addition there is diffuse increased density centrally located and a fine nodularity scattered through the lung field. Another film taken a year later shows an increase in the nodularity but no change in the central shadow (Fig. 1).

DR. WHEELER: Is the nodularity consistent with that which we see in long-standing mitral disease?

DR. ROBBINS: It is consistent with pulmonary congestion and edema.

DR. WHEELER: There is no evidence of primary pulmonary disease?

DR. ROBBINS: Not that I can see.

DR. WHEELER: The PR interval was still within normal limits. The prominent P₁ and P₂ are in keeping with auricular enlargement. Axis deviation had not developed, showing no preponderance of either ventricle; the patient probably had hypertrophy of both ventricles.

The story at the time of his first admission suggests that the diagnosis of pneumonia, which was entertained, was incorrect. He recovered rapidly and had no x-ray evidence of pulmonary consolidation, and the sputum and blood cultures were negative. A diagnosis of pneumonia is often made in patients with mitral stenosis who present these symptoms.

At the time of his second admission he again had hemoptysis, fever and some leukocytosis, which responded much more quickly to bed rest than is the case with pneumonia or pulmonary infarction.

What happened to the sedimentation rate during the second hospital admission?

DR. RONALD C. SNIFFEN: Only one sedimentation rate is recorded.

DR. WHEELER: Quite a degree of partial auriculoventricular block was present at times, suggesting active rheumatic fever. Again, there was no evidence of pulmonary disease as a cause for the hemoptysis.

The third hospital admission was a repetition of the two preceding entries, and the fourth admission varied only in that the patient failed to recover and apparently died in pulmonary congestion.

This, briefly, then was a patient with rheumatic heart disease with aortic and mitral involvement who suffered from recurrent massive hemoptyses

CLOSING THE RANKS

THE continuance of a democracy is dependent on the ability of its people to hold to their ideals of liberty and to find and follow high leadership. This democracy of ours, changing as it has been with the changing years, undergoing modifications in the pattern of its progress, still youthful enough and great enough to be flexible, has always found great leaders in its periods of crisis.

Emerging safely now from the darkness of our second great national crisis, we have achieved unanimity in the realization of the loss of a great leader. So it was after the death of Lincoln. Constructive, positive leadership cannot exist without

opposition, but under such able guidance as we have had, that opposition is loyal, co-operative and appreciative.

If there is one prayer that we can all join in now, it is that our new president, with the best wishes of his country, will have strength to lead it onward along the path of victory and peace. This he can have only with our full loyalty and support, as we had given them to his predecessor. We must close the ranks and push on.

PATULIN INEFFECTIVE AGAINST THE COMMON COLD

IN NOVEMBER, 1943, a group of British investigators reported on a new antibiotic agent, patulin, obtained from a strain of *Penicillium patulin*.¹ This substance was considerably more toxic than penicillin but had a wider range of activity and seemed to be effective against gram-negative bacilli. In preliminary clinical trials in uncomplicated cases of the common cold among naval personnel, there appeared to be a definitely higher cure rate after forty-eight hours among persons who sniffed patulin or sprayed their noses and throats with the drug than there was in comparable controls who used a buffer solution without patulin.

These observations were of considerable interest, since common colds constitute a large source of man-days lost, particularly during the early period of training of fresh recruits and among large industries. Because of these favorable results, the director of pathology and the consulting physician to the British War Office sponsored a series of clinical and laboratory trials in military personnel. A report of their findings has recently been published.²

Patulin was found to be highly toxic for mice, more so when given subcutaneously or intraperitoneally than when injected intravenously. In rabbits, solutions of patulin, unless extremely dilute, produced local reactions in the cornea and in the skin. Small amounts, injected intra-allantoically, resulted in the death of chick embryos. In therapeutic experiments in mice it was shown to have no effect on influenza A virus infections. In mice treated with patulin and infected with typhoid

largest ulcer was on the noncoronary aortic cusp and measured 1 cm. in diameter. Microscopic sections of these lesions showed an active valvulitis, with endothelial destruction. The character and disposition of the reacting cells within the leaflet were those of rheumatic valvulitis. No bacteria could be found in the overlying thrombus. The right ventricular wall was 9 mm. in thickness, which is about twice the normal size; the left ventricular wall measured 23 mm. There was no increase in pericardial fluid.

There was no pleural fluid, and no ascites. The liver, however, showed chronic passive congestion with a mild central necrosis. The lungs weighed almost 2000 gm. and were dark, firm and meaty. Microscopically they showed the changes that we associate with increased pressure in the pulmonary circulation. They were, however, not so pronounced as those described by Parker and Weiss* in cases

*Parker, F., Jr., and Weiss, S. Nature and significance of structural changes in lungs in mitral stenosis. *Am. J. Path.* 12:573-598, 1936.

of severe mitral stenosis. Each alveolar wall showed many more capillary cross-sections than normal, and these capillaries were often dilated to several times the diameter of a red cell. Furthermore, many alveolar walls showed pericapillary edema, which compressed the capillaries. I believe that this is important for, in mitral stenosis, if pericapillary edema is present, gaseous exchange must be hindered. At a later stage in the process some alveolar walls were thickened by a deposit of collagen fibrils, associated with capillary narrowing. In the alveolar spaces there was extensive recent and old hemorrhage, the evidence for the latter being the presence of large numbers of hemosiderin-laden phagocytes. Intra-alveolar edema was slight and scattered. The large and small pulmonary arteries showed sclerosis, but it was not severe.

No Aschoff bodies were found in the myocardium, but unfortunately not enough material was studied to answer the question whether an active myocarditis was present.

The Blue Shield is accomplishing two main objectives: with a service contract for low-income subscribers, it goes farther in the direction of complete protection for serious illness involving surgery than even federal planners and social economists have demanded; and because its policies are controlled and guided by the medical profession itself, the Blue Shield satisfies the demand by doctors that their profession not be dictated to by politicians or outsiders. The reconciliation of these two widely separated aims is difficult. The Blue Shield may properly take pride in the relatively small amount of friction and misunderstanding that have accompanied this complicated task.

Commercial insurance offers cash indemnity, which does not solve the problem for the low-income group. Federal plans, which may aim at satisfying the poor man's need, would accomplish this worthy end through methods that would, in the opinion of most physicians, stultify the medical profession with bureaucracy and federal regulations. The Blue Shield may well be the only possible solution that is tailored both to provide adequate protection for the low-income group and to maintain the highest standards of the medical profession, while preserving the physician's cherished philosophy of freedom of action. It must be reasonably expected that such an enterprise will have its quota of "headaches" and will involve a certain amount of what might be called "postoperative complications."

In 1943 and 1944, Blue Shield payments for surgery, assisting and aftercare, anesthesia and x-rays averaged about \$70 per case. Advisory committees in the various specialties are making continuous progress toward reconciling the differences in opinions regarding certain fees, and in eliminating inconsistencies. Participating physicians are beginning to speak up for the plan, to recommend it for the consideration of influential employers with whom they are acquainted and to distribute Blue Shield pamphlets in their waiting rooms. An average of about five doctors are becoming participating physicians every working day. All this seems to forecast a bright future for the Blue Shield. But, as the December issue of *Fortune* opined in its article "United States Medicine in Transition," if the voluntary or noncompulsory way is to solve the nation's health problem, the following two conditions will have to be met: the country must be prosperous with reasonably full employment, so that people will be able to pay their own contributions without government help; and the government at all levels, employers, the great mass of potential patients and, above all, the medical profession must show a degree of social inventiveness and a determination hitherto unknown.

Physicians cannot afford to be perfectionists in this matter. The Blue Shield is a practical plan, in being, which is becoming more successful each day. It is in a better position now than ever before

to make a new advance toward a better solution. The Blue Shield deserves the united support of the medical profession in Massachusetts.

DEATHS

BRAY — Thomas A. Bray, M.D., of Holliston, died April 1. He was in his fifty-first year.

Dr. Bray received his degree from Georgetown University School of Medicine, Washington, D. C., in 1922. He maintained a general practice in Worcester six years and then entered the New York Eye and Ear Infirmary, where he studied diseases of the eye, ear, nose and throat two years. He returned to Worcester, practicing his specialty and becoming a member of the staff of St. Vincent Hospital. He moved to Holliston in 1944 and was on the staffs of the Framingham Union and Milford hospitals.

His mother, his widow, three sons, one daughter, a brother and five sisters survive.

CASSELBERRY — Clarence M. Casselberry, M.D., of Newton, died February 25. He was in his seventieth year.

Dr. Casselberry received his degree from the University of Pennsylvania School of Medicine in 1897. He was a fellow of the American Medical Association.

His widow survives.

GOOKIN — Edward R. Gookin, M.D., of Washington, D. C., died recently. He was in his sixty-fourth year.

Dr. Gookin received his degree from Baltimore Medical College in 1906. He was a fellow of the American Medical Association.

A sister survives.

GREENE — Jeremiah A. Greene, M.D., of Cambridge, died April 6. He was in his sixtieth year.

Dr. Greene received his degree from Harvard Medical School in 1913. In 1938 he was appointed associate medical examiner for Middlesex County by Governor Charles F. Hurley. He was a member of the Cambridge Medical Improvement Society and the Massachusetts Medico-Legal Society.

His widow, two sons and two daughters survive.

HOPKINS — William T. Hopkins, M.D., of Lynn, died April 10. He was in his seventy-seventh year.

Dr. Hopkins received his degree from Boston University School of Medicine in 1890. He was formerly Lynn health commissioner. He retired seven years ago after practicing in Lynn for more than fifty years. He was a fellow of the American Medical Association.

His widow, four sons and a brother survive.

NOYES — Nathaniel K. Noyes, M.D., of Plymouth, died April 12. He was in his eighty-first year.

Dr. Noyes received his degree from Dartmouth Medical School in 1890. During World War I, he was a captain in the Army Medical Corps. He was health-board physician in Duxbury from 1895 to 1925. He served as visiting physician at the Jordan Hospital, Plymouth, from 1915 to 1925 and as associate medical examiner of the Third Plymouth District for three terms. He was a fellow of the American Medical Association and a member of the Massachusetts Association of Health Boards and the Massachusetts Medico-Legal Society.

His widow, a son, two daughters and a brother survive.

YOUNG — Edward L. Young, III, M.D., of Brookline, was killed in action on March 24 in Germany. He was in his thirty-first year.

Dr. Young received his degree from Harvard Medical School in 1941. He entered the service in May, 1943, after serving his internship at the Massachusetts General Hospital. He went overseas in March, 1944, and was serving at a field hospital in the front lines.

His father, his widow, a daughter and a sister survive.

bacilli the death rate was higher during the first two days after injection than in controls that received no patulin. The controlled clinical trials in the treatment of the common cold with patulin showed no advantage from its use as compared with that of a buffer solution without patulin.

These investigators emphasized the great difficulty in assessing the effect of any treatment in the common cold in view of the lack of objective signs that can serve as a check on subjective findings. They attempted to eliminate bias during treatment and in evaluating the results. Neither the investigators nor the patients knew which type of treatment was used, patulin or control. All the results were obtained before an analysis was attempted. The main trial was carried out in 100 men at a recruiting establishment during the season of autumn colds. Half the men were treated with patulin, and the others with the control buffer solution that served as the vehicle for the patulin. The two groups were comparable with respect to age, severity of symptoms, duration before and after treatment and bacteriologic findings. No dramatic effects were observed in either group. The patulin solutions used in the final trials were tested for bacteriostatic action nine weeks after their preparation and after the trials had been concluded. They retained their full activity as compared with fresh solutions. It was concluded that patulin had no demonstrable effect on the course of this series of colds.

When the preliminary results of these trials became known, the British Medical Research Council undertook an extensive investigation of the contradictory claims.³ A study was carried out in several large factories and post-office units widely scattered throughout England. In these studies the test solutions were used as nose drops, but in two additional trials in public schools the solutions were also used as sprays. These clinical trials were supervised by local medical officers, and all the subjects were volunteers. Attempts were made to exclude cases of hay fever and chronic respiratory disease, and a uniform record system was used. In order to reduce the chances of guessing, four different solutions were used in each establishment, two of them containing patulin and the other two containing

only the buffer solution. The solutions were freshly made, being used before they were three days old. The results in 1348 cases were available for analysis. Of these, 668 were treated with patulin, and 680 with control solutions. No significant differences were found among the separate units. There was an almost identical percentage of cures at different intervals after the treatment was begun in those who received patulin and in those who were given the control buffer solution. This was true irrespective of the duration of illness at the time when treatment was started. From these studies, therefore, no evidence was found to indicate that patulin is effective in the treatment of the common cold.

It is only fair to point out that these results were obtained with a substance that is relatively toxic when applied locally. It may still be possible that other antibiotics that are both more effective against bacterial infections and more innocuous to tissues will prove helpful in the treatment of the common cold and reduce the chances for the establishment of secondary bacterial complications. On the whole, however, most of the experiences thus far with the topical use of sulfonamides or penicillin in mixed infections have not been too encouraging.

MASSACHUSETTS MEDICAL SOCIETY

The Blue Shield, now in its twenty-seventh month of operation, is beginning to make significant gains. The plan has added more new members in the past six months than it acquired in the first eighteen months of business. With nearly 125,000 members and 4000 participating physicians, it would seem that the Blue Shield has established itself as a definite part of the medicoeconomic structure.

Perceiving that the Doctor had no disrelish for my freedom, I ventured a step further, and said: "Doctor, there have been and still are among the people, especially among the more ignorant, many fanciful conceits and absurd notions received by time-honored tradition and confidently relied on as helps or hindrances to a cure, and sometimes a wise prescription might contradict the delusion and disturb, if not destroy the confidence of the patient in the skill of his physician. How far may such delusions be honestly humored? How would you avoid disturbing the patient's confidence?"

The wary Doctor was at no loss for a reply, and ignoring all metaphysics, proceeded at once to illustrate the matter by relating an occurrence in his own early practice. I wish I could tell you the story just as he told it to me, but you know how impossible it is to put on paper flexible tones and looks, so often the very soul of utterance. However, you knew the Doctor too long and intimately not to remember well the imposing gravity he could assume in relating what was either facetious or ridiculous. The story as nearly as I can give it in lonesome black and white is the following:

Not long after I began to practice medicine in Leicester, a well-meaning man, the owner of a few acres and little or nothing else, called on me early in the spring of the year for professional relief. He complained in a forlorn way that he was ailing and felt very weak. He said he was afraid he should not be able to do his spring work himself, and that he was too poor to hire anybody to do it for him. With a pitiful look he desired me to do something for him if possible, that he might get better and he able to go to work in season for planting time. After a little examination and a few inquiries I thought I saw his case, and directed him to get some wild cherrytree bark, make a decoction of it, and take so much, so often daily in spirit. He listened intently to all I said, and when I ended my prescription he said with a look of eager honesty, "Doctor, shall I strip the bark up or down?" the belief being then, and having long been common, that if the bark was stripped up from the tree, the medicine would work up, and if stripped down, it would work down. I replied, "In your complaint it is not of the least importance whatever whether you strip it up or down but don't you strip it sideways for the world! If you do it will work right between your ribs!" The poor man cheered up, got better, did his spring work, and in due season gathered in the fruits of his own honest labor.

BOOK REVIEWS

Artificial Pneumothorax in Pulmonary Tuberculosis: Including its relationship to the broader aspects of collapse therapy. By P. N. Rafferty, M.D. With an introduction by Henry S. Willis, M.D. 8°, cloth, 192 pp., with 26 illustrations and 14 tables. New York: Grune and Stratton, 1944. \$4.00.

Artificial pneumothorax therapy for pulmonary tuberculosis came during the early twenties of this century like a gust of fresh air on a hot and parched summer's afternoon. For years, the world had been waiting hopefully for that elusive cure of the then greatest killer of men — pulmonary tuberculosis. In a period of a few years, it was hailed as an important advance in the control and alleviation of tuberculosis, and the acceptance of this form of therapy was greatly hastened because of the simplicity of administering it and the fact that all sanatoriums could make full use of it. Gradually, however, complications began to ensue and late results came to plague both the physician and the patient, and recently certain authorities have criticized this method of treatment. Thus, many phthisiologists became bewildered and did not know where to turn. It is therefore doubly welcome that Dr. Rafferty has penned this book and has shown them a way out.

In the eighteen chapters, the author has included not only his own experiences but also those of all the major clinics in this country. He knows the limitations of pneumothorax therapy but also understands its benefits. First, he is of the opinion that primary thoracoplasty has its place and should not necessarily follow pneumothorax therapy. He deprecates the use of pneumothorax therapy in extensive disease, in apical cavities and in bronchial involvement. He urges a trial of pneumothorax therapy for a few weeks and its aban-

donment if unsuccessful, especially if many adhesions prevent relaxation of the lung and pneumonolysis is not feasible. He is particularly emphatic on early re-expansion in cases of empyema and bronchial fistula. His discussion on tension cavity is scholarly. He has purposely left out many of the small details, and he deals more with effective and ineffective pneumothorax therapy, pneumothorax with phrenic paralysis, the prevention of complications and so forth.

This small book is written in an excellent style and should be read by all interested in the treatment of pulmonary tuberculosis.

Secretory Mechanism of the Digestive Glands. By B. P. Babkin, M.D., D.Sc., LL.D. 8°, cloth, 900 pp., with 220 illustrations. New York: Paul B. Hoeber, Incorporated, 1944. \$12.75.

Dr. Babkin, who is research professor of physiology at McGill University, Montreal, and former professor of physiology at the University of Odessa, has written a valuable, up-to-date account of the experimental analysis of the secretory function of the digestive glands in carnivorous animals and man. The author writes easily and clearly. Throughout the book he rightly emphasizes the fact that it is only by a combined morphologic and physiologic approach that an understanding of the complicated phenomena of bodily function can be reached. Theories are interestingly presented but merely to serve as guides to facilitate further progress of the problems discussed. The mechanisms involved in the regulation of the secretory activity of the principal digestive glands are critically reviewed historically and then brought to the point where the author indicates the problems that await further investigation. An excellent bibliography covers eighty-five pages, and there is a good index.

This book should serve well the clinician who is charged with the clear understanding and the investigation of the diseases of the secretory apparatus of the alimentary canal.

The Radiology of Bones and Joints. By James F. Brailsford, M.D., Ph.D., F.R.C.P., F.I.C.S. Third edition. 8°, cloth. 440 pp., with 404 illustrations. Baltimore: Williams and Wilkins Company, 1944. \$12.00.

In the third edition of this important roentgenologic treatise the author has attempted to add new information and "bridge the gaps" that were present in previous editions. The four years of war have added to the author's difficulties in gathering data concerning patients. In spite of the difficulties, a most creditable volume has been published. The only adverse change is a poorer grade of paper and a more condensed arrangement of the printed material. The roentgenologic discussion is divided according to anatomic location. This is probably as good a division as can be made considering the varied nature of the lesions described, but it occasionally makes dull reading. The varied picture of injury and disease shown in x-ray films is fully described. There are many helpful sketches, as well as numerous excellent photographs of the roentgenograms. A number of excellent teaching outlines list the diseases that frequently produce a certain type of change in bones in the various areas of the body. There are many references to the recent orthopedic literature.

This book represents twenty-five years of experience of one of the leading roentgenologists of England, and it can be recommended as an authoritative treatise on the roentgenologic aspects of lesions of the bones and joints. It should prove to be a most helpful reference book for both roentgenologists and orthopedic surgeons.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Foundations of Neuropsychiatry. By Stanley Cobb, M.D., Bullard Professor of Neuropathology, Harvard Medical School, and psychiatrist-in-chief, Massachusetts General Hospital. Third edition, revised and enlarged, of the work

*Made reportable December, 1943.

†Pfeiffer-bacillus meningitis only other form reportable previous to 1941.

COMMENT

Anterior poliomyelitis thus far this year has been at the highest point since 1932. The March total exceeded any since 1928.

Diphtheria, although well above the seven-year median, is running lower this year than last.

Meningococcal meningitis during the first quarter of 1945 was consistently below that of the corresponding three months of the last two years.

None of the relatively large number of cases of malaria reported in March originated in Massachusetts. They occurred in returned members of the armed forces.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Cambridge, 1; Framingham, 1; Longmeadow, 1; Lynn, 1; Springfield, 1; total, 5.

Diphtheria was reported from: Boston, 3; Cambridge, 2; Framingham, 1; Hanson, 1; Lowell, 4; New Bedford, 2; Reading, 1; Somerville, 2; Taunton, 3; Wareham, 1; Winchester, 1; Worcester, 1; total, 22.

Dysentery, amebic, was reported from: Waltham Regional Hospital, 1; total, 1.

Dysentery, bacillary, was reported from: Boston, 1; Lawrence, 2; Northampton, 1; total, 4.

Encephalitis, infectious, was reported from: Brockton, 1; Chelmsford, 1; Everett, 1; Lexington, 1; Medford, 1; Quincy, 1; Weymouth, 1; total, 7.

Malaria was reported from: Boston, 1; Camp Edwards, 43; Cushing General Hospital, 11; Haverhill, 1; Lynn, 1; Melrose, 1; Natick, 1; Northampton, 2; Norwood, 1; Waltham Regional Hospital, 11; Waltham, 1; Winchester, 1; Worcester, 1; total, 76.

Meningitis, meningococcal, was reported from: Beverly, 1; Boston, 6; Chelmsford, 1; Fall River, 2; Fitchburg, 1; Holyoke, 1; Milton, 1; New Bedford, 1; Newton, 1; Palmer, 1; Plymouth, 1; Quincy, 1; Southboro, 1; Worcester, 3; total, 22.

Meningitis, Pfeiffer-bacillus, was reported from: Milford, 1; total, 1.

Meningitis, pneumococcal, was reported from: Amherst, 1; Lawrence, 1; Springfield, 1; Worcester, 2; total, 5.

Meningitis, undetermined, was reported from: Brockton, 1; Cambridge, 1; Springfield, 1; total, 3.

Salmonella infections were reported from: Beverly, 1; Boston, 1; Lynn, 1; Natick, 3; Revere, 2; total, 8.

Septic sore throat was reported from: Amesbury, 1; Arlington, 1; Boston, 9; Cambridge, 1; Fall River, 1; Lowell, 1; Medford, 1; Newton, 1; Quincy, 1; Salem, 1; Williamstown, 2; total, 20.

Trichinosis was reported from: Boston, 1; Douglas, 1; Haverhill, 1; Millbury, 1; Norton, 1; West Stockbridge, 2; total, 7.

Typhoid fever was reported from: Adams, 1; total, 1.

Undulant fever was reported from: Brookfield, 1; Northampton, 1; Northbridge, 1; Raynham, 1; Worcester, 1; total, 5.

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

Fall River	May 28	Eugene A. McCarthy

MISCELLANY

NOTE

Dr. Derek Denny-Brown, professor of neurology at Harvard Medical School and director of the Neurological Unit, Boston City Hospital, has been granted leave of absence by these institutions. He is to return to active military duty as a brigadier general with the British forces in India and South East Asia. In 1941, after two years of service in the field, he was temporarily released by the British Army to carry on research and teaching in the United States. He plans to resume his work in Boston at some later date.

CORRESPONDENCE

SPRING TONIC

To the Editor: The following anecdote written by the aged Rev. George Allen for Joseph A. Denny, of Leicester, Massachusetts, has recently come into my possession.

The Austin Flint referred to may have been a connection or even an ancestor of the two famous Austin Flints.

A. E. P. ROCKWELL, M.D.

Shrewsbury, Massachusetts

* * *

Joseph A. Denny, Esq.

Dear Sir:

Herewith I send the promised trifle. I prepared it soon after I last saw you, but knowing that if used at all, other matter must take precedence, I lay it aside to meet other calls of immediate claim; and you know out of sight is out of mind for some, especially an old man.

If you cannot decipher or guess at my hieroglyphics, perhaps I can tell what I meant, should you deem it important enough to trouble yourself about it.

Respectfully yours,

GEORGE ALLEN

Jan. 16, '74

* * *

In conversation with the late Doctor Austin Flint when he was not far from his ninetieth year, I remarked to him that he had passed almost the whole of his professional life in Leicester, and had had many and special opportunities for learning the ways and sentiments of all classes of the people. To these remarks the Doctor of course assented.

I next intimated with respectful deference my opinion that a patient's faith in the skill and practice of his physician is sometimes an effective auxiliary to mere medical treatment. To this he replied, "It is so in cases not a few."

PANCREATODUODENAL RESECTION*

A Preliminary Report of Eighteen Cases

RICHARD B. CATTELL, M.D.†

BOSTON

DURING the past decade a new field in abdominal surgery has been explored with the successful removal of the duodenum and pancreas for malignant tumors by a radical block pancreatoduodenal resection. Previously, all attempts to remove carcinomas in this area had been confined to local excisions of malignant tumors of the duodenum or ampulla of Vater, which, in the light of the present knowledge, could be considered little more than palliative resections, with a small chance for complete extirpation of the tumor. Furthermore, these excisions were frequently followed by serious complications, such as retroperitoneal sepsis, external and internal fistulas and strictures of the common bile duct and pancreatic duct. The radical removal of tumors at other sites, such as carcinomas of the breast, stomach, colon and rectum and uterus, has been proved conclusively to give the best results. If it can be demonstrated that the block type of resection (pancreatoduodenal resection) for malignant tumors in this region can be feasibly done with few complications and a low operative mortality, it may then be accepted and more widely applied. Experiences at the Lahey Clinic with 18 resections of this type are presented in the hope of furthering interest in these cases, which are usually considered hopeless.

HISTORY

Although Halsted¹ performed a local excision of carcinoma of the ampulla as early as 1898, and Mayo² resected a hyperfunctioning carcinoma of the pancreas in 1927, it remained for Whipple,³ in 1935, to focus interest on these cases when he and his associates reported a successful resection. Since that time Hunt⁴ has reported 4 cases, with a review of the literature, including both local and radical operations, Trimble⁵ has reported a successful one-

stage operation, and Harvey and Oughterson⁶ have reported 6 cases, not all of them radical. More recent reports by Brunschwig⁷ and Gray⁸ and previous reports by me⁹⁻¹¹ indicate a growing interest in the field. Approximately 100 operations that could be termed radical in the usual sense applied to the surgical treatment of malignant tumors have been performed.

GENERAL CONSIDERATIONS

From our experiences with these cases, approximately 30 per cent of malignant tumors causing jaundice as a primary symptom are suitable for resection. One of the most difficult problems in the management of such cases is that of establishing the diagnosis at operation when it has been suspected preoperatively. The clinical course of carcinoma of the pancreas and carcinoma of the ampulla is quite similar. As shown by Kiefer,^{12,13} the development of symptoms associated with carcinoma of the pancreas is slow, with jaundice developing somewhat late, with weight loss, anemia and cachexia appearing first. We have found that in patients with carcinoma of the ampulla, jaundice is the presenting symptom, with the general systemic effects following. Unless a palpable mass is present, the time of development of jaundice is the only clinical means of differentiating these two conditions. In the past the diagnosis of carcinoma of the pancreas has been made in all cases of painless jaundice, irrespective of the order of the development of the symptoms. In our experience, carcinoma of the ampulla is more frequent than carcinoma of the pancreas. Since jaundice develops late with cancer of the pancreas, many of these cases are unsuitable for resection, since metastases or local spread makes it impossible. The degree of malignancy is high in cancer of the pancreas and low in cancer of the ampulla, and it is our experience that most carcinomas of the ampulla are suitable for resection.

*Presented at the annual meeting of the New England Surgical Society, Boston, September 20, 1944.
†From the Department of Surgery, Lahey Clinic.
‡Surgeon, Lahey Clinic.

formerly known as *A Preface to Nervous Disease*. 8°, cloth, 252 pp., with 13 illustrations and 3 tables. Baltimore: Williams and Wilkins Company, 1944. \$2.50.

This standard text has been revised and enlarged to bring it into line with recent advances in the field of neuropsychiatry. New knowledge in the experimental field hitherto confined to animals has been tested on human beings with success. A new chapter has been added dealing with the psychopathologic concepts that are important in medicine.

The Trials and Triumphs of the Surgeon, and Other Literary Gems. By J. Chalmers Da Costa, M.D., LL.D. Edited by Frederick E. Keller, M.D. 8°, cloth, 401 pp. Philadelphia: Dorrance and Company, 1944. \$5.00.

Here for the first time are collected the minor writings of Dr. Da Costa, who was the Samuel D. Gross Professor of Surgery at Jefferson Medical College of Philadelphia from 1910 to 1930. The papers are mostly historical.

Gynecological and Obstetrical Urology. By Houston S. Everett, M.D., associate professor of gynecology, Johns Hopkins University, associate in gynecology, University of Maryland, assistant visiting gynecologist and gynecologist in charge of the Cystoscopic Clinic, Johns Hopkins Hospital, and visiting gynecologist, Church Home and Hospital, Hospital for the Women of Maryland and Union Memorial Hospital. 8°, cloth, 517 pp., with 220 illustrations. Baltimore: Williams and Wilkins Company, 1944. \$6.00.

This new textbook is based on the author's ten years' experience in the teaching of urology in the Department of Urology of Johns Hopkins University Medical School. It has been written for medical students, general practitioners, gynecologists and obstetricians, who may be confronted with urologic problems in their practice. Particular stress has been made on the general nature of urologic disease and its relation to general medicine and the other specialties.

A Textbook of Pathology: Pathologic anatomy in its relation to the causes, pathogenesis and clinical manifestations of disease. By Robert A. Moore, M.D., Edward Mallinckrodt Professor of Pathology, Washington University School of Medicine, Saint Louis. 8°, cloth, 1338 pp., with 513 illustrations. Philadelphia and London: W. B. Saunders Company, 1944. \$10.00.

This new textbook on pathology embodies a new departure in classification in which degeneration is approached by disturbances of metabolism rather than by anatomic types. In the section on special pathology, diseases with similar causes have been grouped together; and those diseases of which the causes are unknown or obscure have been considered according to the organ or the system in which they occur. Bacterial diseases have been classified according to the portal through which the bacterium enters the body and the source of bacterium. The work is well printed on good paper with a good type and copiously illustrated. There are extensive citations to the literature scattered throughout the text.

Taber's Dictionary of Gynecology and Obstetrics. By Clarence W. Taber, with the collaboration of Mario A. Castallo, M.D., assistant professor of obstetrics, Jefferson Medical College, gynecologist to St. Mary's and St. Agnes hospitals and obstetrician to St. Mary's Hospital. 16°, cloth, 700 pp., with illustrations. Philadelphia: F. A. Davis Company, 1944. \$3.50.

This is a specialized medical dictionary designed for all those interested in gynecology and obstetrics. No attempt has been made to supply a general vocabulary, but the selection of words has been limited to those dealing with the two principal subjects. Many of the definitions are encyclopedic in character, and some of the subjects are treated at considerable length. The unusual method of numbering the pages by sections, such as A-51, O-17, and so forth, is confusing and does not seem to possess any particular advantage over the usual system. The long section on the common infectious diseases of infancy and the emergencies in infancy and childhood seem to be out of place in this particular work.

Neurology of the Eye, Ear, Nose and Throat. By E. A. Spiegel, M.D., professor of experimental and applied neurology and head of the Department of Experimental Neurology, Temple

University School of Medicine; and I. Sommer, M.D., lecturer in ophthalmology, Long Island College of Medicine, and consultant ophthalmologist and otolaryngologist, Chicago Eye and Ear Hospital. 8°, cloth, 667 pp., with 118 illustrations. New York: Grune and Stratton, Incorporated, 1944. \$7.50.

This book is intended to cover the borderland between the field of neurology and the fields of otolaryngology and ophthalmology. The text is based on postgraduate lectures given within the last twenty-five years at the University of Vienna and at Temple University. The present publication has been based partly on the 1931 Berlin edition but has been completely rewritten. A bibliography of 1719 selected references is appended to the text. The book is well printed on good paper, with a good sight-saving type.

The Diagnosis and Treatment of Acute Medical Disorders. By Francis D. Murphy, M.D., professor of medicine and head of the department of medicine, Marquette University School of Medicine, and clinical director of the Milwaukee County General Hospital and Emergency Unit, Milwaukee. 8°, cloth, 503 pp., with illustrations. Philadelphia: F. A. Davis Company, 1944. \$6.00.

This book is intended for the general practitioner and the medical student and is based on an experience of more than twenty years at the Milwaukee County General Hospital.

Operations of General Surgery. By Thomas G. Orr, M.D., professor of surgery, University of Kansas School of Medicine, Kansas City, Kansas. 4°, cloth, 723 pp., with 1396 illustrations. Philadelphia: W. B. Saunders Company, 1944. \$10.00.

In this new text on general operative surgery, illustrations have been emphasized and the text has been purposely made as brief as is consistent with a step-by-step description of each operation. The chapters have been arranged, in so far as possible, according to the systems of the body or under special headings, such as plastic and neurologic surgery, urology and gynecology. Chapters on wound healing and on the treatment of fresh wounds have been included.

NOTICES

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MAY 10

FRIDAY, MAY 11

- *9:00-10:00 a.m. Carcinoma of the Prostate. Dr. William C. Quimby. Joseph H. Pratt Diagnostic Hospital.
- *9:00-10:00 a.m. Medical clinic. Isolation Amphitheater, Children's Hospital.
- 10:50 a.m. X-ray Diagnosis of Syphilis. Dr. Max Ritvo. (Post-graduate clinic in dermatology and syphilology.) Amphitheater, Mallory Building, Boston City Hospital.
- 12:00 m.-1:00 p.m. Clinicopathological conference (Boston Floating Hospital). Joseph H. Pratt Diagnostic Hospital.

SATURDAY, MAY 12

- *10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, MAY 14

- *12:00 m.-1:00 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY, MAY 15

- *9:00-10:00 a.m. Clinicopathological conference. Drs. Chester S. Keefer and H. F. MacMahon. Joseph H. Pratt Diagnostic Hospital.
- *9:00-10:00 a.m. Medical clinic. Infants' Hospital.
- *12:15-1:15 p.m. Clinicorontgenological conference. Peter Bent Brigham Hospital.

WEDNESDAY, MAY 16

- *9:00-10:00 a.m. Endocrine Problems in Childhood. Dr. Richard Wagner. Joseph H. Pratt Diagnostic Hospital.
- *12:00 m. Clinicopathological conference. Children's Hospital.

*Open to the medical profession.

(Notices continued on page xvii)

the gastrointestinal or the biliary tract. Extension of the tumor makes resection inadvisable. If the superior mesenteric vessels are found to be involved and cannot be freed, this can be determined early in the dissection. If these are freed, the portal vein is then exposed and a finger is placed under the neck of the pancreas to be sure that it can be detached. If the case is deemed inoperable, some benefit may follow ligation of the gastroduodenal artery and inferior pancreaticoduodenal artery in continuity. In a patient with complete obstruction of the duct of Wirsung we were able to do a side-to-side anastomosis in continuity between the dilated duct

creatoduodenal area should be avoided if possible in this stage. I recommend that a cholecystjejunostomy be done 30 to 45 cm. from the ligament of Treitz, and accompanied by jejunojejunostomy 15 or 20 cm. proximal to the cholecystjejunostomy. The enteroenterostomy defunctionalizes the loop of jejunum used for the biliary anastomosis, and at the second stage the pancreatojejunal anastomosis can be made in the afferent loop distal to the jejunojejunostomy. This biliary anastomosis is simple to perform, and if the omentum is drawn down over it the field for the pancreaticoduodenal resection will be uncomplicated by adhesions at the second stage.

FIGURE 2. *A Technical Method of Avoiding External Pancreatic Fistula.*

a — the serosal and muscular layers of the jejunum have been incised, the incised pancreas has been closed, and the pancreatic duct has been ligated; b — the serosa and muscularis have been spread, and the pancreatic duct has been transfixed by a silk suture; c — the posterior surface of the pancreas has been joined to the lateral wall of the jejunum, and the transfixing silk suture now transfixes the mucosa of the jejunum; and d — the pancreatojejunal anastomosis is completed by the anterior suture line. (Reproduced from Cattell⁹ with permission of the publisher.)

and the jejunum, with considerable temporary improvement in the patient's condition.

There is as yet no unanimity of opinion relative to the employment of the one-stage versus the two-stage operation for these cases. In my opinion, the two-stage operation should be employed if jaundice is severe, with the bilirubin over 5 mg. per 100 cc., if the liver function is shown to be low by liver-function tests or if the patient's general condition is poor. Since jaundice is usually the presenting symptom, many of these cases can be done in two stages with less risk. If the two-stage operation is chosen, the first stage should consist solely of an anastomosis of the biliary tract to the intestine. Any exploration of the common duct or of the pan-

There is little question that the patient will be much improved after the first stage and that a definite lowering of operative risk will result. The magnitude of the second stage is little affected by the first-stage operation, since the only difference between the second stage and the one-stage resection is that the common duct is closed off rather than used as a choledochojejunostomy.

TECHNIC

The technic of pancreaticoduodenal resection will not be presented in this paper, but the order of procedure will be briefly summarized.

The duodenum and pancreas are elevated by division of the peritoneum, carrying the dissection

There may be considerable difficulty in proving the presence of cancer at the time of operation. Biopsies of the pancreas when taken as deeply as possible from a pancreatic mass obviously cancerous are frequently negative. Tumors of the ampulla are usually small, being 1 to 2 cm. in diameter even three to six months after they have produced obstruction of the common bile duct, and are difficult to palpate through the head of the pancreas or duodenum. The head of the pancreas frequently has extensions and divisions, due to its racemose character, that on palpation may be confused with tumor. We have explored 3 cases at a second stage, in which a tumor was palpated at the first stage, without finding a tumor, and one resection carried out in a fourth patient with a palpable tumor but cancer could not be demonstrated microscopically. It is important to emphasize the difficulties of establishing the diagnosis at operation, and it is necessary in many cases to do the radical operation without the benefit of a positive biopsy. If cancer is shown by biopsy to be present in the gastrohepatic or gastrocolic ligaments, the radical operation may not be justified. A positive diagnosis can be established by transduodenal exploration of the ampulla, since cancerous tissue can readily be procured. Dilatation of the common duct has been present in all our cases in which cancer was proved. The 3 patients who had an exploratory second stage with the possibility of resection did not have dilated common ducts. In cases in which malignancy cannot be proved, unless dilatation of the common duct is present, resection should not be done. It has been our experience in patients with carcinoma of the ampulla that biopsy is unnecessary, since the projecting tumor can usually be palpated through the duodenal wall.

GENERAL OPERATIVE PLAN

Pancreatoduodenal resection is a formidable operative procedure (Fig. 1) that is time-consuming and difficult, and good operating conditions are essential. We prefer fractional spinal anesthesia, using pontocaine weighted with glucose, with 40 to 50 mg. of the drug in divided doses of 15, 10, 10 and 10 mg., since the operation may take two and a half to four and a half hours. Two transfusions are usually given during the procedure.

The major operative problems are the control of the blood supply as it enters the general field by ligating large vessels and the interruption and restoration of continuity of the gastrointestinal tract, the biliary tract and the pancreas. In the earlier reported cases it was considered unnecessary to restore the pancreatic juice to the intestine, and several successful cases were reported in which no external pancreatic fistula developed and no spontaneous internal fistula could be proved, and in which good health was maintained in spite of its loss. It is our opinion, however, that many of the

complications following pancreatoduodenal resection are related to internal or external pancreatic fistulas in spite of ligation of the pancreas and its duct.

FIGURE 1. The Completed One-Stage Pancreatoduodenal Resection.

All anastomoses are antecolic. a — end-to-end gastrojejunostomy; b — end-to-side pancreatojejunostomy; c — end-to-side choledochojejunostomy; and d — jejunojejunostomy. (Reproduced from Cattell¹ with permission of the publisher.)

This was true in our first case, in which digestion of the stump of the gastroduodenal artery resulted in hemorrhage. Similarly, a longer convalescence may result and retroperitoneal sepsis is likelier to follow. I have previously described a technic of anastomosis of the duct of Wirsung to the jejunum to avoid pancreatic fistula (Fig. 2). The re-establishment of the biliary tract is not difficult, and in the one-stage operation the common duct is anastomosed to the jejunum, whereas in the two-stage operation a cholecystjejunostomy is performed at the first stage. The third or fourth portion of the duodenum has been reported as used for both the pancreatic and biliary anastomoses, but we have utilized a long loop of jejunum for this purpose. It is preferable to use a defunctionalized loop of jejunum, which can be accomplished by side-to-side jejunojejunostomy or by utilizing the Roux principle as described by Whipple.³ Jejunojejunostomy is unnecessary if the stomach is joined to the efferent jejunum below the pancreatic and biliary anastomoses.

OPERATION

The first step of operation is to establish the diagnosis by the means outlined earlier in this paper, following which operability is determined. If the patient's condition justifies a one-stage operation, a dissection of the entire field can be carried out with good mobilization without dividing either

ampulla. In addition, 3 patients were explored at the second stage; after freeing of the pancreas no tumor was found, and the operation was discontinued.

The first patient was operated on in August, 1939, and the remainder have been operated on since August, 1942. During the two-year period from August, 1942, to August, 1944, 51 patients with carcinoma of the pancreatoduodenal region have been observed, with 24 having no operation or having exploration, drainage of the common duct or cholecystjejunostomy performed for palliation only.

was found. Weight loss was a conspicuous symptom, with only 2 patients having none. The average weight loss was 20 pounds, and 1 patient lost 42 pounds in six months. Anorexia, weakness, malaise, diarrhea, mushy stools, pruritus and indigestion were frequent later symptoms. One patient had severe epigastric pain, with deep jaundice, but at the time of operation was found to have gallstones and carcinoma of the ampulla.

The laboratory findings were similar to those of other abdominal cancers. The blood bilirubin was consistently elevated, varying from 1.6 to 21.4 mg.

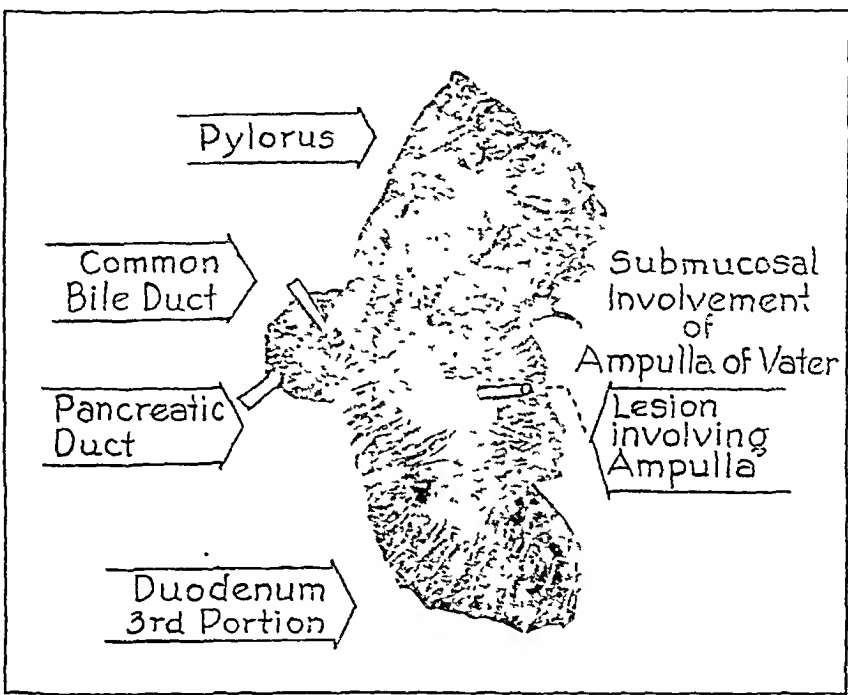

FIGURE 4. *The Mucosal Surface of a Pancreatoduodenal Resection*
The circumscribed adenocarcinoma projects through the duodenal wall.

Seventeen patients were submitted to radical resection during this period, and in an additional 10 the second stage was planned but not done.

Comprising these 18 cases in which operation was performed, there were 13 men and 5 women. Two patients were between forty and forty-nine years old, 8 between fifty and fifty-nine, 6 between sixty and sixty-nine, and 2 over seventy. One of the patients explored at the second stage with no tumor being found was only twenty-seven years of age, with the age incidence in this series cancer seems unlikely to occur at such an early age.

Four patients had had symptoms for less than one month, 6 for one to three months, 4 for three to six months, and 1 for six to twelve months. Three had had symptoms for over a year.

The presenting symptom in 16 cases was jaundice, and in 2 other patients anemia of unexplained origin

per 100 cc. The 2 patients without clinical jaundice had a bilirubin of 1.6 and 1.9 mg., respectively. The prothrombin time was little affected

Preoperative Diagnosis

The diagnosis of stones in the common duct was made in 4 cases, cancer of the stomach in 1, retroperitoneal sarcoma in 1, in which there was no jaundice, and cirrhosis of the liver in 1. Six patients were operated on with a diagnosis of carcinoma of the pancreas, and a diagnosis of carcinoma of the ampulla was made in 8. Two diagnoses were made in 3 cases, so that twenty-one diagnoses are listed for the 18 cases. Common-duct stone and cancer of the pancreas were diagnosed in 1 case, carcinoma of the ampulla and cirrhosis of the liver in 1, and common-duct stone and carcinoma of the ampulla in 1.

under the superior mesenteric vessels. The two anterior layers of the gastroduodenal omentum are then divided, freeing the distal third of the greater curvature of the stomach. The gastrohepatic ligament is next divided, with ligation of the right gastric artery. Following this, the common duct is elevated and the portal vein demonstrated to be free under the pancreas. To determine this, it may be necessary to ligate and divide the gastroduodenal artery at the upper border of the pancreas. If resection is then shown to be feasible, the prepyloric area of the stomach is divided between clamps. Careful

The resection is completed by dissection of the uncinate process, and the entire block is removed in one piece.

The reconstruction is done in the following order. The pancreas is closed by mattress sutures, and a transfixion silk suture is passed through the duct of Wirsung proximal to the tie.⁹ The pancreatojejunal anastomosis is then completed, utilizing the afferent loop of jejunum. In the one-stage procedure, anastomosis of the common duct is done 5 cm distal to the pancreatojejunal anastomosis over a tube, following which an end-to-end gastrojeju-

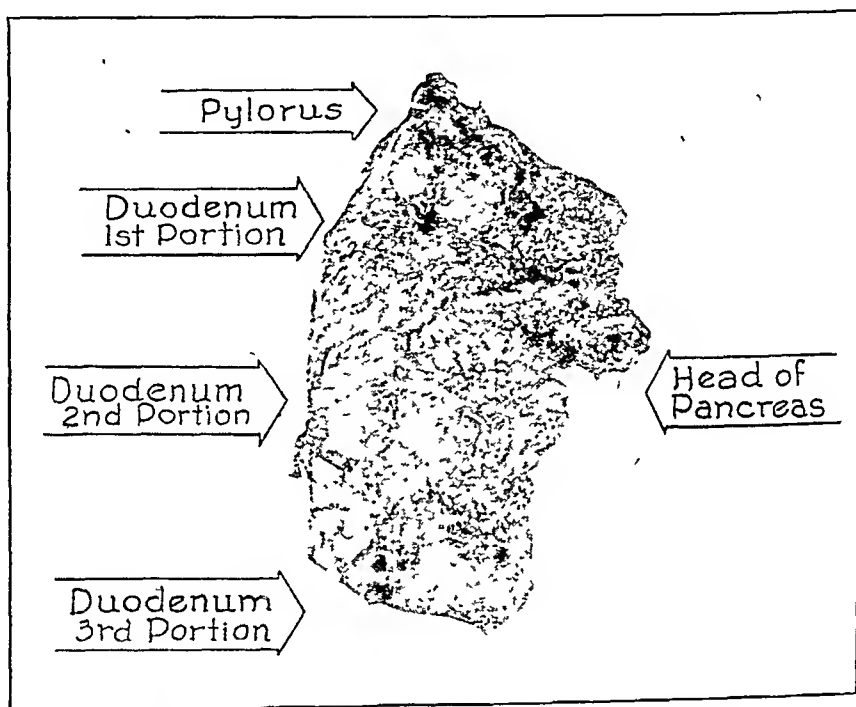

FIGURE 3. *The Serosal Surface of a Pancreatoduodenal Resection.*

dissection of the common duct must be done, and if a previous stage of cholecystjejunostomy has been performed, the common duct must be divided well below the entrance of the cystic duct. If there is any doubt of the patency of the cystic duct when the common duct is turned in, it must be reopened and implanted in the jejunum, leaving two biliary anastomoses. The pancreas is then elevated, with division at the neck if there is carcinoma of the ampulla and through the body if there is carcinoma of the head of the pancreas, followed by ligation of the duct of Wirsung. The junction of the third and fourth portions of the duodenum is severed in carcinoma of the ampulla, but in carcinoma of the head of the pancreas the jejunum is sectioned 5 cm. below the ligament of Treitz and the upper jejunum and fourth portion of the duodenum are withdrawn under the superior mesenteric vessels.

nostomy is carried out. If the latter is done to the efferent loop of jejunum, it is an end-to-side anastomosis and no enteroenterostomy is necessary, but if it is done proximally, it should be followed by the jejunojejunostomy.

CLINICAL MATERIAL

Eighteen patients have been submitted to pancreatoduodenal resection. Ten additional patients had a first-stage operation, with a second operation planned. One refused the second procedure, 1 was considered to be in too poor condition to withstand it, in 1 case operation was discontinued because of vessels resembling hemangioma throughout the operative field, 2 patients were found to be inoperable because of metastases, 1 had involvement of the superior mesenteric vessels, and 1 had a benign tumor that could be removed from the

THE CARDINAL MANIFESTATIONS OF PAROXYSMAL TACHYCARDIA*

II. Vascular Collapse

LOUIS WOLFF, M.D.†

BOSTON

VASCULAR collapse is frequently associated with paroxysmal tachycardia. The medical literature consists for the most part of single case reports and reveals that whereas in some cases collapse is associated with rapid ventricular rates, in others it is absent with equally rapid rates.¹⁻¹⁵ ¹⁶ have observed vascular collapse in 15 of 125 cases of tachycardia, and have pointed out that it occurred only under specific conditions, thus justifying its designation as one of the cardinal manifestations of paroxysmal tachycardia. In the present study 128 new cases have been added to the 125 previously reported, making a total of 253. All cases, had an electrocardiogram confirming the presence of an abnormal rhythm and providing the ventricular rate during the paroxysm. To evaluate the role of tachycardia in the genesis of vascular collapse, cases in which circulatory failure was ap-

or more in 18 cases, 180 to 199 in 9, 170 to 179 in 5 and less than 150 in 4 cases. There were no signs of organic heart disease in 12 patients, 2 of whom

parent before the onset of paroxysmal tachycardia were excluded. This study accordingly concerns the 40 patients (16 per cent) in whom vascular collapse complicated paroxysmal tachycardia, and 21 in whom vascular collapse did not occur despite extremely rapid heart rates. This larger series has confirmed the previous conclusions and has furnished additional facts of clinical interest and importance.

VASCULAR COLLAPSE

The ages in the 40 cases ranged from thirteen to eighty-eight years, with 4 cases in the fourth decade, 7 in the fifth, 9 in the sixth, 14 in the seventh and 4 in the eighth decade. Paroxysmal auricular tachycardia and paroxysmal auricular fibrillation were each present in 13 cases (33 per cent), and paroxysmal auricular flutter and paroxysmal ventricular tachycardia each in 7 cases (18 per cent). The ventricular rate ranged from 130 to 233, but was less than 180 in only 13 cases. The rate was 200

had hyperthyroidism; the ventricular rate in these cases was 200 or more in 6, 180 to 189 in 3, 170 to 179 in 2 and 140 in 1. It is noteworthy in itself that 12 of the 40 patients had normal hearts, but even more revealing is the fact that the ventricular rates were not significantly slower in the 28 patients with organic heart disease than in those with structurally normal hearts. Vascular collapse and paroxysmal tachycardia were noted in 9 cases with acute or recent myocardial infarction, the collapse and tachycardia occurring later than the tenth day in 7 of them: the ventricular rate was 200 or more in 3, 180 in 2, 170 to 179 in 2 and 160 and 145, respectively, in 2 cases. In 7 cases of coronary heart disease, with a past or present history of angina pectoris or old myocardial infarction or post-mortem evidence of coronary-artery disease, the rate was 200 or more in 3, 190 in 1, 187 in 2 and 160 in 1. There were 6 cases of mitral stenosis (1 with coro-

nary heart disease), and the ventricular rates were 200 or more in 4, 187 in 1 and 140 in 1. A case of subacute bacterial endocarditis and dissecting mycotic aneurysm of the aortic valve had the slowest ventricular rate in the entire series, namely, 130. There were 2 cases of aortic and mitral valvular disease with ventricular rates of 170 and 200, re-

*From the Cardiac Clinic and Electrocardiographic Laboratory, Beth Israel Hospital.

†Instructor, Courses for Graduates, Harvard Medical School; associate visiting physician and chief of the Cardiac Clinic and Electrocardiographic Laboratory, Beth Israel Hospital.

Because of the painless jaundice in all but 1 of 15 cases, it is evident that the diagnosis of carcinoma of the pancreas, ampulla or biliary tract should have been made oftener.

Pathology

Thirteen of the 18 patients had carcinoma of the ampulla, although one of these was a carcinoid without metastasis; 3 had cancer of the pancreas; 1 had a large carcinoma of the second portion of the duodenum, and in 1 patient no cancer was found. This high preponderance of carcinoma of the ampulla in this series of 18 cases may give an incorrect idea of the incidence of malignancy in this area, since in many of the patients with carcinoma of the pancreas the process was too advanced for resection. In 1 case, resection was carried out, but without question some cancerous tissue was left. The fact that so few cases of carcinoma of the pancreas are suitable for resection makes us believe that the operation of pancreatoduodenal resection at present offers little hope for any case of extensive carcinoma of the head of the pancreas.

Operation

Five patients had a one-stage pancreatoduodenal resection, with 1 death. The two-stage operation, as described by me,⁹ was employed in 13, with 2 deaths. One patient had had a first-stage cholecystoduodenostomy performed elsewhere, and a second had had a two-stage operation elsewhere that was discontinued because of hemorrhage. These cases were of course listed under two-stage resections, although only one operation in each case was done by us.

The 3 deaths give an operative mortality of 17 per cent. The first patient operated on in 1939, died of hemorrhage. This occurred through an external pancreatic fistula and did not seem to be alarming in amount, but the patient succumbed two days later, on the seventeenth postoperative day. An autopsy did not reveal the site of bleeding, and no other cause for death could be determined; the death was listed as having been due to secondary hemorrhage. Because of reaction around the ligated stump of the gastroduodenal artery it was suspected that the hemorrhage had occurred from this source. The second death, in March, 1943, occurred from shock and anuria twenty-eight hours after operation. The third death, in May, 1943, occurred sixty-two days postoperatively. Autopsy showed pyelonephritis, with cortical abscesses, retroperitoneal sepsis and pericarditis.

Subsequent Results

These patients have been observed over too short a period of time to report late results. One patient has been well for two years, 5 for eighteen months, 4 for a year, and 3 are in good condition, having been operated on within the past year.

There have been 2 deaths subsequent to discharge from the hospital. The first of these patients had an extensive carcinoma of the duodenum with lymph-node metastases and died eight months postoperatively. The second had an extensive carcinoma of the pancreatic head, and at the time of operation it was thought that some cancerous tissue was left. Death followed in ten months from recurrence with generalized abdominal metastases.

Thirteen of the 18 patients are living and in good condition. One patient has had mild recurrent epigastric discomfort, and 2 have had transient attacks of chills and fever. None have had recurrent jaundice. All have maintained their nutrition.

SUMMARY

Eighteen pancreatoduodenal resections are reported, with 3 deaths, an operative mortality of 17 per cent. Clinical data are presented briefly.

The general plan of operative management is discussed. The one-stage operation was employed in 5 cases, and the two-stage operation in 13. Since many patients are over sixty years of age, have severe obstructive jaundice and are in poor condition, the two-stage operation is considered necessary in most cases. An antecolic long-loop cholecystojejunostomy is recommended, since it permits rehabilitation and does not complicate the resection. Restoration of the external pancreatic juice to the intestine is accomplished by direct anastomosis of the duct of Wirsung to the jejunum as a means of avoiding the serious complication accompanying pancreatic fistula, and in order that normal pancreatic and digestive function may be accomplished. Antecolic gastric, biliary and pancreatic anastomoses are advised.

Results for a period up to two years are reported, with satisfactory results in 13 of 18 patients.

Present experiences demonstrate that pancreatoduodenal resection for carcinoma can be successfully carried out.

189 in 8 and 190 to 199 in 2. The rate in 8 patients with normal hearts, including 2 cases of hyperthyroidism, was 200 or more in 6, 193 in 1 and 180 in 1. Paroxysmal tachycardia did not induce vascular collapse in 2 cases of acute myocardial infarction, 1 of which was further complicated by congestive failure; the ventricular rates were 188 and 187, respectively. The rates in 5 other cases of coronary heart disease — 1 of them with complicating hyperthyroidism — were 215, 190, 188, 187 and 180, respectively. In 3 cases of hypertensive heart disease the rate was 200, 200 and 180, respectively, and in a case of subacute bacterial endo-

at the faster ventricular rates, but promptly disappeared when the ventricular rates halved. Similarly, vascular collapse was not induced by paroxysmal auricular tachycardia at a rate of 150 in a patient with a normal heart, but promptly appeared a few days later with the onset of a second paroxysm at a rate of 186. The duration of the paroxysm and the type of cardiac mechanism do not appear in themselves to be decisive in provoking circulatory failure. The lesser incidence of paroxysmal auricular fibrillation and the correspondingly greater incidence of the other types of tachycardia in the cases with collapse than in the entire series are due to the fact

TABLE 5. *Data on Ten Cases of Congestive Heart Failure. Six with Vascular Collapse and Four without Vascular Collapse despite Ventricular Rates of 180 or More.*

carditis it was 200. Two patients with cardiac enlargement of undetermined etiology had ventricular rates of 187 and 214. Frank congestive failure was noted in 4 cases, and the rates were 215, 200, 200 and 187.

DISCUSSION

When vascular collapse is associated with paroxysmal tachycardia, the one factor invariably present is an extremely rapid ventricular rate. The critical rate level for the induction of collapse is in the vicinity of 200, which is consistent with the observations of Wiggers¹⁷ that the total cardiac output falls when the heart rate exceeds 180. That this is the only necessary factor is evident from the fact that collapse is induced by extreme rates in cases with normal hearts uncomplicated by severe infection, embolism, surgery and so forth. The importance of the rate is shown by 2 cases of paroxysmal auricular tachycardia with auricular rates of 233 and 214, respectively, and intermittent 2:1 auriculoventricular block; signs of circulatory failure were evident

that extremely rapid ventricular rates are less frequent in paroxysmal auricular fibrillation than with other mechanisms.¹⁶ Congestive failure plays no part in the genesis of vascular collapse. The age factor is largely unimportant, except that circulatory failure may be induced by somewhat slower rates in the aged than in younger patients. With aortic valvular disease, collapse may be induced at rates considerably below the critical level.

Vascular collapse occurred in 27 of 48 cases with ventricular rates of 180 or more, but in only 13 of 205 cases in which the ventricular rate was less than 180; the view that an extremely rapid ventricular rate, and it alone, is responsible for circulatory failure is strengthened by a review of these 13 cases. One of the patients had mild collapse with a ventricular rate of 177, which is too near the critical rate level to require any comment; an eighty-year-old man had collapse with a rate of 170, and 2 patients had aortic valvular disease. Pulmonary embolism, in addition to paroxysmal tachycardia, was present in 7 cases and, as is well known, may itself be respon-

spectively. There was 1 case of cor pulmonale, with a ventricular rate of 187, 1 case of pericarditis with a rate of 214, 1 case of hypertensive heart disease with a rate of 150 and 1 case of heart enlargement of undetermined etiology with a rate of 166. Frank congestive failure was observed in only 6 cases, and the ventricular rates in these were 210, 200, 187, 170, 140 and 130, respectively. The slowest rates were noted in 7 cases complicated by pulmonary embolism — 140 in 2 cases and 150, 160, 166, 170

times. Paroxysmal auricular tachycardia with a ventricular rate of 170 induced vascular collapse in an eighty-year-old man; the heart was normal and there were no complicating factors; stimulation of the carotid sinus interrupted the tachycardia, with immediate resumption of a normal circulation. The last patient in this group had mild vascular collapse with paroxysmal auricular tachycardia and a ventricular rate of 177; his heart was normal, and although he was seventy years old, he had had similar

TABLE 4. *Cases of Vascular Collapse with Ventricular Rates of Less than 180.*

CASE No.	AGE yr.	RHYTHM	VENTRICULAR RATE per min.	DIAGNOSIS	COMMENT
9	53	Paroxysmal auricular fibrillation	160	Angina pectoris	Pulmonary embolism
12	64	Paroxysmal auricular fibrillation	170	Recent myocardial infarction	Pulmonary embolism
30	57	Paroxysmal auricular tachycardia	130	Subacute bacterial endocarditis; congestive failure.	Free aortic insufficiency
31	70	Paroxysmal auricular tachycardia	177	Normal heart	Mild collapse; attacks for 20 years.
124	34	Paroxysmal auricular fibrillation	140	Mitral stenosis; congestive failure.	Pulmonary embolism and infarction; autopsy.
133	64	Paroxysmal auricular fibrillation	170	Mitral stenosis; aortic stenosis; congestive failure	Aortic stenosis
145	64	Paroxysmal ventricular tachycardia	175	Recent myocardial infarction	Large pulmonary infarct
149	62	Paroxysmal ventricular tachycardia	145	Acute myocardial infarction	Recurrences of collapse later during normal rhythm
153	65	Paroxysmal auricular fibrillation	150	Hypertensive heart disease	Phlebitis; pulmonary embolism and infarction.
179	60	Paroxysmal auricular tachycardia	165	Large heart (questionable etiology)	Pulmonary embolism; shock continued after normal rhythm restored.
180	66	Paroxysmal auricular fibrillation	140	Normal heart	Phlebitis and pulmonary embolism
197	80	Paroxysmal auricular tachycardia	170	Normal heart	
235	62	Paroxysmal auricular fibrillation	160	Acute myocardial infarction	Shock appeared 4 hours after the onset of paroxysmal auricular fibrillation and chest pain; there was possible fresh myocardial infarct or possible pulmonary embolism with a probable toxic quinidine reaction

and 175, respectively, in 5. There were only 6 other cases in which the ventricular rate was less than 180. One of these patients had free aortic insufficiency, and another mitral and aortic stenosis. The third had chest pain and paroxysmal auricular fibrillation with a rate of 160 on the tenth day of acute myocardial infarction. Four hours after the onset of the arrhythmia and one and a half hours after the second intramuscular injection of quinidine, when the ventricular rate had dropped to 130, vascular collapse suddenly appeared and death occurred half an hour later. In another case, vascular collapse and paroxysmal ventricular tachycardia with a rate of 145 occurred on the thirteenth day after acute myocardial infarction. Quinidine restored normal rhythm, which was maintained until the patient's death fourteen days later; during this period the temperature and white-cell count were elevated and vascular collapse recurred several

attacks, according to his own statement, for twenty years.

EXTREMELY RAPID RATES WITHOUT VASCULAR COLLAPSE

Vascular collapse is not invariably induced when extremely rapid ventricular rates are attained. Forty-eight patients in this series had rates of 180 or more, but without vascular collapse in 21. The 2 youngest patients were two and six years old, respectively, and there were 3 patients each in the fourth and fifth decades, 7 in the sixth and 6 in the seventh decade. Seven patients (33 per cent) had paroxysmal auricular fibrillation, 10 (48 per cent) paroxysmal auricular tachycardia, 1 (5 per cent) paroxysmal auricular flutter and 3 (14 per cent) paroxysmal ventricular tachycardia. The ventricular rate was 200 or more in 11 cases, — the fastest rate being 250 in a two-year-old child, — 180 to

EPIDEMIOLOGY

There has been a marked decline in the severity of scarlet fever in the last thirty years.⁴⁰ The mortality rate has dropped materially in the northern states, but this has not been apparent in the South.⁴¹ Furthermore, as pointed out by Stebbins,⁴¹ where the incidence of scarlet fever has declined there is not always a comparable reduction in the incidence of other streptococcal infections. This statement applies more to states and municipalities than to military organizations.

In the last few years the newer technics of identifying beta-hemolytic streptococci have been used in several studies of the epidemiology of scarlet fever. These studies give a rational explanation of how this disease is spread from person to person and how epidemics start and spread, and point out the factors that appear to be necessary in the control of this disease. The work of Keefer and his associates³⁸ on the epidemiology of scarlet fever has already been described. Schwentker, Janney and Gordon⁴ made a study of streptococcal infection in Rumania over a period of three years, and have pointed out many of the important factors having to do with the epidemiology of the diseases produced by this group of organisms. They found that there is a gross mathematical relation between the incidence of scarlet fever in a country and its latitude. In temperate countries, the logarithm of the morbidity was found to be directly proportional to the latitude, whereas in the tropics streptococcal diseases are rare. In this connection, they neglect to bring out that whereas these diseases are not prevalent at sea level in the tropics, they become extremely prevalent at high altitudes, as in Bogotá and Mexico City.

These authors noted that no one of several serologic types of streptococcus was universally responsible for the disease over the world, although in any given country one or a few types usually predominated. The incidence of any one type among the total scarlatinal strains varied from time to time, one type gradually diminishing as another increased in frequency. It was found that more than one group or type of streptococcus could be recovered from the throats of healthy carriers as well as those of convalescent carriers, but that

patients with acute disease usually harbored only one serologic type. In Rumania there was a cyclic rhythm in the gross and Group A carrier rates, the highest rate occurring during the late autumn and winter, and the lowest in the summer months. The same incidence with respect to season applies to New England, and this carrier rate is directly correlated with the incidence of streptococcal infections, which are also most frequent in the fall and winter and least prevalent during the summer months. In a study of the carrier problem in Rumania, Schwentker and his co-workers found that the gross and Group-A carrier rates bore a crude direct relation to each other, whereas the carrier rates for all groups other than Group A remained constant. They concluded that the incidence of scarlet fever is dependent on the carrier rate rather than the reverse.

In a study of the different serologic types present in the various villages in which the work was done, it was shown that all the known types of streptococci could be found but that the majority occurred only infrequently. In each village a few types predominated in general, but the outstanding bacterial flora was different for each community. Many of the types fluctuated in frequency of occurrence with time. The streptococcal types most frequently found in scarlet fever also caused most of the other streptococcal diseases in the same region. The same types that produced disease were also the ones that were prevalent in carriers. The differences in streptococcal flora between communities with and without scarlet fever were slight, and greater than between two different areas free from scarlet fever. From these facts it was concluded that some condition other than lack of scarlatinal strains must have been responsible for the absence of scarlet fever. A study was also made of the Dick reaction. It was found that in villages free of scarlet fever the distribution of positive Dick reactions in various age groups was the same as in other parts of the world, as has been described above. The percentage distribution of positive Dick reactions had much the same general pattern as the age distribution of cases of scarlet fever.

An epidemic of scarlet fever due to a Type 10 strain of hemolytic streptococcus was studied. Just before the outbreak of the epidemic there occurred an increase in the gross, Group A and Type 10 carrier rates, and this increase was maintained until almost the end of the epidemic. Patients who developed tonsillitis without a rash were shown to be infected with the same type of streptococcus.

least partly responsible for the circulatory failure; the late appearance of collapse, with sudden death shortly after its onset in one of them, and recurrence of collapse after restoration of normal rhythm in the other, are not to be expected when collapse is due solely to extreme tachycardia; an untoward quinidine reaction may have been present in one of the cases.

The question why extremely rapid rates induce collapse in some cases but not in others cannot be answered from the above data; even soon after recovery from vascular collapse unassociated with paroxysmal tachycardia, extremely rapid rates may fail to induce circulatory failure. It is interesting that, in the absence of complicating factors, the critical level for the ventricular rate is not lower in cases of myocardial infarction or other types of heart disease—with the exception of aortic valvular disease—than it is in normal hearts. Nevertheless, when the critical rate level is reached or surpassed, the susceptibility to collapse is somewhat different in the various groups. Vascular collapse is induced by rates of 180 or more in about half the cases with normal hearts and of those with coronary heart disease, in about three quarters of the cases of acute or recent myocardial infarction and in all the cases of mitral stenosis. Collapse did not occur in the 3 cases of uncomplicated hypertensive heart disease, a number too small to warrant any conclusions.

When vascular collapse is induced by paroxysmal tachycardia, it promptly disappears when the abnormal rhythm is abolished or a significant reduction of the heart rate is effected. When this does

not happen, some factor other than the tachycardia must have caused the collapse. Other factors must be sought also when collapse occurs with rates well under 200, except in cases of aortic valvular disease. The most frequent additional factor in this series was pulmonary embolism.

SUMMARY

The clinical data of 253 cases of paroxysmal tachycardia are analyzed with reference to the occurrence of vascular collapse.

Vascular collapse occurs under constant conditions and is therefore one of the cardinal manifestations of paroxysmal tachycardia; it occurs in 16 per cent of the cases.

Extreme tachycardia itself induces vascular collapse in more than half the cases with rates at or above the critical level, which is in the vicinity of 200; below this level, collapse is not induced by tachycardia alone. The critical level is not lower in cases of myocardial infarction or other types of heart disease, with the exception of aortic valvular disease, than in normal hearts.

Extremely rapid ventricular rates induce vascular collapse in about half the cases with normal hearts and with coronary heart disease, in about three quarters of the cases of acute or recent myocardial infarction and in all the cases of mitral stenosis.

Causes other than tachycardia must be suspected when collapse is associated with rates well under 200 or when termination of the abnormal rhythm or significant reduction of heart rate is not promptly followed by resumption of a normal circulation.

All those who came down with scarlet fever were shown to be Dick positive. Among those who escaped infection some were Dick positive and others Dick negative; these did not become ill in spite of the fact that they were proved by culture to be harboring the causative agent. It was concluded that they must have had a sufficient degree of antibacterial immunity to protect them.

These authors give a concise and clear description of their conception of the epidemiology of scarlet fever:

A scarlatinal strain of streptococcus, either newly introduced or already present in a community, is distributed throughout the population. The number of persons reached depends on the distribution factor, as previously described [measured by the carrier rate]. The distribution factor determines the degree of dissemination of the streptococcus in the community, and by the law of chance, the greater the dissemination, the greater the number of persons who will come in contact with the organism. Some persons escape contact with the streptococcus entirely; these naturally remain well. Among the others who are reached by the organism, some will be resistant by virtue of antibacterial immunity. Regardless of their Dick reaction or antitoxic immunity, they remain well. These persons either eliminate the organism promptly or become healthy carriers. Those without antibacterial immunity sicken. The Dick-positive individuals, having no antitoxic immunity, develop scarlet fever; those with antitoxic immunity have streptococcal tonsillitis without the scarlatinal rash. The difference is purely clinical. Should the portal of entry be other than the nasopharynx, the relationship is still the same. Puerperal fever may develop with or without the scarlatinal rash; or erysipelas or some other kind of infection may occur. From the three groups of individuals who harbor the streptococcus, the organisms are still further distributed and the cycle repeats itself.

Schwentker, Hodes, Kingsland, Chenoweth and Peck⁴² studied a company of sailors in "boot training" in whom there occurred an outbreak of streptococcal infection. Six different types of streptococci were found to be responsible for sickness in the company. Of these, Types 1 and 6 were outstanding. Together they accounted for 30 of 42 cases of infection. These types did not cause scarlet fever. The 2 cases of scarlet fever that occurred were both due to Type 3. The percentage distribution of the various types was the same among cases of illness as in normal carriers. The distribution of the various types among normal carriers in six other companies on the station was practically the same as in the study company. In all companies, Types 1 and 6 predominated. Nevertheless, among cases of scarlet fever occurring at the station, Types 3 and 19 were outstanding. No case of scarlet fever due to Type 6 was discovered, and only 2 were due to Type 1. It appeared that the streptococci present at the station could be divided into two types — those that were highly pathogenic but had little scarlatigenic ability, and those that were scarlatigenic as well as pathogenic.

The carrier rate of streptococci was found to be high in the groups that were studied. Whereas the rate in the general population is usually 10 per cent, at this station it was found to be as high as 69 per cent. Where more than one type of streptococcus was active during an outbreak, the number of cases due to each type was found to be proportional to the carrier rate for the respective type. This makes it appear that the carrier was instrumental in transmitting the disease. The high carrier rates were found to develop among the men during the period of training, because only 4 per cent of incoming inductees were found to harbor beta-hemolytic streptococci.

A group of 73 men who did not develop any illness were also studied. These men remained well in spite of the fact that as many as five different types of streptococci of known pathogenicity were recovered from their throats. The Dick reaction apparently played no role in resistance to infection, since the amount of illness in Dick-negative men was proportionately the same as that in Dick-positive ones. Some persons were found to resist infection with one type of streptococcus but became ill when infected with another type. No person was found who had two illnesses due to the same serologic type of streptococcus. It is interesting that the authors were able to show that some of the strains isolated from those who had a streptococcal infection without a rash — that is, no scarlet fever — were capable of producing erythrogenic toxin.

Schwentker⁴³ also studied the role of the carrier in the spread of an epidemic of streptococcal infection. He observed an epidemic of scarlet fever in an Army camp due to an organism that gave reactions with both Types 17 and 23 by the Griffith technic and with Type 19 by the Lancefield precipitin method. These findings were due to the fact that the organism contained T antigens of both Types 17 and 23 but M antigen only of Type 19. The number of cases of scarlet fever in different companies studied varied from zero to 10 per cent. The case incidence was found to be related to the carrier rate for the Type 19 strain of streptococcus causing the outbreak. The logarithm of the incidence of scarlet fever was directly proportional to the Type 19 streptococcus carrier rate. The same relation was found to exist between the incidence rate of the disease and the gross (all groups) and Group A carrier rate, but in each of these cases it was merely a reflection of the Type 19 relation. The carrier rates for groups other than Group A and for all Group A strains except for Type 19 were found to be roughly the same in all companies.

In 1944, Coburn⁴⁴ reported some studies on the problem of the role of the carrier in the transmission of streptococcal disease. He described two outbreaks set up by carriers. In a group of 200 patients with throat infections due to Type 19 streptococcus,

some of whom had scarlet fever whereas others did not, there were two persons who proved to be dangerous carriers after discharge from the hospital, both giving rise to additional cases. One of these men had an acute pharyngitis followed by mastoiditis, sinusitis and bronchitis. He gave rise to 4 cases of scarlet fever or acute pharyngitis during readmission to the hospital for a mastoidectomy. The other man had a sinusitis and a focal pneumonitis following an attack of scarlet fever and later, while in an orthopedic ward containing 40 bed patients for observation following a minor head injury, was responsible for 16 cases of streptococcal infection in that ward. In neither carrier was the number of streptococci in the throat culture found to be large, and in neither of them was the organism highly invasive. In both, however, the communicability was high and outbreaks occurred. Coburn believes that a high degree of communicability, and thus a dangerous carrier state, may be acquired by the streptococcus during secondary infections and during an outbreak of virus infections of the respiratory tract. The latter finding is in direct contrast to that of Schwentker, Janney and Gordon, who were unable to demonstrate any effect of the incidence of the common cold or the nonspecific infection referred to as "influenza" on the incidence of streptococcal infection.

Communicability in the two patients described by Coburn was thought to cease when the infectious process subsided under the influence of sulfonamides. In discussing the property of communicability, Coburn expresses the belief that this is acquired by an adaptive change in the bacteria with relation to the changing immune state in the host under conditions of an infection in which neither the host nor the bacterium can promptly establish supremacy. Because of the change, the bacteria become able to multiply in the presence of inhibitory substances present in the normal mucous membranes and thus become host-fast. This property may be quickly lost, but so long as it exists the organisms have a high degree of communicability. Coburn speculates that fundamentally this phenomenon may depend on the development of adaptive enzyme systems.

A study of the factors concerned in the transmission of streptococcal infections has been made by Hamburger.⁴⁵ It was found that when only as few as one or two carriers were present, cross-infection spread rapidly on open wards where there were patients with streptococcal infections. On the other hand, cross-infection might not occur if as high as 50 per cent of the patients on a ward were harboring Group A streptococci in their throats. Subclinical cross-infections by hemolytic streptococci were found to be not infrequent. Patients who were recovering from German measles seemed to share the well-recognized susceptibility of patients with measles to

streptococcal infection. These authors also point out that there is insufficient proof that because a person is a streptococcal carrier he is responsible for cases of infection, since he may be harboring a serologic type entirely distinct from that producing disease.

Hamburger⁴⁶ also made a study of the content of the saliva of 156 patients who had beta-hemolytic streptococci in their throats, studying this as a factor in the transmission of streptococcal infections. He found that in the acute stages of scarlet fever over 80 per cent of the patients had the same serologic type of beta-hemolytic streptococci in the saliva as in the throat. In the remainder of the patients no streptococci were demonstrated in the saliva. Several day-to-day patterns of streptococcal content of the saliva were found to exist. In 51 per cent of the patients, the number of hemolytic streptococci in the saliva diminished with the passage of time, usually gradually but in some cases abruptly. In 25 per cent, there was no change in the salivary flora during a period of weeks; about half these showed the presence of streptococci in the saliva, and the other half showed none. Hamburger could find no significant difference in the number of hemolytic streptococci in the saliva at various stages of the scarlet fever as compared with that from cases of tonsillitis and pharyngitis without a rash. In patients who had had their tonsils removed it was found that hemolytic streptococci were present in smaller numbers and for shorter periods than in those in whom the tonsils were still present.

Hamburger and his associates⁴⁴ also made a study of the air and the floor dust in a ward and the bedclothes in their relation to the transmission of streptococcal infections. They found that air-borne organisms were present in large numbers in wards in which streptococcal disease was present, and that these were most numerous around the beds of patients whose respiratory secretions contained the largest numbers of streptococci. They showed that the number of organisms in the air is important in any consideration of the role that air plays in transmission of disease, and that even a small number of streptococci in the air are capable of producing disease in a susceptible person. Thus, a technician who was working on a streptococcal ward became infected when the number of organisms present in the air was shown to be less than 1300. It is pointed out that the reservoir from which the organisms get into the air is the floor dust and the bedclothes of patients with streptococcal infections. Therefore, the control of air-borne streptococcal infection in hospital wards may be largely a question of control of the secondary reservoirs in dust and bed linen. Hodes and his co-workers⁴⁷ have studied scarlet fever as an air-borne infection. They conclude that the direct transmission by air from a patient with scarlet fever is a more important means of spread

than is the general reservoir of air. Wheeler and Jones⁴⁸ have demonstrated that one of the most significant factors in the genesis of epidemics is the rapid introduction of susceptible persons into an infected population, as in the reception of recruits.

From these more recent studies on the epidemiology of scarlet fever several pertinent facts become obvious. First, epidemics of this disease are usually due to one or two serologic types of streptococcus, whereas sporadic cases may be due to any of the types that have been described. Furthermore, just preceding and during an epidemic there is often an increase in the carrier rate of the serologic types that are most prevalent in the sick. The exact role of the healthy carrier in the transmission of streptococcal infections is not clear. The studies of Foley, Wheeler and Aycock⁴⁹ indicate that the spread of scarlet fever through secondary cases is not limited to case-to-case transfer, but includes nonscarlet-fever and subclinical infection as well as intermediate carriers. Schwentker, Janney and Gordon⁴ and some of the other workers who have been cited maintain that the so-called "healthy carrier" may be an important factor in the dissemination of streptococci, with the subsequent production of actual infection. Coburn's⁴⁴ hypothesis regarding the adaptive abilities of the streptococci with respect to their degree of communicability deserves further investigation. Hamburger's¹⁴ investigations have emphasized the well-known significance of the role played by air, floor dust and bedclothes in the transmission of streptococcal infections in hospital wards. The crowding together of large numbers of men from various parts of the country in the various establishments of the armed forces has afforded an exceptional opportunity for studying the epidemiology of outbreaks of streptococcal disease in sufficiently large numbers to yield invaluable data, in drawing conclusions from which the greatest care must be taken. There is still much to be learned concerning the epidemiology of the streptococcal infections.

METHODS OF CONTROL

Granting that scarlet fever is merely one manifestation of streptococcal infection and is dependent on the ability of the invading strain to elaborate an erythrogenic toxin in a susceptible host, it becomes clear that many persons may harbor toxin-producing strains without manifesting signs of scarlet fever. First, the person may be a carrier and thus show no manifestation of disease. It has been seen that the carrier rate of the epidemic strain often rises abruptly prior to and during an epidemic, but this fact does not establish that cases of scarlet fever originate from carriers. The recent studies of Hamburger⁴⁵ in an Army hospital cast some doubt on the part played by the healthy carrier in the spread of scarlet fever. Thus, although the carrier index may

give valuable warning concerning a probable outbreak of an epidemic of scarlet fever and the etiologic type, the carrier is not necessarily the means of spreading the disease, unless he himself succumbs to an invasion of the streptococcus and becomes ill. Further studies are necessary to determine whether as a result of the illness he may change from a harmless carrier to a dangerous one. The complexity of this problem from the standpoint of extremely mild or so-called "missed" cases is apparent.

The carrier here referred to is not to be confused with the patient who is convalescent from scarlet fever and still harbors the etiologic strain in some localized infection, whether this be a subacute rhinitis, tonsillitis, otitis media, paronychia or discharging wound. Aside from such a low-grade infection he may be afebrile and enjoy good health, but such a person is not a healthy carrier in the true sense of the term.

After uncomplicated scarlet fever the upper respiratory tract usually returns to normal by the end of the second week in adults and by the end of the third week in children. It is often difficult to say just what constitutes normality, since only parts of the upper respiratory tract are visible on examination. Therefore, some patients may seem to be clear of infection at the end of the isolation period and yet be capable of infecting others. If this were the only source of scarlet fever, one might consider the advisability of a longer period of isolation, but prolonged isolation has not reduced the incidence of scarlet fever. A small percentage of the uncomplicated cases are still infectious after four weeks. When scarlet fever is epidemic, there are always many persons about with sore throats but without the rash who disseminate the same streptococci as freely as those with the full-blown rash—indeed, much more so, since they are apt to be out and about rather than confined to bed. This is the explanation of the inability to control scarlet fever adequately by isolation in the home or in the hospital. If all patients with streptococcal disease were isolated instead of only those with one manifestation of streptococcal disease, something approaching control might be accomplished. But here again one is confronted by the fact that streptococcal infections, as determined by the presence of antistreptolysin, may be so exceedingly mild as to go unnoticed.^{4,50} The role played by such subclinical cases in the spread of these infections is unknown. Certainly any attempt to control scarlet fever by quarantining carriers is impractical. Likewise it is difficult to control the influx of susceptible persons into an infected population. This has, however, been done with success in controlling an epidemic.⁴⁷ Thus, stopping the reception of raw recruits stops the spread of the disease as definitely as when new patients are refused admission to a ward where scarlet fever has broken out. Without new fuel a fire dies out.

In certain streptococcal epidemics an extremely high proportion of the cases exhibit scarlet fever. In others the opposite is true. In either instance it is inconsistent to isolate those with a rash for four weeks and to isolate the others for only the duration of the fever or not at all.

The new conception of scarlet fever has brought about a reduction of the isolation period in many cities in the United States. Three weeks for children and two weeks for those over seventeen years of age are now recommended by the Massachusetts State Department of Health. This is a gesture in the right direction, but it is still arbitrary. In Bergen and Trondheim in Norway, prior to the German invasion, scarlet fever was left to the attending physician to handle as a streptococcal infection, the rash being disregarded.¹⁸ After eighteen years the results were sufficiently satisfactory to justify continuing the abolition of any set period of isolation. Aberdeen in Scotland followed this example and was still satisfied with the ruling after five years of a similar experiment.

Hospitalization

Hospitalization for streptococcal disease, including scarlet fever, should depend on circumstances. Isolation at home is desirable if the case is mild or moderate and exhibits no serious complications. The patient with a mild case who is placed on an open scarlet-fever ward is more liable to have a relapse and to have complications than if he were left at home. Poverty or unco-operative parents may be proper indications for hospitalization. Hospitalization is desirable in all severe cases and in all threatening complications, such as mastoiditis, sinus empyema and nephritis. Stockholm furnishes an excellent example. There, according to the latest accounts,⁵¹ hospitalization for scarlet fever is required by law. Every case goes to the hospital, not because hospitalization has reduced the incidence of scarlet fever, but because the mortality rate has been found to be lower in the hospital in spite of open ward care than in the home. In other words, hospitalization affords better results through the prompt and effective handling of complications. If all patients with severe cases and complications were promptly hospitalized, the same good results would be obtained. Every possible effort should be made to avoid the overcrowding of scarlet-fever wards. The policy in this regard at the Belmont Hospital in Worcester deserves the greatest praise.

The hospital, then, should serve for those cases arising in homes where facilities for good care do not exist. It stands to reason that hospitalization is necessary for those mild cases that arise in military establishments and in boarding schools, colleges and other institutions where people are herded together in dormitories. Thus it is that in a large educational center, such as Greater Boston, adequate facilities for the hospitalization of upper

respiratory streptococcal disease should be available; furthermore, such hospitalization to be effective as a means of control should not be confined to those manifesting the rash of scarlet fever. It is particularly desirable that patients should be sent to a hospital when other members of the household are food handlers. Thus, hospitalization does play its part in the control of the disease. It should by no means be a routine procedure but should be applicable only to the exigencies of the individual situation.

Inconsistencies in Regulations

Not long ago a nurse after attending a case of scarlet fever was required to take a week off before signing on again for general nursing, in spite of the fact that she took a bath and changed her clothes on coming off the contagious case, whereas the doctors who insisted on this outrageous ruling had so little conception of contagious technic that they often went directly to other patients without even washing their hands. Other doctors donned caps, gowns and masks, insisted on having sheets soaked in bichloride of mercury hung in the doorway, and after examining the patient put their hands in their pockets to get their watch, glasses, handkerchief or thermometer. They then relied on dipping their hands in an antiseptic solution rather than washing them in soap and water. It is well to remind the medical profession of these sins of the past. Or shall it be admitted that the contagious technic of too many eminent physicians is vastly inferior to the aseptic technic of all eminent surgeons?

A child is sent to the hospital with scarlet fever, and at the same time another child in the family has a sore throat. The second child is not allowed at school but plays with her schoolmates on the street and goes to motion-picture shows. Any attempt to curtail the second child's activities is objected to by the parents on the ground that the child with the scarlet-fever case has been isolated in the hospital and that the other child has only a sore throat. Education of the public is sorely needed, but what chances are there of impressing the public when there is no agreement on isolation periods? The State Department of Public Health merely makes recommendations regarding isolation, whereas the local boards of health make the rules. Hence it is that in Greater Boston there is a wide variation in the requirements. A patient over seventeen years of age with uncomplicated scarlet fever is isolated for two weeks in Boston and Newton, for three weeks in Cambridge and Brookline and for four weeks in Lexington. If he lives in Boston he can go back to work in Lexington for the last two weeks of his convalescence, because Lexington has no report of his having had scarlet fever. The ignoring of the advice of the Department of Public Health by some local authorities leads to confusion and to lack of confidence in the methods of control.

In a certain military establishment the practice is to hospitalize all patients with upper respiratory streptococcal disease under the diagnosis of streptococcosis, and to isolate those with uncomplicated cases of scarlet fever. At the end of not over fourteen days these patients are allowed to leave by the main gate and to mingle with the townspeople. But these same military authorities insist that a carpenter employed in the erection of a new building in this establishment shall be laid off work for four weeks without pay because his young son has scarlet fever at home. It is, indeed, extremely difficult to educate the public to co-operate with the medical profession in the control of streptococcal disease when the laity sees the perpetration of such glaring inconsistencies.

Chemoprophylaxis

The control of streptococcal infections and their sequelae, including rheumatic fever, through mass prophylaxis with small doses of sulfonamides has been carried out extensively in the last two years.^{47, 52-57} The morbidity rate has been a serious problem in certain localities where these organisms flourish. Several recent reports in the literature indicate a successful program of control. Sulfonamide-resistant strains, however, are beginning to show up to a disturbing extent in certain localities.

Watson and his co-workers⁵⁵ reported their results in a study of the use of sulfadiazine in a Navy establishment in 1943. They were faced by an epidemic of scarlet fever due to a Group A, Type 19, beta-hemolytic streptococcus. As soon as the epidemic began all the personnel at the station were given 0.5 gm. of sulfadiazine twice a day. During the first week after the start of the sulfonamide therapy, the incidence of scarlet fever dropped markedly. In another group of men who did not receive daily dosage of the sulfonamide the incidence of scarlet fever remained high. When this second group was given the same dosage of sulfadiazine, there was a similar reduction in new cases. After the sulfonamide was discontinued scarlet fever remained absent. The carrier rate for Type 19 still remained high, although there was some reduction. The average blood level for the drug in the men who were treated was 2.5 mg. per 100 cc. Of the several thousand men treated prophylactically only 3 developed toxic manifestations in the form of a rash. No severe toxic reactions were observed.

A study of the same problem in the Army Air Forces by Holbrook⁵³ showed that when acute rheumatic fever became prevalent it was always preceded by a high incidence of hemolytic streptococcus infections. A 50 to 75 per cent reduction in the incidence of respiratory diseases and streptococcal infections was accomplished by the use of sulfadiazine prophylaxis under carefully controlled conditions in a significantly large troop population. A study of the data indicated that a reduction in

the incidence of rheumatic fever paralleled the reduction in the occurrence of respiratory and streptococcal diseases.

Coburn⁵⁶ has reported his observations on the use of sulfadiazine prophylaxis against streptococcal infection in a group of 30,000 men stationed at three different Navy camps. It was found that the ingestion of 1 gm. of the drug daily accomplished the following things: outbreaks of streptococcal infection were checked at their onset, well-advanced outbreaks of streptococcal disease appeared to be checked in their spread, and 85 per cent of the susceptible recruits were protected from implantation with bacterial respiratory pathogens. It seemed that a continuous daily dosage of 0.5 gm. of sulfadiazine yielding an average blood concentration of 1.4 mg. per 100 cc. and one of 0.8 mg. per 100 cc. in the respiratory secretions was almost 85 per cent effective in preventing implantation of *Str. haemolyticus*. The only untoward effects noted in this experiment in mass sulfadiazine prophylaxis were the occurrence of evanescent rashes in 0.5 per cent of the patients treated and severe constitutional reactions in 0.01 per cent.

The largest group of subjects in whom the experiment of mass prophylaxis with sulfadiazine has been attempted is mentioned in a recent report by the Bureau of Medicine and Surgery of the Navy Department,⁵⁸ covering observations carried out for a period of six months, with 600,000 men receiving daily doses of the drug. It was found that sulfadiazine, in either prophylactic or therapeutic doses had little effect on the throat flora of carriers of hemolytic streptococci. Implantation of streptococci was prevented regardless of the pathogenicity of the strains that were prevalent, although in some instances the organisms were able to overcome the inhibitory effects of sulfadiazine. This occurred after the drug in doses of 1 gm. daily had been ingested for several weeks, and was observed in areas where exposure to streptococcal infection was greatest and at times when the incidence of measles was high. Usually, however, it was evident that the presence of sulfadiazine in the secretions of the nasopharynx prevented the implantation of a new strain of hemolytic streptococcus and prevented frank infection in 95 per cent of the persons given the drug.

The percentages of untoward reactions observed were the same as those previously noted by Coburn⁵⁶ in the study of chemoprophylaxis in a smaller group of naval personnel. It is pointed out that coincident virus infections, particularly measles and influenza, increased the communicability of hemolytic streptococci, but that prophylaxis with sulfadiazine was highly effective in preventing the implantation of the bacteria in the upper respiratory tract of susceptible groups of persons living in camps in which measles was present. No sulfonamide-resistant strains were encountered, and there was no evidence

of such resistance during the six months that the study was carried out. There is some suggestion, however, that in the final month Type 19 may have developed some degree of fastness to the sulfadiazine, since at that time this organism became the prevalent one at several establishments. The importance of this problem to the Navy is stressed by the following quotation:

In these groups of naval personnel a saving of a day per man per month can be expected when bacterial respiratory pathogens are active. If the center's recruit complement is 50,000 and all hands receive sulfadiazine prophylaxis, one can anticipate a saving of 30,000 hospital days each month during seasons conducive to respiratory diseases. This is equivalent to freeing a 1000-bed hospital and all the labor and personnel associated with the care of the sick.

Keith and his associates⁵⁷ found that sulfadiazine in 1 gm. daily doses reduced hospital admissions for nasopharyngitis and scarlet fever to one third in a station of the Canadian Navy. Hodges⁵⁴ found this drug equally effective in this respect among troops in the United States Army.

The data that have been presented on the effect of prophylaxis with small doses of sulfadiazine for the prevention of outbreaks of scarlet fever and for the control of epidemics already under way are indeed impressive. The effect that this program has had in the saving of man-hours of duty in the armed forces has certainly been extremely helpful to the war effort.

Although mass prophylaxis with sulfonamides has been used extensively and with striking success in the armed forces, it must be kept in mind that this was carried out under medical supervision. This, of course, could be done under equally good medical supervision in boarding schools and similar institutions, but it is questionable whether it should be recommended for the population at large. Furthermore, tabulated reports from the stations where sulfonamide-resistant strains prevail have not been published, and we have yet to be told whether such mass prophylaxis encourages the development of sulfonamide-resistant strains

* * *

The recognition that scarlet fever is not a disease entity is a milestone of progress, but there is still much to be learned about the pathogenesis of scarlet

fever and its complications, its mode of spread and the possible role of carriers. Active immunization is a valuable means of protection, but this is indicated only where the chances of exposure are great, as in nurses' training schools. Great care should be taken in the selection of those to be immunized, as well as in the method employed. Serum therapy and chemotherapy have proved to be effective weapons in prophylaxis and treatment, but both these measures have distinct indications and definite limitations

EDITH E. PARRIS, *Assistant Editor*

CASE 31191

PRESENTATION OF CASE

A sixty-nine-year-old gateman was admitted to the hospital because of jaundice, nausea and vomiting.

Three weeks before admission he noticed that his abdomen had become quite distended, and six days before entry he developed nausea and vomiting, which persisted until admission. He also observed that the urine was "dark." During the week before admission he passed only an occasional small scybalous stool, despite taking three Alophen pills each day. Usually two pills resulted in three movements a day. Three days before admission his physician noticed that he was icteric. He had experienced no pain, weight loss, anorexia or weakness. He became quite short of breath on climbing a long flight of stairs and had occasional cramp-like pains in the calves and feet. He had recently noticed difficulty in starting to urinate. Until the present illness he had always been active and well.

His wife and five children were in good health.

Physical examination revealed a mildly icteric man, with a moderately severe right scoliosis. He had varicose veins, as well as telangiectatic vessels over the legs and feet. The breath sounds were diminished over the right chest posteriorly. The heart was normal, and the pulse strong. The liver edge was felt well below the level of the umbilicus, even to the left of the midline. The left lobe of the liver was enlarged, as indicated by percussion over the posterior chest wall, and the spleen was not felt; the abdomen was otherwise negative. A large fairly smooth prostate was palpated.

The temperature, pulse and respirations were normal. The blood pressure was 165 systolic, 90 diastolic.

Examination of the blood showed a red-cell count of 5,600,000 and a white-cell count of 12,400, with 82 per cent neutrophils. The stool was formed, dark and guaiac negative. The urine was acid, with a specific gravity of 1.020, and gave a + test for albumin, a ++++ test for bile and a green precipitate with Benedict's solution; it contained 30 white cells per high-power field and showed a posi-

tive urobilinogen test in a dilution of 1:512. The serum nonprotein nitrogen was 125 mg. per 100 cc., the cholesterol 192 mg. and the phosphorus 4.2 mg. The total protein was 5.78 gm. per 100 cc., with an albumin-globulin ratio of 1.8. The van den Bergh test was 10.6 mg. direct and 13.6 mg. indirect, the cephalin flocculation test + + + +, the alkaline phosphatase 11.5 Bodansky units per 100 cc., and the prothrombin time 19 seconds (normal, 18 to 20 seconds).

An electrocardiogram showed a normal tracing. X-ray examination revealed a marked right dorsal scoliosis. The right diaphragm was somewhat elevated. Several linear areas of increased density were seen in the right lower lung field. The aorta was tortuous and calcified in the arch. The heart was not remarkable. By fluoroscopy the liver appeared enlarged.

On the third hospital day the patient became progressively more stuporous, responding only to pain. The temperature rose to 100.5°F. The pulse and respirations became moderately elevated. He became comatose and expired quietly on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. MARIAN W. ROPES: It is apparent that this patient had severe liver-cell damage, and I believe that his death was due to hepatic failure.

The disease, in so far as he was aware of it, was of short duration, a total of three and a half weeks, and there was some evidence in the laboratory studies to indicate that the acute liver damage was also of rather short duration. For instance, in severe liver-cell damage a prothrombin time of 19 seconds—a perfectly normal reading—is unusual if such damage has persisted for a long period of time. Similarly, in liver failure of considerable duration a normal cholesterol level is a somewhat unusual finding, a low reading usually being expected. If there is an obstructive element, an elevation on this basis might balance the lowering due to parenchymatous damage. I am sure, however, that this differential is not reliable. Furthermore, in liver damage of long duration one expects more of a decrease in the serum albumin and an elevation of the globulin. The other tests give adequate evidence of liver-cell damage—the high urobilinogen, the + + + + cephalin flocculation test, the high van den Bergh values and the high nonprotein nitrogen. I assume that the increase in nonprotein nitrogen was due to an increase in amino acids,—the usual finding in cases of hepatic failure,—and I suspect that the urea was only slightly elevated. There is little or no evidence of renal failure. The phosphatase level is somewhat higher than one would ordinarily expect in parenchymatous liver damage of short duration and suggests a slight element of obstruction, as does, theoretically, the high direct-indirect ratio in the van den Bergh test. Obviously

*On leave of absence.

if any obstruction was present, it was relatively minimal compared to the parenchymatous damage.

One must next consider what caused this damage. Probably the most significant factor is the large size of the liver. May we look at the x-ray films?

DR. MILFORD D. SCHULZ: You can see this great mass filling the entire epigastrium. If it is not liver, it cannot be distinguished from it. The diaphragm is somewhat elevated. What this airless area in the right lung field is, I cannot say.

DR. ROPES: Assuming that the mass is liver, there surely is no question that it is tremendous.

DR. SCHULZ: I agree.

DR. ROPES: The first problem to be considered is whether an acute liver disease, such as acute infectious hepatitis, can produce this picture. Against that is the size of the liver; it being extremely unusual to observe a liver of this size at any stage of acute hepatitis, particularly at a terminal stage, when acute failure and death are imminent. Similarly, I should expect the spleen to be palpable in a hepatitis of this degree.

There are two other acute liver diseases that should be mentioned in passing. Thus, acute liver poisoning from any source might be considered on the basis of the history, but the large liver and the lack of further details permit us to discard this cause. Similarly there is no evidence for an infectious process, such as Weil's disease. So the evidence, to me, indicates underlying liver disease in which there was final failure of the remaining liver cells due to some superimposed factor.

There are three possibilities to consider: syphilis, a malignant tumor and cirrhosis. Unfortunately we are not told anything about the Hinton and Wassermann tests. The size of the liver, particularly that of the left lobe, demonstrated by a test that Dr. Aub will perhaps mention later, namely, posterior chest percussion, is entirely consistent with syphilis. Although syphilis cannot be ruled out, it also cannot be proved in this case.

A malignant neoplasm, either primary or secondary, must be considered. If it were metastatic carcinoma, it would be unusual to have so few symptoms, including absence of weight loss, up to three and a half weeks before death. Also there is no evidence of a primary source. Constipation came on during the last few weeks of life, and I interpret this as being secondary to hepatic failure rather than indicating a lesion of the gastrointestinal tract. I do not believe that the patient had prostatic carcinoma. If a malignant tumor was the etiologic factor, the course is more consistent with a primary carcinoma of the liver than with a metastatic lesion.

The third possibility is portal cirrhosis. There is no evidence of the biliary type from either the history or the laboratory findings. It is possible, although unlikely, for portal cirrhosis to cause a liver of this size, with left lobe enlargement. The absence of symptoms up to the terminal event, with failure

of the residual liver cells, is not inconsistent. I think again, however, that the relatively slight change in some of the chemical findings would be unusual in a cirrhosis of this duration and degree. Also, I should have expected more in the way of anemia, splenic enlargement and further evidence of portal-vein obstruction.

In addition there were arteriosclerosis, prostatic hypertrophy and something in the right lower chest that may have been atelectasis secondary to the liver enlargement. I doubt that this was related to the primary process in any other way.

To summarize I think that this man died because of hepatic failure and that he had underlying liver disease before the final terminal damage of the remaining liver cells. I favor a malignant tumor, although it is absolutely impossible to rule out syphilis.

DR. BENJAMIN CASTLEMAN: Do you want to go any farther in classifying the tumor?

DR. ROPES: I believe that it was a liver-cell carcinoma.

DR. JOSEPH C. AUB: I thought that this man had a primary tumor in the liver on the basis of hepatoma. I have always believed that these usually occurred in the left lobe of the liver, although Dr. Castleman disagrees with me.

Dr. Ropes has asked me to demonstrate one way of pointing out the size of the left lobe of the liver. One should percuss down just to the left of the spine until one comes to flatness; having come to flatness, one should percuss out laterally to resonance. This is a sharp line that should be 5 cm. from the midline in a normal person. With a big left lobe of the liver, it may measure 8 or 9 cm. The reason for this is that, the left lobe of the liver being in the back just behind the stomach, resonance develops when the liver edge ends and the gas bubble in the cardiac end of the stomach begins. This gives a quite accurate indication of left-lobe enlargement.

DR. CASTLEMAN: In our experience hepatomas are more frequent in the right lobe than in the left; when the left lobe is enlarged, we think oftener of syphilis than of primary tumor.

DR. CHESTER M. JONES: I am interested in the emphasis that Dr. Ropes has put on syphilis, since I would not have seriously thought of it. The liver was very large by the x-ray films and on physical examination, indicating a diffuse process, which I suppose would be called a cirrhosis. In a syphilitic process I believe that the physical findings are different — the mass is lobular.

In this case I thought immediately of primary hepatoma. Furthermore, primary hepatoma, or even metastatic cancer of the liver, may go for a long period of time without producing many symptoms or much interference with liver function, except when superimposed on cirrhosis. There is a difference in statistical figures, if one compares what we see here with what they see on the West Coast.

Wilbur, Wood and Willett* report primary hepatoma without cirrhosis in a high percentage of cases; our cases are usually superimposed on cirrhosis.

DR. CASTLEMAN: About 90 per cent of our cases are associated with cirrhosis.

DR. JONES: There is an end picture of hepatic failure, as this patient exhibited, in any form of diffuse liver disease. In the final stage it is essentially the same clinical picture, regardless of whether the failure is due to acute yellow atrophy, infection, a specific toxin or any other cause. Incidentally, I should think that one would have found an enlarged spleen if this were a syphilitic cirrhosis, just as in any other form of cirrhosis.

DR. CASTLEMAN: For a syphilitic liver to be as big as this one was it would have to be the hepar lobatum type, which as a rule does not lead to liver failure unless acute hepatitis of some sort is superimposed. Acquired diffuse syphilitic cirrhosis is extremely rare, and I doubt that the liver would be so large.

CLINICAL DIAGNOSIS

Liver-cell carcinoma.

DR. ROPES'S DIAGNOSES

Liver-cell carcinoma.

Arteriosclerosis.

Pulmonary atelectasis: right lower lobe.

Prostatic hypertrophy.

ANATOMICAL DIAGNOSES

Malignant lymphoma, lymphoblastic type, involving liver, mesenteric and retroperitoneal lymph nodes and vertebral bone marrow.

Arteriosclerosis.

Pulmonary fibrosis and emphysema: right lower lobe.

Prostatic hyperplasia.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy the liver weighed 5000 gm., a tremendous liver. We do not usually see livers of that size, and when we do, they are almost always due to metastatic carcinoma. We have one liver of this size due to so-called "Hanot's cirrhosis," that is, a biliary type of cirrhosis. I believe that we had one or two almost that size during the extreme fatty stage of acute alcoholic hepatitis before the onset of fibrosis.

The liver was infiltrated with grayish-white, obviously neoplastic tissue, and we assumed that it was metastatic carcinoma. The mesenteric and retroperitoneal nodes were also involved, but we were unable to find the primary site. Microscopic examination showed why we did not find it. The tumor proved to belong to the malignant-lymphoma group. Most of the liver cells were completely re-

placed by cells of the lymphocytic series, predominantly lymphoblasts. There was no cirrhosis. Except for the mesenteric and retroperitoneal lymph nodes, which were replaced by neoplasm, the only other organ involved was the vertebral bone marrow.

The prostate was enlarged and showed hyperplasia. The abnormal x-ray shadow in the chest proved to have been due to fibrosis of the lungs with large emphysematous blebs in the right lower lobe.

CASE 31192

PRESENTATION OF CASE

A fifty-three-year-old engineer was admitted to the hospital because of mental confusion and severe headache of approximately twenty hours' duration.

Five years before entry he passed an examination for life insurance. The patient had been well and active until one year before admission, when he began having severe headaches at night, and was found to have a systolic blood pressure of 225 and albuminuria. Despite severe headaches he continued to work. At noon on the day before admission the patient had some teeth extracted. The oral surgeon reported that the patient did not look well and appeared somewhat confused. Two hours later the patient telephoned his wife and complained of pain in the jaw. Three hours later he called her again and told her that he was extremely sick. In the meantime his automobile was found in a badly wrecked condition. When the patient was found, it was observed that he had a small bruise on his forehead. He had no recollection of an accident, but he did recall wandering about the city, in the early afternoon, constantly bumping into people and being unable to find his office. At home that evening he spoke incoherently and appeared to be blind. During the night he complained of headache and was able to get up and go to the bathroom twice. On the following morning he was brought to the hospital.

Physical examination revealed a well-developed, poorly nourished, pale, sweating, extremely drowsy man who complained of a throbbing frontal headache. There was a small bruise on the forehead. The alveolar sockets were bleeding. All but the canine teeth had recently been extracted. The heart border was 8.5 cm. to the left of the midsternum in the fifth interspace. The sounds were distant and of poor quality. There were frequent extrasystoles. A systolic murmur was best heard at the apex. The dorsalis pedis arteries were easily felt. There was diminished visual acuity, with a left homonymous hemianopsia. Fundoscopy showed choked disks, retinal hemorrhages and spasm of the arteries, with marked bilateral arteriovenous nicking. There was a left lower facial weakness, but no weakness of arm or leg was detected. The

*Wilbur, D. L., Wood, D. A., and Willett, F. M. Primary carcinoma of liver. *Ann. Int. Med.* 20:453-485, 1944.

neck was moderately stiff. There was a bilateral Kernig's sign. The left knee jerk was more prominent than the right. The abdominal reflexes were absent on the left. There was a questionable extensor plantar reflex on the left side.

The rectal temperature was 100°F., the pulse 105, and the respirations 10. The blood pressure was 220 systolic, 120 diastolic.

The urine was slightly alkaline, with a specific gravity of 1.014, and gave a +++ test for albumin; the sediment showed 10 to 15 white cells, 8 to 10 red cells and 3 granular casts per high-power field. Examination of the blood revealed a red-cell count of 4,200,000 and a white-cell count of 20,600, with 88 per cent neutrophils. The stool appeared normal and was guaiac negative. The serum non-protein nitrogen was 40 mg. per 100 cc., the protein 8 gm., and the carbon dioxide 29 milliequiv. per liter. A lumbar puncture gave an initial pressure equivalent to 300 mm. of water. All three tubes appeared equally "bloody," and the fluid contained 5850 red cells and 3 lymphocytes per cubic millimeter, but no polymorphonuclears; the supernatant fluid was xanthochromic. A spinal-fluid Wassermann test was negative, and the total protein was 129 mg. per 100 cc. The patient's headache was improved following the lumbar puncture. A lumbar puncture on the second day revealed an initial pressure equivalent to 350 mm. of water; there were 7800 red cells, 1400 polymorphonuclears and 700 lymphocytes per cubic millimeter, but no organisms were seen on smear. Cultures of the spinal fluid, urine and blood showed no growth.

An x-ray examination of the skull was negative. The pineal gland was calcified and not displaced. A chest film showed the heart to be prominent in the region of the left ventricle. The aorta was tortuous. There was evidence of healed pulmonary tuberculosis.

An electroencephalogram was grossly abnormal; the high-voltage, slow activity that constituted this abnormality appeared to be strongest in the anterior half of the head and was symmetrical except in the occiput where it was more marked on the left than on the right.

On the second day the patient was drowsier and more disoriented. No petechiae were seen. The temperature and pulse remained unchanged, and the respirations were about 20. The blood pressure varied from 220 systolic, 120 diastolic, to 240 systolic, 140 diastolic. The heart border was found by several examiners to lie 12 cm. from the midsternum in the fifth interspace. The pulmonic second sound was slightly greater than the aortic. The lungs were clear. The edge of the liver was felt two finger-breadths below the costal margin. There was no edema or dyspnea. The neurologic examination showed no change except for absent abdominal and cremasteric reflexes and increased rigidity of the neck. There was right horizontal nystagmus.

The extraocular muscles were normal, and the pupils reacted normally to light. The ophthalmoscopic findings were unchanged.

On the third hospital day the patient suddenly began to gasp, became unconscious and cyanotic and, within a few minutes, expired.

DIFFERENTIAL DIAGNOSIS

DR. MADELAINE R. BROWN: This is a remarkable case history and if I miss the diagnosis, it certainly will be my own fault. When I first read this record, it seemed to me to indicate a straightforward case of cerebral hemorrhage. After reading it a second time I began to see a few other things and it did not seem quite so simple.

We should consider several diagnoses. There are two that I need only mention. Brain tumor, such as angioma, may cause bleeding into the cerebrospinal fluid, but the onset here was sudden and the x-ray films showed that the pineal gland was in the midline; I think it unlikely that there was a tumor. The second diagnosis that needs mention is cerebral laceration. The patient bumped his head, but he had no fracture of the skull and I doubt that the blood was coming from a cerebral laceration. The conditions that we have to consider more seriously are a subarachnoid hemorrhage due to a ruptured aneurysm, a subdural hematoma and a cerebrovascular accident — either embolus, thrombosis or hemorrhage.

If we go back and attempt to reconstruct the story, the stage was set for a cerebrovascular accident. He had had hypertension for at least a year and possibly longer. He probably had cerebral arteriosclerosis and arteriosclerotic kidneys, and we know that he had retinal arteriosclerosis. He went to the dentist and had several teeth removed. Following this operation the dentist noticed that the patient was confused. Before the onset of a cerebral hemorrhage it is common for patients to complain of mental confusion, dizziness and headache. This patient knew that something was wrong and complained to his wife over the telephone that his jaw ached. He got into his car and started to drive, presumably to the office. He had an accident, probably because he lost consciousness. At least he remembered nothing about it, and the car was rather badly damaged. He escaped without any visible signs except a small bruise on the forehead. He got out of the car and started to wander around the city, although I do not know why he was allowed to. Apparently he bumped into people all the way because of his hemianopsia and could not find his office. Since he was able to walk, he had no hemiplegia, but he was confused and had a terrific headache. He again called his wife and said that he felt extremely ill. When he arrived home he was drowsy and confused but was well enough to get up and go to the bathroom that night. He still had no weakness

of the left side, but his headache became worse; he became more confused and finally was brought to the hospital. The next morning he had a stiff neck, bilateral Kernig signs, evidence of mental confusion and a spinal fluid that contained a great deal of blood.

If we try to localize this lesion before we discuss the nature of it, the electroencephalogram is not helpful. We have to depend on the clinical findings, and since all the signs are on the left, we must assume that the lesion was on the right side. What part of the right side? The hemianopsia seems to have been the most marked sign. Without hemiplegia or hemianesthesia we have to place the lesion in the occipital lobe, which indicates hemorrhage from the posterior cerebral artery and is rare. The most frequent source of cerebral hemorrhage is, of course, one of the short branches of the middle cerebral artery; the next is one of the long branches of the middle cerebral, then the anterior cerebral, the posterior cerebral and, finally, the basilar artery.

If we choose the posterior cerebral artery, even if it is an unusual site of hemorrhage, there are other signs for which we have to account — the weakness of the face, the questionable extensor plantar response, the hyperactive reflexes and absent abdominal reflexes on the left. So it seems to me that we have to make a diagnosis of two lesions: the second might have involved a small branch of the middle cerebral artery, supplying the right anterior central gyrus, or was possibly something outside the brain, such as a subdural hematoma.

If we place the chief lesion in the occipital lobe, what was its nature? Could there have been a subdural hematoma or ruptured aneurysm in the occipital area? Could there have been embolism or thrombosis rather than hemorrhage? It is possible that he had a subdural hematoma. He had an accident, and we know that people with arteriosclerosis are more susceptible to subdural hematoma than are those with normal vessels. But apparently the bruise on the forehead was a minor one. With a contrecoup effect one would expect involvement of the occipital region of the brain. It is possible, but not likely, that a recent subdural hematoma caused the blood in the spinal fluid, but it would not have caused the increased white-cell count, which usually comes from a rupture into the ventricle.

So far as aneurysm is concerned, certainly the homonymous hemianopsia is not typical of a ruptured aneurysm. Aneurysms of the cerebral vessels usually occur around the circle of Willis or at the beginning of the middle cerebral artery. It is possible that the mild hemiplegia was due to a ruptured aneurysm, but not the homonymous hemianopsia. So I do not believe that a ruptured aneurysm is likely.

Last of all we must consider the various kinds of vascular accidents. The chief lesion must have been a hemorrhage to account for the blood and white

corpuscles in the spinal fluid. There may have been a secondary lesion in the low parietal area to account for the weakness of the face, and that might have been an embolus in a small branch of the middle cerebral artery, following extraction of the teeth — an infected embolus. Or it might have been another small hemorrhage, but that is difficult to say.

I shall close with the following diagnoses: generalized arteriosclerosis, particularly retinal, cerebral and renal; hypertensive heart disease; hemorrhage into the right occipital lobe, with rupture into the ventricle; and possibly an embolus in a small branch of the right middle cerebral artery.

DR. JOST MICHELSEN: How do you account for the retinal hemorrhages?

DR. BROWN: Simply by the increased intracranial pressure, which was equivalent to 300 mm. of water. He may have had a subdural hematoma in addition to account for such an increase in pressure, but it does occur only with hemorrhage.

DR. FRANCIS M. RACKEMANN: Is not the story of the slow development of symptoms against severe hemorrhage?

DR. BROWN: Patients with severe cerebral hemorrhage generally do not have a sudden exitus. They usually last about as long as this patient did — from twenty-four hours to three days.

CLINICAL DIAGNOSIS

Cerebral hemorrhage.

DR. BROWN'S DIAGNOSES

Cerebral hemorrhage, right occipital region, with rupture into ventricle.
Embolus, branch of right middle cerebral artery?
Generalized arteriosclerosis.

ANATOMICAL DIAGNOSES

Cerebral hemorrhage, right posterior parietal region.
Dissecting aneurysm of aorta, with rupture into pericardium.
Cardiac hypertrophy, hypertensive type.
Generalized arteriosclerosis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Before I call on Dr. Kubik to tell what was found in the brain I shall describe what was found in the heart.

This man was a hypertensive. He had a large heart, which weighed 500 gm. In the aorta just above the aortic valve was an intimal tear that had produced a dissecting aneurysm in the aorta as far as the arch, where it stopped (Fig. 1). This is quite unusual, for it is customary for a dissecting aneurysm to continue down the aorta into the abdominal portion and into the iliac vessels. This one stopped at the orifice of the right innominate artery, below which there was another intimal tear communicating with the aneurysm. There was an external rup-

ture through the adventitia at about the level of the proximal tear, so that there was a hemopericardium, which was the cause of the sudden exitus. This unusual condition could not have been suspected clinically.

DR. CHARLES S. KUBIK: There was moderate to

into the lateral ventricle, but the ependyma of the inferior horn was blood stained, indicating that there had been some leakage, which unquestionably accounted for the bloody spinal fluid. Although cerebral hemorrhage may occur in practically any part of the brain, including the cerebellum, it is

FIGURE 1.

marked arteriosclerosis, affecting particularly the basilar artery. There were small cerebellar and right temporal pressure cones. The right cerebral hemisphere was considerably enlarged because of a massive hemorrhage, 6 cm. in diameter, in the right posterior parietal region. There was no rupture

unusual in the posterior parietal or occipital regions. The most frequent site is the region of the lenticular nucleus, and the next, the pons, whereas a small number are scattered about in different places.

DR. CASTLEMAN: It is interesting to speculate whether the accident had anything to do with the

of the left side, but his headache became worse; he became more confused and finally was brought to the hospital. The next morning he had a stiff neck, bilateral Kernig signs, evidence of mental confusion and a spinal fluid that contained a great deal of blood.

If we try to localize this lesion before we discuss the nature of it, the electroencephalogram is not helpful. We have to depend on the clinical findings, and since all the signs are on the left, we must assume that the lesion was on the right side. What part of the right side? PSYCHOSOMATICS

WHEN, in 1822, William Beaumont, a native of Lebanon, Connecticut, exercised his Yankee ingenuity by holding a pannikin under Saint Martin's gastric fistula and catching the drippings, he was selling the world no wooden nutmeg. He was anticipating the work that Pavlov would do later with considerable refinement in technic, — Pavlov, for instance, early abandoned the use of gunfire in producing his fistulas, — and he was paving the way for the conclusions that Cannon would arrive at somewhat later on the bodily changes in pain, hunger, fear and the various subsidiary emotions.

Beaumont, in other words, laid the groundwork for a scientific approach to the study of mind and matter, and the influence of the former over the latter — a reality empirically accepted and never for an instant doubted by Bishop Berkeley, the homeopaths, the mesmerists, Elisha Perkins and the followers of Mary Baker Eddy.

Except for a few ardent and credulous cults, however, and a numerically less imposing group of psychologically and scientifically minded physicians, it has required for the population at large a second world war and a popular pictorial magazine to acquaint them with the actuality of psychosomatics.

It is time for the public to tire of chasing vitamins, as a cat chases its tail, having it always with him but never catching up with it — the matter of vitamins was practically settled, as we are beginning to learn, with the discovery of food. But the psychic origin of peptic ulcer is something new over which to agonize, and the thought that a cold in the head, an attack of asthma or a cardiovascular crisis may have its inception in the imagination is, for many, a novel idea with which to toy.

We had not, as a matter of fact, entirely failed to realize that an appreciation of the power of the intellect over our more earthy functions is no new idea, regardless of the enthusiasm of the neopsychosomatists. John Hunter proclaimed his life to be in the hands of any man who dared annoy him; followers of the cult of voodoo will lay themselves down and die if they so much as think that the witch doctors are after them; and a combat soldier in any war has known that no intestinal pathogen is necessary to produce an attack of uncontrollable diarrhea. Any radio listener, indeed, who has been unable to avoid suffering at the sound of a warbled commercial plug while waiting for his favorite commentator knows how these silly symphonies of the air may inspire in some of their hearers feelings of the blackest melancholy and, in others, those of incipient nausea.

It is something to be aware of the psychic stimuli that can erupt at the somatic level; when we can control them we may indeed know the peace that passeth understanding.

dissecting aneurysm. We know that occasionally a dissecting aneurysm results from trauma. If this were so, there should have been evidence of trauma to the chest, which was lacking. The aorta did show medial degeneration or what is called "media necrosis cystica," which predisposes the aorta to the development of a dissecting aneurysm. I suppose that the symptoms that he might have had

because of the aneurysm were masked by those of the cerebral hemorrhage.

DR. KUBIK: How old was the dissecting aneurysm?

DR. CASTLEMAN: Just a matter of a few days. The blood in the dissecting aneurysm was rather fresh, not the organized clot that one usually sees in an old dissecting aneurysm.

HODGKIN'S DISEASE*

IV. Involvement of Certain Organs

HENRY JACKSON, JR., M.D.,† AND FREDERIC PARKER, JR., M.D.‡

BOSTON

IN THIS article the involvement of certain organs will be discussed.

HILAR NODES AND MEDIASTINAL TUMOR

Hodgkin's Paragranuloma

As has already been noted, involvement of the mediastinal lymph nodes occasionally occurs in Hodgkin's paragranuloma, and from the limited series of cases that have been under our observation, such involvement does not appear to alter the prognosis. Massive mediastinal tumors do not occur.

Hodgkin's Granuloma

It is a frequent event in Hodgkin's granuloma to find enlargement of the hilar nodes or the development of a large mediastinal tumor (Figs. 1 and 2). Peirce,¹ not all of whose cases were subjected to biopsy or autopsy, found in an exhaustive study of 198 cases that 38 per cent had either intrathoracic tumor or adenopathy, and he wisely noted that the roentgenographic evidence of such lesions was far greater than the clinical signs or symptoms of intrathoracic abnormality indicated.

Of 174 cases that were carefully followed at the Pondville Hospital or the Collis P. Huntington Memorial Hospital, 90 (52 per cent) had enlargement of either the hilar or mediastinal nodes, and in 26 of these the mass was sufficiently large to be dignified by the adjective "massive," for it involved at one time or another, well over half the diameter of the chest. In general, involvement of these nodes may be found at any time of life, although there is a tendency for the more massive tumors to develop in patients under thirty years of age.

Implication of the mediastinal and hilar nodes, although usually an early accompaniment of Hodg-

kin's granuloma, may occur at any time during the course of the disease. In 36 per cent of 90 cases in the present series with mediastinal involvement, it was found simultaneously with the apparent onset of the condition; in another 38 per cent, it appeared within less than a year; and in but 13 per cent had the fundamental disorder been outwardly manifest for over three years before the development of the mediastinal tumor. Such facts indicate clearly the necessity for roentgen-ray study of the chest when the patient is first seen, even though there are no symptoms or signs even remotely suggesting such lesions.

It is noteworthy that in but 1 case was there evidence during life of an intrathoracic mass without coincident or antecedent peripheral lymphadenopathy. This fact should be of considerable value in the differential diagnosis of mediastinal Hodgkin's granuloma from aneurysm of the aorta and from benign tumors amenable to surgical removal, and indicates the wisdom of searching with meticulous care for enlarged lymph nodes, especially in the neck and axillas, in the presence of mediastinal tumor.

In the case of a forty-three-year-old man who died of lobar pneumonia, autopsy showed involvement of the para-aortic and peribronchial lymph nodes without the slightest evidence of Hodgkin's granuloma elsewhere. The diseased nodes were markedly sclerotic and showed evidence of spontaneous healing. This case indicates the possibility of primary involvement of the mediastinum, and we have previously pointed out in the discussion of the pathological aspects of the disease that primary mediastinal involvement appeared in 9 of the autopsied cases.

The symptoms or signs that may properly be attributed to involvement of the mediastinum are summarized in Table 1. It will be seen that dyspnea, occasionally extreme, and cough, often harassing and persistent, were the most frequent symptoms. Pleural effusion, clubbing of the fingers and cyanosis were the most frequent signs, but it was not always

SCARLET FEVER AND STREPTOCOCCAL SORE THROAT

SOME time ago the *Journal* called attention to the fact that the rules of isolation and quarantine now in force in many communities have not kept pace with present-day understanding of the epidemiology of certain infectious diseases.¹ This is particularly true with regard to scarlet fever, which has been singled out from the group of hemolytic streptococcus infections as the only one in which isolation and quarantine are required. Although patients with scarlet fever are quarantined for three or four weeks, there are no restrictions placed on cases of tonsillitis or pharyngitis, which may be equally important in spreading streptococcal infections, including scarlet fever.

An important step has recently been taken by the Department of Health of New York City in an attempt to remedy this situation. The provisions regarding scarlet fever have been changed in the latest revision of the Sanitary Code in that city to read as follows²:

1. The reportable disease scarlet fever is now included in a wider classification, namely, streptococcal sore throat, including scarlet fever.
2. The isolation period for streptococcal sore throat, including scarlet fever, is as follows:

Uncomplicated case. Until the mucous membrane of nose and throat appear normal, but for not less than seven days after onset of the disease.

Complicated case (discharging nose and ears, mastoids, enlarged or suppurating glands, pneumonia). Until recovery from the complicating condition, except that, if the complication persists for forty-five days from onset, two cultures not less than twenty-four hours apart may be taken, and if these are negative for *Streptococcus haemolyticus*, the case may be discharged. Such cultures must be submitted to and examined by the laboratory of the Department of Health

3. Contacts are not excluded from school or work.
4. Visits by nurses to the homes of cases of scarlet fever are no longer required.
5. Children recovered from streptococcal sore throat, including scarlet fever, may be readmitted to school on a card issued by the Department of Health or the Department of Hospitals, or on a signed statement of a physician certifying that the child has recovered.

There will probably be some objections to the wording of the new regulations. It also remains to be seen whether they can be carried out as readily and effectively as the older ones. Nevertheless, it appears to be a step in the right direction. The

efficacy of the older regulations in reducing the spread of infection has been seriously questioned and it will be interesting to see whether these changes will in any way affect the epidemiologic pattern of scarlet fever and hemolytic streptococcus infection in New York City.

MASSACHUSETTS MEDICAL SOCIETY DEATH

MOIR — Marguerite W. Moir, M.D., of Boston, died December 3, 1944. She was in her seventy-second year. Dr. Moir received her degree from Boston University School of Medicine in 1918.

MISCELLANY PRIZE ESSAY

Modern Hospital has recently announced a competition for an essay on the subject "A Plan for Improving Hospital Treatment of Psychiatric Patients." Three prizes, totaling \$900, will be awarded by the judges, who will be drawn from the United States Public Health Service, the American Psychiatric Association and the National Committee on Mental Hygiene. The competition is open to anyone except the judges and the employees of *Modern Hospital*, and essays must be received by October 1, 1945. Further details may be obtained from the Modern Hospital Publishing Company, 919 North Michigan Avenue, Chicago 11.

NOTICES

ANNOUNCEMENTS

Dr. John B. Hall announces the removal of his office from 60 Windsor Street to 108 Dudley Street, Roxbury.

Dr. Savvas E. Theodore announces the removal of his office from 14 Chestnut Street, Springfield, to 510 Commonwealth Avenue, Boston.

MEDICAL ART SHOW

Modern Medicine's Medical Art Show will open at Yale University School of Medicine in the Harvey Cushing Room on May 20 and will continue until June 3. Previous showings at Baltimore's Enoch Pratt Library, the Cleveland Health Museum, the Minneapolis Public Library, Rochester Rundel Memorial Building and the Brooklyn Public Library have attracted over 100,000 people. The work of the late Mr. Broedel, often called the father of medical art, together with that of many of the artists who studied with him in the School of Art as Applied to Medicine, which he founded at Johns Hopkins University School of Medicine, forms a large part of the exhibit. Included among the exhibitors is Miss Muriel McLatchie, head of the school of illustration at the Massachusetts General Hospital. The collection has been assembled by *Modern Medicine* as a tribute to the American medical artist, too long unknown and unsung, and yet such a vital factor in recording all progress in medicine.

symptoms listed may well have been due to concomitant pathologic lesions not necessarily located within the chest. We are forced to the conclusion that x-ray examination of the chest is not only wise but necessary.

It is especially noteworthy that pleurisy with effusion frequently accompanies mediastinal involvement. In such cases the attendant physician should not only remove the fluid but should subsequently search carefully for evidence of hilar or mediastinal nodes so that appropriate x-ray therapy may be instituted if necessary.

In certain cases, the mass can be outlined by percussion anteriorly or gives rise to D'Espine's sign posteriorly, but it is often difficult to detect even a large mediastinal tumor by physical signs alone. It is, furthermore, necessary to remember that early involvement of the hilar or mediastinal lymph nodes may be completely masked, in the frontal plane, by the normal shadow of the heart and great vessels. Lateral or oblique views capable of visualizing the anterior and posterior mediastinal spaces should therefore always be taken. Early there is only an increase in the hilar shadows. Later there is obliteration of the normal outlines of the supracardiac shadow or a blocking out of the normally aerated substernal or retrocardiac space. As the process extends still farther, there appears a homogeneous, dense shadow, usually bilateral, with outlines that as a rule are sharply demarcated from the surrounding lung parenchyma, although there may be direct involvement of the lung parenchyma as well, and although in certain cases atelectasis of part of a lobe — particularly the lower — is brought about.

In some cases, the contour of the tumor is that of a truncated cone; in others, the mass is irregularly lobulated, and more rarely semicircular shadows project from the hilar region. On the basis of the x-ray findings alone, it is often impossible to differentiate mediastinal Hodgkin's granuloma, bronchiogenic carcinoma and aneurysm of the aorta, and we have seen a case in which a cervical lymph node

showed on biopsy Hodgkin's granuloma, whereas autopsy showed a large bronchiogenic carcinoma close to the hilar region. Of considerable value in differentiating tumor from aneurysm is the fact that in the former there is frequently a homolateral elevation of the diaphragm, a sign rarely seen in the presence of an aortic aneurysm.

Erythema nodosum should also be borne in mind. We have seen several patients who had considerable enlargement of the mediastinal nodes due to this condition, and as the enlargement may persist for a long time after the skin lesions have disappeared, the diagnosis may be difficult.

The course of the disease does not appear to be materially altered by the presence of hilar or mediastinal nodes, which usually respond surprisingly well to radiation. Of the 90 patients with mediastinal involvement in this series, 80 have died, with an average duration of life of 2.7 years. The average duration in the 10 living patients is 4.7 years, and 1 patient is still in reasonably good health thirteen years after onset. In rare cases, however, the mediastinal tumor develops so fast and to such an extent that death rapidly ensues.

Hodgkin's Sarcoma

Involvement of the mediastinal lymph nodes occurs in approximately one third of the cases of Hodgkin's sarcoma and is not infrequently associated with an extension of the process into the lung. In none of the present cases was there mediastinal involvement without coincident peripheral lymphadenopathy. It is evident from Table 2 that the symp-

None	2

toms are few in comparison with those of mediastinal involvement in Hodgkin's granuloma.

All patients with mediastinal involvement were over thirty-five years of age. This age distribution does not differ in general from that of Hodgkin's sarcoma.

Mediastinal involvement usually occurs late in the course of the disease. Very rarely it is the initial sign.

The nodes are usually only slightly enlarged. Rarely there is massive involvement. In 1 case, the process extended into the lung, giving rise to dullness over the entire right lower lobe. In view of the fact that the patient was admitted with a high temperature and these signs, the case was initially mistaken for one of lobar pneumonia. In the second case, there was extension into the parenchyma of the lung, but the process was not extensive.

without involvement of the mediastinum. In contrast to Hodgkin's granuloma, pleurisy with effusion is notably rare; we have seen but 1 case in which this complication occurred, and in this the effusion was bloody.

GASTROINTESTINAL TRACT

Hodgkin's Paragranuloma

Involvement of the gastrointestinal tract does not occur in this form of the disease.

Hodgkin's Granuloma

Gastrointestinal symptoms are frequent in Hodgkin's granuloma, but demonstrable lesions of the alimentary canal, either during life or at autopsy, are comparatively rare. Sherman⁵ has reviewed the literature pertaining to this interesting aspect of the subject, and the reader is especially referred to his excellent paper and the earlier more detailed study of Coronini.⁶ From many available articles it is difficult to be certain in many cases whether the lesions referred to are actually those of Hodgkin's granuloma, Hodgkin's sarcoma, lymphosarcoma or reticulum-cell sarcoma. In view of the fact that the incidence of gastrointestinal lesions as well as their treatment and prognosis differs according to the type of pathologic process present, this confusion is unfortunate yet readily understandable, for the histologic picture of lymphoma in the gastrointestinal tract is by no means so simple and definite as it usually is in the lymph nodes.

It seems clear, however, that Hodgkin's granuloma occasionally occurs as a primary and possibly as an isolated lesion of the alimentary canal and that secondary gastrointestinal lesions are found in the generalized disease, usually rather late in the course. There are few reliable statistics concerning the actual frequency of such lesions. Sternberg,⁷ however, whose criteria for the diagnosis were clear-cut and definitive, found that in 52 autopsies the stomach was involved in 6 cases and the small intestine in 5. As already stated in the part of this article dealing with the pathological aspects of the disease, our experience is similar. Twenty-four of the 213 patients in this series had gastrointestinal symptoms at onset, yet only 9 of these could subsequently be shown to have any intrinsic lesion of the stomach or bowel. During the course of the disease such complaints are more frequent, and indeed they may for a time dominate the clinical picture. Anorexia, abdominal pain, nausea, vomiting and constipation — occasionally alternating with diarrhea — were the most frequent symptoms in 174 cases followed to date or death (Table 3).

Among all these patients exhibiting gastrointestinal symptoms late in their course, only 3 were shown during life to have actual intrinsic lesions of the alimentary canal. In 2 cases, the lesion was in the lower part of the large intestine and responded

well, at least for a time, to cautious x-ray therapy (Figs. 5 and 6). In the third case, the lesion was in the esophagus (Fig. 7), and there was poor response to radiation.

It is probable that such symptoms as loss of appetite, nausea and vomiting can be attributed to the general systemic effects of the disease, and all are likely to be temporarily aggravated by x-ray therapy, although often subsequently relieved by the same therapeutics. It is well to advise patients that this is so.

Abdominal pain seems to be caused in the majority of cases by enlarged lymph nodes pressing on sensory nerves. Dysphagia may be due either to pressure from a mediastinal tumor on the esophagus or to an intrinsic lesion of that structure. Extremely rarely, it is due to massive involvement of

the tonsils by the granulomatous process. Hematemesis was directly traceable in 1 case to a widespread involvement of the stomach, but in 2 cases in which this symptom was a prominent feature, no gastrointestinal lesion could be demonstrated even after careful clinical study. It is possible that in such cases the vomiting of blood is secondary to the general hemorrhagic diathesis that is occasionally seen, particularly toward the end of the disease, or that the cause would have been found at autopsy. Similarly, melena was obviously caused by gastrointestinal lesions in 3 cases, yet in 2 cases in which this symptom appeared late in the disease no cause could be found during life.

In the 174 cases followed to date or to death, definite clinical evidence of lesions of the gastrointestinal tract was found in 9 cases (5 per cent). In 6 of these, the lesions proved at autopsy to be primary in the gastrointestinal tract and confined almost entirely to the viscus concerned and the immediately adjacent lymph nodes, so that there seems to be some justification for speaking of the gastrointestinal form of Hodgkin's granuloma. The stomach was involved in 3 cases, the cecum in 2, the sigmoid in 2, and the duodenum and esophagus each in 1.

It is to be noted that in no case was there multiple involvement of the gastrointestinal tract, although in a larger series, of course, such might well be true. In no case were these lesions suspected or demonstrated during life. The clinical importance of these post-mortem findings lies in the fact that such lesions may for some time be asymptomatic, yet the

It seems doubtful whether mediastinal involvement has any particular bearing on the prognosis of any given case.

LUNGS

Hodgkin's Paragranuloma

In Hodgkin's paragranuloma, involvement of the lung does not occur. Occasionally, however, there is implication of the mediastinal nodes, and the occurrence of such an event, as previously indicated, does not necessarily imply that the prognosis is poor.

Hodgkin's Granuloma

Evidence of involvement of the lung is not infrequent during the course of Hodgkin's granuloma, and pulmonary lesions are found at autopsy with even greater frequency. Peirce,¹ in a careful study of 198 cases, in 85 per cent of which the diagnosis had been substantiated by biopsy or autopsy, found that 14 per cent showed roentgenologic evidence of parenchymal infiltration without pleural involvement and noted that the lesions might simulate acute inflammatory disease, pulmonary abscess, tuberculosis, primary carcinoma or metastatic neoplasm. In the present series of proved cases followed to date or to death, roentgenologic evidence of lung involvement was also found in 14 per cent. As already pointed out, pulmonary lesions are even more frequent at autopsy; in this series, there was involvement in 41 per cent.

Versé² has carefully reviewed the literature pertaining to this aspect of Hodgkin's disease, and concludes that the lung is involved either primarily or secondarily in approximately one third of all cases coming to autopsy. Enlargement of the mediastinal and hilar nodes may, furthermore, bring about partial or complete stenosis of the bronchi, with consequent pulmonary atelectasis, and the pulmonary signs or symptoms arising from such a sequence of events are not infrequently of greater import than those due to direct involvement of the lung. Moreover, it should be pointed out that not infrequently, under x-ray therapy, a mediastinal mass entirely disappears while the parenchymal lesions remain relatively unchanged.³ It is possible that some of these so-called "parenchymatous lesions" are in reality small areas of atelectasis peripheral to obstruction of a small bronchus.

In very rare cases, necrosis of some magnitude develops so that cavities simulating those of tuberculosis or abscess are seen. Versé² cites 8 such cases; we ourselves have not seen this type of lesion.

Invasion of the lung may occur at any time during the course of the disease. Weber⁴ describes the case of a seventy-three-year-old woman in whom a diagnosis of primary bronchiogenic carcinoma had been made on clinical grounds. Autopsy showed Hodg-

kin's granuloma involving the main bronchi on the left, together with a small portion of the adjacent lung tissue. No metastases, even in the hilar nodes, could be demonstrated. Versé³ has collected from the literature and from his own material 10 cases in which the pathologic process was apparently primary in the lung or bronchi. Such cases are, however, admittedly extremely rare, and we have not seen any.

In our own series, pulmonary lesions were demonstrated by x-ray studies as early as one month after the apparent onset of the disease and as late as twelve years after it. It must be remembered, however, that unless routine x-ray studies are carried out at fairly frequent intervals, the precise time of the development of the parenchymal infiltration may be misjudged, for it is obvious that many of the symptoms and signs depend not on parenchymal involvement itself but rather on enlargement of hilar or mediastinal nodes.

The most frequent symptoms found in patients with parenchymal disease are dyspnea, cough and fever. More rarely the patient complains of pain in the chest. Hemoptysis is extremely unusual, and its presence should arouse one's suspicion of tuberculosis. Occasionally there are neither symptoms nor signs, — a fact that serves to emphasize the importance of routine x-ray examination of the chest, — and it is worth while to draw attention once more to the obvious fact that any of the signs and symptoms of parenchymal involvement may be occasioned by the presence of a mediastinal mass. Twenty per cent of patients showing pulmonary involvement have pleurisy with effusion. Only extremely rarely is this effusion bloody.

The x-ray picture of pulmonary Hodgkin's granuloma is in no sense pathognomonic. As has already been said, the picture may simulate acute inflammatory disease, pulmonary abscess, tuberculosis, primary bronchiogenic carcinoma or metastatic neoplasm¹ (Fig. 3), and it must be remembered that pulmonary tuberculosis is a not infrequent complication of Hodgkin's granuloma (Fig. 4).

Hodgkin's Sarcoma

The lungs are involved in Hodgkin's sarcoma in approximately 28 per cent of the cases, or nearly twice as often as in Hodgkin's granuloma. In all cases, there were cough and dyspnea, which were frequently severe. Fever is not unusual, although it is rather unusual in Hodgkin's sarcoma as a whole, and chills are rarely seen. Conversely, the presence of persistent cough generally indicates that the parenchyma of the lung has been invaded. The pulmonary lesions may extend outward from the mediastinum or they may resemble patches of bronchopneumonia. Rarely there is massive involvement of an entire lobe.

Parenchymal involvement of the lung is usually associated with involvement of the mediastinal nodes. Much more rarely there are isolated areas

patient may die suddenly from a rupture of a gastric or intestinal granulomatous lesion. This event took place in 1 patient, who was discharged apparently in good condition but died six hours later from a ruptured large intestine.

Clinically, Hodgkin's granuloma of the gastro-intestinal tract most frequently simulates carcinoma, ulcerative colitis or enteritis, or obstruction of the bowel.⁵ The majority of published cases have occurred in the fifth and sixth decades of life, and this was so in the present series.

Coincident enlargement of the superficial lymph nodes is said to be infrequent.^{5, 6} One patient had what appeared on x-ray examination to be a carcinoma of the stomach. There was no peripheral lymphadenopathy. He was operated on later, and the stomach was found to be extensively involved with Hodgkin's granuloma.

With involvement of the stomach, the signs and symptoms do not differ materially from those of carcinoma, and epigastric pain, melena, loss of weight, hematemesis and vomiting are the most frequent ones. Rarely a mass is felt. Singer⁹ believes that the disclosure at operation of a soft, flat, infiltrating tumor associated with isolated soft lymph nodes in the adjoining mesentery should arouse the suspicion of Hodgkin's disease. He adds, however, that for a final diagnosis the microscope is indispensable. With this we agree. Involvement of the intestine produces symptoms that are much the same, although abdominal pain and constipation are usually more prominent than they are with involvement of the stomach. Hemorrhage and perforation are rare but, as has been pointed out, may be fatal.

On x-ray examination, the findings again are usually those of carcinoma. A single case with an esophageal lesion illustrates this point.

E. J. (H 59-583), a 59-year-old man, was admitted to the hospital on May 8, 1939. The past and family histories were uneventful. In April, 3 weeks before entry, he noticed a lump above the right clavicle. This was removed at another hospital, and a microscopic diagnosis of Hodgkin's granuloma was made and confirmed by us later.

Physical examination on admission showed a well-developed and well-nourished man. No abnormalities of importance were found other than a few bean-sized lymph nodes in the right axilla. The laboratory findings were essentially normal. Deep x-ray therapy was given, with a total of 1000 r, divided between the right side of the neck and the right axilla, and within a few weeks the enlarged nodes had disappeared.

The patient remained symptom-free until December, when he began to complain of difficulty in swallowing. X-ray studies showed an extensive irregularity of the middle third of the esophagus (Fig. 7), and an esophagoscopy on January 10, 1940, showed a large, freely bleeding and obstructive neoplastic process at the junction of the middle and lower thirds. A biopsy taken at that time showed a lesion with the characteristic picture of Hodgkin's granuloma. After appropriate x-ray therapy no trace of the lesion could be found by x-ray studies. After several months, the patient died of unknown causes.

It is impossible to say with any degree of assurance whether the esophageal lesion was primary or secondary, although the latter seems the likelier. In

any event, it was the only lesion of the esophagus seen in the 174 cases of Hodgkin's granuloma.

In 2 cases, the gastric lesion involved the greater curvature. In a third case, there was tremendous dilatation of the stomach owing to an obstructive lesion at the pyloric area, an unusual finding in gastric carcinoma. In all there was marked reduction of the peristaltic waves over a wide area. In no case was there the convoluted appearance that has been said to be characteristic of lymphoma.

C. H. (BCH 828826), a 56-year-old woman, was admitted to the hospital on July 9, 1936. The past history was uneventful, except that she had had a chronic productive cough for many years. Two months before entry, she noticed considerable weakness and fatigue, and during the next few weeks she vomited on numerous occasions and lost much weight. For a week before admission, she had had fever and night sweats. There was no abdominal pain, anorexia, nausea, melena or hematemesis.

Physical examination showed an emaciated, rather drowsy woman. There was a harsh, rasping systolic murmur over the entire precordium, heard best at the apex and transmitted up the vessels of the neck. The heart was enlarged 2 cm. beyond the midclavicular line. There were dullness and moist rales at the bases of both lungs. In the right para-umbilical area was felt a small, irregular, firm mass that descended freely on respiration. Otherwise the physical examination revealed no abnormalities of importance.

The red-cell count was 2,750,000, the hemoglobin 46 per cent, and the white-cell count 4000 with 60 per cent segmented neutrophils, 21 per cent young neutrophils, 2 per cent eosinophils, 5 per cent lymphocytes, 5 per cent myelocytes and 4 per cent myeloblasts. The stools gave a strongly positive guaiac test.

The temperature was of the septic type, ranging each day from 99 in the morning to 103°F. at night. The respirations were normal. The pulse averaged 115.

X-ray films of the lungs showed congestion of both bases. Those of the gastrointestinal tract showed that the second portion of the duodenum was irregular and mottled in appearance, with a definite narrowing at the junction of the second and third portions. A diagnosis of carcinoma of the duodenum was made.

The patient continued to run a septic temperature, became increasingly drowsy and died less than a month after admission.

Autopsy (A 56-449). This showed Hodgkin's granuloma primary in the second and third portions of the duodenum, with extension to the immediately adjacent mesenteric lymph nodes. That portion of the jejunum immediately distal to the duodenum was necrotic, and it ruptured as the bowel was being dissected out. Death appeared to have been brought about by inanition and terminal multiple pulmonary emboli.

In the large intestine, two types of lesions may be seen — an annular constriction and a destruction of the mucosal pattern with hypermotility and increased irritability.

C. L. (BCH 490440), a 50-year-old woman, was admitted to the hospital on December 27, 1924. A year before she had noted some loss of weight, and on two occasions had passed a small amount of bright blood by rectum. Two months prior to entry she noticed increasingly severe constipation, alternating with short bouts of diarrhea. Six weeks later, there developed a severe dull pain in the right lower quadrant of the abdomen, made worse by eating, and on three occasions during the next month she again passed blood by rectum. Physical examination revealed only a firm, irregular, slightly tender mass the size of a small orange in the right lower quadrant. X-ray examination showed some mottling of the cecum near the ileocecal valve, and the cecum was displaced upward, as if by a mass outside the gastrointestinal tract.

Operation was performed on January 1, 1925, and a large mass was found involving the appendix and the cecum.

FIGURE 8. *Hodgkin's Sarcoma of the Stomach.*

Only from a series of cases that has been carefully studied and painstakingly followed can one properly judge of the frequency of such changes. We have derived our figures from the cases observed and followed at the Collis P. Huntington Memorial Hospital and the Pondville Hospital. In neither institution have routine bone plates been taken, but each patient has been so studied clinically and radiographically that at least the majority of gross lesions have been detected during life.

One hundred and thirty-three cases of proved Hodgkin's granuloma have been followed to date or to death at these two hospitals only, and of these, 30 (23 per cent) showed during life one or more bone lesions. Both Uehlinger¹⁰ and Dresser¹¹ found the changes most frequent in the spine and pelvis. Such has also been our experience (Table 5). Dres-

ser's¹¹ distribution figures on 66 cases are comparable, although it should be borne in mind that, in all probability, not all his patients had Hodgkin's granuloma.

Age does not appear to be a factor, for cases with bone lesions were distributed almost as evenly throughout the decades as the disease itself (Table 6).

Uehlinger¹⁰ believes that bone lesions occur late in the course of the disease. This is not in accord with our experience, for in 30 cases showing bone

TABLE 6. *Age Distribution of Patients with Hodgkin's Granuloma Who Had Bone Lesions.*

involvement the lesion was found in less than one year from onset in 22 per cent, and in only 6 cases had the disease been present for over four years before the bone change was noted. In 5 cases, the bone lesion was the first recognizable indication of the disease or occurred within six months after its onset. Dresser and Spencer¹¹ arrived at similar conclusions, for they write, "In our series of 66 cases there were 16 in which the bone lesions gave rise to the presenting symptoms; that is, the bones

were involved early in the course of the disease in nearly 25 per cent." Their figure may be a little too high, for there is good evidence that some of the cases they refer to were actually examples of primary reticulum-cell sarcoma of bone, a condition not described or recognized as such at the time they wrote. In view of the fact that primary reticulum-cell sarcoma of bone is probably best treated by amputation and subsequent prophylactic radiation, it is of great importance to maintain a nice distinction between these two conditions.¹²

The following case illustrates the early bone lesions in Hodgkin's granuloma.

M. L. (P-3650), a 44-year-old man, was admitted to the hospital on August 24, 1931. In the previous January he had complained of severe pain in his right hip, especially on walking. The pain steadily increased, and in June he was admitted to another hospital, where it was noted that there was both cervical and inguinal lymphadenopathy. A biopsy was done, and a diagnosis of Hodgkin's granuloma was made. On September 1, x-ray studies showed a greatly increased hilar shadow. Roentgen films revealed a large bony outgrowth from the lateral margin of the right ilium and considerable lacework-like new bone formation about the upper end of the right femur in the intertrochanteric region and the upper end of the shaft. There was also slight thickening of the cortex of the upper end of the left tibia, and the lumbar spine showed a slight but definite increase in the density of the body of the fourth vertebra. These changes were regarded as consistent with Hodgkin's granuloma. The patient failed rapidly and died on January 23, 1932 (Uehlinger's¹⁰ Case 9 presented a similar x-ray appearance.)

In this case it is clear that the bone lesion first attracted the patient's attention to his condition, and it appears from the history that it occurred early in the course of the disease, if, indeed, it was not the initial lesion.

The roentgen-ray picture is in no way characteristic (Figs. 9-12). It generally simulates metastatic carcinoma, but may be confused with Ewing's tumor, osteogenic sarcoma, osteomyelitis or multiple myeloma. The lesion is usually destructive, especially in the spine, where it occasionally results in the collapse of one or more vertebrae. As a result of this collapse there may be flaccid, or more rarely spastic, paralysis. Paralysis occurred in 8 of our cases in which the spine was involved. It must be remembered, however, that collapse may occur without paralysis, and indeed without symptoms, and, on the other hand, that the vertebrae may be involved by direct extension from adjacent lymph nodes and that simultaneous extension from these same lymph nodes to the dura or the epidural space with tumor formation is probably a much more frequent cause of neurologic symptoms than is vertebral collapse as such. This has at least been our experience.

It is chiefly the bodies of the vertebrae that are involved. More rarely, the transverse processes or the spines are the site of disease. The intervertebral disks are characteristically spared. Occasionally the lesion is chiefly proliferative. Exceptionally one sees the *Elfenbeinwirbel* or ivory vertebrae so

There were several soft lymph nodes in the adjacent mesentery. The mass and the nodes were removed, and an ileocolostomy was performed. On histologic examination the lesion proved to be Hodgkin's granuloma. At operation there was no evidence of disease elsewhere.

The patient died of bronchopneumonia 2 days later. Since there was no autopsy, it cannot be said with any certainty that the disease was confined to the cecum and adjacent nodes, although this seems probable.

In patients with gastrointestinal lesions, an anemia of moderate or severe grade is frequent. We cannot agree that any diagnostic significance can be ascribed to the white-cell count, for both leukopenia and leukocytosis are encountered with equal frequency and indeed often alternate in the same patient. Fever is frequent and was present in 4 of the 6 cases with primary disease in the gastrointestinal tract; in 1 of these it was a striking feature. Since fever is usually present in patients with Hodgkin's granuloma, no special diagnostic importance can be attached to it.

It is doubtful whether a clinical diagnosis of Hodgkin's granuloma of the gastrointestinal tract can be made with any degree of assurance, although the presence of a lesion reminiscent of carcinoma in a patient with an unexplained septic temperature and either a leukopenia or a marked polymorphonuclear leukocytosis not readily explainable on other grounds is suggestive.

Hodgkin's Sarcoma

The symptoms referable to the gastrointestinal tract, particularly anorexia, which is often severe, occur in approximately 50 per cent of cases during life (Table 4). Constipation is not infrequent;

TABLE 4. *Gastrointestinal Symptoms in Thirty-Two Cases of Hodgkin's Sarcoma.*

SYMPTOM	NO. OF CASES
Anorexia	14
Constipation	7
Vomiting	7
Nausea	6
Hematemesis	3
Diarrhea	1

diarrhea is rare. Hematemesis, not always explainable either clinically or at autopsy, occurs occasionally. As in the case of Hodgkin's granuloma, gastrointestinal symptoms may occur without any lesion's being demonstrable. On the other hand, it is extremely unusual to have an asymptomatic lesion of the stomach or intestine, such as one not infrequently seen in Hodgkin's granuloma.

Both clinical and autopsy findings indicate that multiple involvement of the gastrointestinal tract is not infrequent. Thus, in 6 cases with clinical evidence of gastrointestinal disease, the colon was involved in 4, the duodenum in 3, the stomach in 2, and the rectum in 1, there being multiple involvement in 3. Again, there is marked contrast to the situation in Hodgkin's granuloma, in which gastrointestinal lesions are almost invariably single.

The following case illustrates the course of Hodgkin's sarcoma when the gastrointestinal tract is involved.

J C. (BCH 974896), a 52-year-old woman, was admitted to the hospital on March 10, 1940, with the chief complaint of a painless lump in the neck of 2 months' duration. In addition, she had experienced some difficulty in swallowing and hoarseness. She was constantly nauseated and had no appetite, but there was no vomiting. There was marked weakness. She had occasional distress in the left upper quadrant of the abdomen but no real pain. The past and family histories were uneventful.

Physical examination showed a moderately obese woman with a rather sallow complexion. There was a moderately firm mass about 2 cm. in diameter in the right side of the neck. Otherwise the examination showed no notable abnormalities.

X-ray studies of the gastrointestinal tract showed a large, fungating tumor arising from the superolateral wall of the cardia (Fig. 8). Gastric analysis showed normal amounts of hydrochloric acid and a + guaiac reaction. There was no anemia. The white-cell count and differential count were essentially normal. All stools gave a +++ guaiac reaction.

The patient failed rapidly and died on April 20, less than 4 months after the initial symptoms.

Autopsy. This showed Hodgkin's sarcoma of the stomach with metastases to the pleura, diaphragm, spleen, liver, large intestine, pancreas and abdominal lymph nodes.

BONES

Hodgkin's Paragranuloma

Involvement of the bones does not occur in Hodgkin's paragranuloma.

Hodgkin's Granuloma

Lesions of the bones in Hodgkin's granuloma are frequent, important and usually serious.¹⁰ It should be emphasized that we are concerned only with the lesions giving rise to signs or symptoms during life and usually, although not invariably, recognizable by proper radiographic technic. The frequency or paucity of such lesions in no way reflects the incidence of involvement of bones as determined by complete study of autopsy material, for it has repeatedly been shown that medullary lesions demonstrated post mortem may not be detected by x-ray. This fact does not detract from the usefulness of searching for lesions during life.

The frequency of bone involvement at autopsy has already been discussed. Uehlinger,¹⁰ dealing almost entirely with autopsy material, places the incidence as high as 34 per cent, and he expressly states that he is concerned only with Hodgkin's granuloma. Dresser and Spencer¹¹ say, "One may expect to find roentgen changes ante mortem in approximately 10 per cent of all cases of Hodgkin's disease." The series from which they derived their data, however, included not only that condition but also lymphosarcoma and reticulum-cell sarcoma. Since in our experience bone lesions in the latter conditions are comparatively infrequent, it is probable that the incidence in these authors' series of Hodgkin's granuloma was, in actuality, higher than that reported.

accurately described and superbly pictured by Hultén.¹³ Not infrequently both new-bone formation and bone destruction are present. Very rarely multiple punched-out areas indistinguishable from those of multiple myeloma are seen.

Pathologic fracture occurs rarely. We have seen only one example, and that in a rib. In contrast, pathologic fracture is fairly frequent in primary reticulum-cell sarcoma of bone.

Periosteal new bone formation may be seen alone or, oftener, in conjunction with medullary lesions.

In the long bones the metaphyses are chiefly involved. Dresser and Spencer¹¹ report involvement of the shaft. This we have not seen.

The ribs, especially those portions close to the vertebrae and sternum, are frequent sites of invasion. The sternum may be invaded directly from an underlying mediastinal mass, and it is of some practical importance that such sternal lesions seem to do exceptionally well under treatment. The pelvis is oftenest involved in the region of the iliac crest or the sacroiliac joints.

Unequivocal cases of Hodgkin's granuloma confined to bone have not been described.

Uehlinger¹⁰ and others believe that abnormalities of the peripheral blood picture, especially leukopenia, are frequently the best indication of a bone lesion. We have not found this to be so. Neither the red-cell nor the white-cell count altered in any material manner after the development of the bone lesion. Of the 2 cases with the most extensive bone changes in this series, one showed a marked polymorphonuclear leukocytosis, and the other a moderate leukopenia. Both had only a moderate degree of anemia, even at the time of death. We have seen no evidence that an eosinophilia is indicative of bone involvement as some have claimed.

The most frequent symptom is pain, and when one considers that the patient's attention may be drawn to his condition primarily by the bone lesion and that lymphadenopathy may be minimal at that time, and therefore often overlooked, the importance of the search for and recognition of early bone lesions is obvious.

It is important further to recognize that pain due to bone lesions may be present for a considerable period of time before the x-ray films show any recognizable change. In 13 per cent of our cases with bone lesions, pain was present for a period of two to twelve months before the lesion was visualized, in spite of repeated x-ray examinations. The therapeutic implications of this observation are obvious. In the presence of proved Hodgkin's granuloma, the appearance of pain referable to a bony structure or a joint may properly be regarded as an indication for irradiation even though no bony lesion can be found at the time. On the other hand, one occasionally finds on routine x-ray examination gross bone lesions without concomitant symptoms. This is particularly true of the skull,

invasion of which frequently gives no other clinical evidence than the appearance of a soft-tissue mass directly over the area of bone destruction. Similarly, lesions of the pelvis are apt to be painless unless they involve the sacroiliac joint or the hip joint. Under the latter circumstances, the pain is apt to radiate down one or both legs and be mistaken by the unwary for back strain or simple "sciatica." Tenderness over involved bones is surprisingly infrequent.

Hodgkin's Sarcoma

Clinically apparent involvement of bone is comparatively infrequent in Hodgkin's sarcoma, occurring in less than 10 per cent of our cases. In one case, there was a small destructive lesion in the upper end of one tibia. In another, there was a localized, proliferative lesion in the upper end of the femur. In still another, there was an extensive destructive process of the skull. In a fourth case, there was direct extension from the pharynx into the bony structure of the antrum, causing severe and intractable pain. In all the other cases, the bone lesion resulted merely in a moderate degree of pain.

In our experience, the bone lesions usually occur early in the course of Hodgkin's sarcoma. They may appear later, but in view of the fact that the majority of patients die within a year and a half of apparent onset, such observations on the time of appearance of the bone lesions are of little practical value.

SKIN

Hodgkin's Paragranuloma

Skin lesions do not occur in Hodgkin's paragranuloma.

Hodgkin's Granuloma

Skin lesions in Hodgkin's granuloma are of common occurrence.^{14, 15} Severe generalized pruritus, not infrequently resulting in marked excoriation of the skin, is perhaps the most frequent one. Generalized or, more rarely, localized pigmentation occurs aside from that due to radiation therapy. Herpes zoster (Fig. 13), not infrequently of a hemorrhagic type and often leaving behind it an indurated scar (Fig. 14), is not unusual. The more specific lesions, — that is, those which on biopsy show the characteristic features of Hodgkin's granuloma, — are most frequently nodular (Fig. 15) or ulcerated (Fig. 16). These may exist for a long time prior to unequivocal evidence of the disease elsewhere.¹⁶ Generalized exfoliative dermatitis has been reported, and we have seen 1 case with this complication.

Hodgkin's Sarcoma

In Hodgkin's sarcoma, lesions of the skin occur in approximately 30 per cent of the cases and may

FIGURE 12 *Hodgkin's Sarcoma of the Skull*

be extremely marked. They are usually papular, and dull red and frequently scaly, resembling closely the lesions of mycosis fungoides. Rarely there are subcutaneous lesions 1 to 3 cm. in diameter. We have never seen ulceration.

Patchy or extensive erythematous lesions are occasionally seen. Itching is extremely rare.

THE INCREASING COST OF MEDICAL CARE: ITS RELATION TO HOSPITALS AND SPECIALIZATION IN MEDICINE*

GEORGE W. HOLMES, M.D.†

BOSTON

THE purpose of this paper is to state briefly the causes that, in my opinion, have led to an increase in the cost of sickness, to review the various attempts that have been made to meet it, and to suggest certain lines of approach that might lead to a solution of the problem.

The present high cost of sickness had its beginning in the latter part of the last century, and is due almost entirely to the rapid advances of medical science and the general acceptance of the community hospital instead of the home as the best place for the care of the sick. That both these trends are sound is shown by the rapid growth of specialization in medicine and the increasing use of hospital service by the well-to-do, the patient of moderate means and the practitioner of medicine.

Fifty years ago the care of sickness in those able to pay was largely in the hands of the family physician. The indigent were cared for in the great charity hospitals. There were very few so-called "private hospitals." Even such major therapeutic procedures as surgical operations were often done in the home. When the cause of the illness could not be established, or the patient did not improve under treatment, a consultation was sought. Often another general practitioner was called; at times, the advice of a surgeon or some other specialist was obtained. In either case, the patient remained in his home and was cared for by the members of the household. Only the well-to-do employed a professional nurse.

An accident that occurred in my own family some fifty years ago will serve as an example to

contrast the procedure then and now. My brother, a boy of ten, fell from a scaffold in the barn, fracturing his femur in the middle third of the bone. Our family doctor was called, the diagnosis was established, a temporary splint was applied, and the patient was placed in his bed. Of course there was no x-ray examination, and I doubt very much if any search was made for injury elsewhere in the body. In due time the doctor returned with some cords and pulleys, which he had obtained from the hardware store, a can of ether and some adhesive. My father gave the ether under the doctor's direction. The fracture was reduced, and the splints and traction were applied. My mother and other members of the family attended to the nursing care. The fracture healed in the usual time; there was no deformity or limp. The doctor's bill was twenty-five dollars, and there were no other expenses.

Now, let us consider what would happen if the same accident occurred today. My father was a prosperous farmer and would have been classified in the "moderate means" group. The boy would have been taken to the hospital, roentgenograms would have been taken before and after reduction, and the operation would have been done by a surgeon who would have required two assistants, with the usual nurses. There would have been an operating-room charge, the routine laboratory charges and the charges for room, board and nursing care during the stay in the hospital. This would have constituted the hospital bill and would have had to be paid at once. In addition, there would have been the surgeon's fee and the x-ray charges. A moderate estimate of the total cost would be between five and six hundred dollars, which is more than the

placed on a full-time salaried basis. This was also a departure from established custom in hospital-staff relations. Since the simple plan, worked out at that time, has been in operation for twenty-eight years with complete satisfaction to all concerned, it would seem that it might be considered as a basis for the establishment of hospital-staff relations in other branches of medicine and in other hospitals. The following abstract presents the important features of this plan.

The roentgenologist is to give his entire time to the work and the direction of the work done in the roentgenologic department of this hospital, excepting such teaching as may be required of him by the Harvard Medical School and its postgraduate school. The amount of this teaching is controlled by the executive staff of the hospital and the faculty of the school. According to this arrangement the roentgenologist is to receive a yearly salary of a stated amount, but should the income to the hospital from his work in connection with the private pavilion at any time considerably exceed the expense of maintaining this branch of the work plus his salary, he is to receive a proportionate part of such earnings. It is also understood that the roentgenologist may reduce his earnings from private fees if he so desires in order that he may have sufficient time for research.

In other words, the roentgenologist is allowed to control his income and the character of his work within reasonable limits. The general principles of this plan can be applied to any form of hospital-physician arrangement.

If a working agreement of this sort could be established between the hospitals and their medical staffs, the only problem remaining would be that of arranging the cost to the individual patient in such a way that it could be met without too much difficulty.

The cost of hospital service is already being handled satisfactorily by such forms of voluntary insurance as the Blue Cross. This type of insurance is inexpensive, and it protects the patient against the largest and most urgent expense in case of illness. It should be encouraged and expanded.

As yet no satisfactory form of insurance against the cost of medical service has been devised, although many attempts to do so have been made, and the literature on the subject is voluminous. Faxon,¹ in a recent paper, has discussed the advantages and disadvantages of voluntary and compulsory insurance. A symposium on this subject was conducted at the annual meeting of the American Medical Association in June, 1944. Of the various plans discussed at this symposium, that presented by McCann² seems the most likely to be workable, and it is the plan sponsored by the Massachusetts Medical Society.

One of the stumbling blocks in all the plans suggested has been the high cost — to the patient, to

the state or to the medical profession. Any plan to cover the complete cost of sickness must of necessity be expensive and will not be voluntarily accepted by the public. One reason why complete health insurance is expensive is because it tends to increase the number of patients applying for treatment. It is a well-known trait of human nature to feel dissatisfied when there is no return from an investment in protection, and as a rule an attempt is made to get something back, especially if this can be done without additional cost. Insurance companies have long recognized this fact, and have met the problem by providing cash returns at a specified time, or by requiring the insured to pay a part of the initial cost.

If an insurance plan to protect the paying patient against the cost of specialized medical service could be worked out, it might offer a satisfactory solution of the problem. By "specialized medical service" is meant all consultations and such therapeutic procedures as require special training on the part of the physician. It does not mean routine visits and treatment by the attending physician. Such a plan would not disturb the present relation between the patient and the family physician. It would operate only when the patient's illness was such that hospitalization and the advice of, or treatment by, a specialist became necessary. If the amount allowed for any one illness were limited, it would tend in the long run to establish a standard of charges for specialized services, and since the patient would have to meet the first cost, — that of the family physician, — it would not be abused. The amount necessary for such coverage would therefore be low enough to make it attractive and to ensure its general acceptance. There are, of course, many difficulties to overcome, most important of which is a satisfactory arrangement between those doing specialized medicine outside the hospital and those doing all, or the greater part of, their work within the hospital. None of these difficulties, however, are insurmountable, and all could, I think, be solved by a properly selected board. It is possible that the Blue Shield, sponsored by the Massachusetts Medical Society, could be modified to meet the requirements.

* * *

In conclusion, the following statements seem to summarize the problem.

There is widespread demand on the part of the public for a plan to meet the increasing cost of sickness. This problem should be solved by the medical profession, not by the state.

The increase in the cost of sickness is largely due to the increasing demand for hospital care and specialized medical service.

There must be a clear understanding of what constitutes hospital service and of what constitutes

average farmer can meet without considerable sacrifice. Is it any wonder that there is a widespread demand on the part of the public that some plan be devised to safeguard it against the high cost of sickness?

The answer is not in a return to old methods. In the case just described, the boy was fortunate that the fracture did not involve the epiphyseal line and that no internal injury occurred. Under the treatment that he received the former would have resulted in a short leg, the latter possibly in his death. Present-day treatment would meet successfully both these problems.

Nor is it possible to care for the sick in the modern home. Space is limited, domestic help, which used to be the rule, is now the exception, and modern diagnosis and treatment require elaborate equipment, all of which is available in a hospital.

The services of the family doctor may still be had at only a slight increase in cost. Probably the average family today pays no more to the family doctor than did their fathers before them. The increased cost, of which one hears so much, is then almost entirely due to hospital service and the fees of the specialist. If these were taken care of, the well-to-do and those of moderate means would be able to receive the benefits of modern medicine, already supplied free to the poor, without having to meet any greater financial burden than they have been able to carry in the past. If this general statement of the problem can be accepted, the solution seems to lie in the providing of some form of insurance, first against the cost of hospital care, and second against the cost of specialized medical care.

Before attempting to set up any form of insurance against the cost of sickness it is necessary to have a clear understanding of what constitutes hospital service and what constitutes medical service. The first objective of a hospital is to furnish housing and nursing care for the sick; its second is to provide the laboratories and tools with which the physician makes the diagnosis and carries out treatment of the patient. Together the medical staff and the hospital should form a center for the advancement of medical knowledge and the improvement of the general health of the community. The early hospitals were charitable institutions supported either by donations or taxation. They were expected to operate at a loss. They received no private patients, and medical service was free. In other words, the community supplied the funds for the maintenance of the hospital, and the members of the medical staff donated their services. The problem of what constituted medical or hospital service did not arise. It was only with the introduction of the paying patient into this established setup that a definition became necessary. It is probably fundamentally wrong to pay for medical service out of funds raised for the maintenance of the hospital, or to use a

part of the medical fee for hospital support. Both tend to lower the standard of *medical service*, and in the long run the patient is the loser. In the care of the paying patient, the hospital, as in any other business venture, is entitled to a reasonable profit on its investment. The doctor, on the other hand, should charge only what he considers a fair return for his services. He should not divide his fee with a third party even if the third party is a charitable institution.

It is recognized that for the hospital to carry out its function, certain members of its staff must spend a part, or the whole, of their time in administrative work. The salaries that these men receive for this type of service are part of the cost of maintaining good hospital service, and should be considered as part of the cost of hospital care in those hospitals that receive paying patients, as well as in those in which the general medical service is free. It has become a custom for members of the medical staff to spend a considerable part of their time in the diagnosis and treatment of paying patients within the hospital. This is desirable from the point of view both of the doctor and of the hospital. The increased income that the doctor receives in this way tends to raise the standard of services both to the hospital and to the patient. It makes no real difference whether the medical fees are collected by the hospital and returned to the doctor in the form of a salary or whether he collects his own fee, provided that the hospital recognizes the principle that it is not to make a profit from the collection of medical fees.

If the income from medical fees is divided between the physician and the hospital, the cost to the patient for that particular service is increased by whatever profit the hospital makes from such practice. In other words, the hospital is forcing each paying patient to make a contribution toward the support of some other department of the hospital. This practice is not only unfair to the paying patient but also tends to disturb interdepartmental relations of the hospital. The department showing a substantial profit is apt to be given undue importance in general planning. Any increase in hospital charges, beyond that which is based on hospital service, is in the long run injurious to the patient, the hospital and the physician.

One has a right to assume, I think, that both the hospital and the members of its staff are anxious to have their patients receive the best possible service at a minimum cost consistent with that service. Any plan that tends to defeat this object should therefore be avoided.

In 1916, the Massachusetts General Hospital, in response to popular demand, opened a pavilion for the care of private patients. This was a radical departure from a long-established practice. At the same time it arranged for its roentgenologist to be

that I have never seen a case in which a portion of the stomach was removed for carcinoma and the patient had a recurrence after remaining free of one for thirty-five years, so I do not anticipate any recurrence in this case. I think that we are both fortunate to be here before this society.

319 Longwood Avenue

DISCUSSION

DR. PHILEMON E. TRUESDALE, Fall River: Any good news on the surgical treatment of cancer of the stomach is welcome. Dr. Lund has created what seems to me to be a record title for himself and his patient. In addition to that, he has cast a bright spot on an otherwise extremely drab picture — that of the surgical treatment of cancer of the stomach, the location where one third of the cancers of the body occur.

In making a study of our cases of cancer of the stomach, I find that we have treated 85 cases surgically. Gastroenter-

and causes obstruction early there is generally an opportunity for radical operation. If it is discovered by palpation, as with a tumor invading the greater curvature of the stomach, the case may be hopeful, but one never knows what patient is operable and what patient is inoperable until he opens the abdomen. Until there is some other more effective means for the early detection of cancer of the stomach, we must rely on exploratory laparotomy to differentiate the operable and the inoperable cases.

DR. DAVID CHEEVER, Boston: Was there a pathological note on the condition of the lymph nodes?

DR. ARTHUR W. ALLEN, Boston: I did not expect to discuss Dr. Lund's paper, but I am so delighted that he can report such a remarkable cure of carcinoma of the stomach, that I should like to make a few remarks on this subject.

In a group of patients followed by Parsons at the Massachusetts General Hospital the end results about ten years ago showed a five-year curability rate of about 20 per cent. This included the operative mortality, which was about 35 per cent. Five years later Parsons and Welch reported an-

FIGURE 1.

ostomy was done in 38 of these. This operation has been abandoned for the last decade. Forty patients were treated by gastric resection, and 7 patients had a total gastrectomy. The mortality of gastroenterostomy was 26 per cent and that of partial gastrectomy 22 per cent. In 7 cases of total gastrectomy, the mortality was 29 per cent.

It is needless to say anything about the results of gastroenterostomy. They were invariably unsatisfactory. But of the patients who had a partial gastrectomy, 1 lived for sixteen years and died of arteriosclerosis, 3 lived for ten years, 3 lived for five years and 2 lived for four years.

Of the patients with total gastrectomies, 2 died in the hospital, 3 died within a year, 1 is living two years after operation, and 1 is living three years after operation.

It seems to me that we can gather a little comfort from this, but the case that Dr. Lund has told us about eclipses my report of results after surgical treatment of cancer of the stomach.

The diagnosis of cancer of the stomach is not easy. The patient seldom comes to the physician until the disease is advanced. If the disease happens to be near the pylorus,

other series of cases. The resectability had increased about 10 per cent. and the operative mortality rate had decreased about 10 per cent. In spite of this, there was only an additional 1 per cent added to the number of five-year cures. In other words, as the development of more radical surgery came along, the actual number of five-year respites had not appreciably increased. There were, however, a great many additional added months of life and comfort for this group of patients.

So often we have had the experience of doing a long, hard resection, taking all the strength that one has to put into any effort in one day, only to have the patient live a short period of time. This, of course, is terribly discouraging. On the other hand, we have had many patients with extremely malignant carcinomas of the stomach, including positive lymph nodes, live for several years after resection.

The first total gastrectomy that I did was in an extremely unfavorable case — Grade 4, with positive nodes. The patient lived for four years and eight months and worked four years of that time. He finally died of recurrence.

The question whether these patients are operable can often

medical service. Neither the hospital nor the physician should receive financial returns for services rendered to the patient by the other.

Plans such as that of the Blue Cross to cover hospital service should be encouraged and expanded.

A plan of insurance to cover the cost of specialized medical service should be developed.

PARTIAL GASTRECTOMY FOR CARCINOMA THIRTY-FIVE YEARS AGO*

FRED B. LUND, M.D.†

BOSTON

SOME of you may have noticed that there is a war in progress, as a result of which we are restricted in gasoline. Therefore, in order to go to Boston last winter, I embarked on the Worcester bus. A Joseph Dawson, who was a fellow passenger and whom I have asked to appear before you today, recognized me and asked me whether I remembered him. I had to confess I did not, when he told me that I had operated on him for removal of carcinoma of the stomach thirty-five years before. I then remembered him very well, because I had followed his case for about twenty years before losing track of him.

This patient was admitted to the Boston City Hospital on August 16, 1909. He was forty-four years old, born in England. Four or five years previously he had been laid up for a couple of weeks with gallstones but was not operated on. He had severe pains in the right side. Two or three years previously he had "neuralgia" around the heart, and he had also had "malaria" off and on for seven years. Since early spring he had had continuous dull pain in the region of the stomach two or three hours after eating, and then vomited dark, almost black vomitus, especially after eating fruit. He had done this two or three times a week for two or three months. His weight had dropped from one hundred and fifty-eight pounds to one hundred and thirty pounds, and he was sallow and cachectic-looking. The skin was yellow, but the scleras were white and clear. He was somewhat emaciated. There was tenderness over the epigastrium and in the midline. Five centimeters above the umbilicus was a movable tumor, hard, round and about the size of a tennis ball.

At that time x-rays were not available for the study of such cases. Examination of the stomach contents showed no stasis, no lactic acid and no free hydrochloric acid. The guaiac test was positive for blood. The hemoglobin was 80 per cent, and the differential count showed 70 per cent polymor-

phonuclear cells and 23 per cent lymphocytes; there was slight achromia.

On August 17, the abdomen was opened under ether anesthesia and a large mass was found on the greater curvature of the stomach, extending from the anterior surface around to the posterior surface above the pylorus. The stomach at the site of the mass was slightly adherent posteriorly. The gastrocolic omentum contained firm, hard lymph nodes. The nodes were freed from the omentum, and the stomach was clamped off just to the right of the pylorus and at about its middle above the mass. About half the stomach was removed between the clamps, together with the lymph nodes. The open end of the stomach was closed with layer sutures, and the duodenum with a double purse-string suture. A posterior gastroenterostomy was then done, close to the beginning of the jejunum. The mesocolon was sewed to the stomach, and the wound closed in layers. This type of operation was then known as the Billroth No. 2.

The patient vomited once the following morning. The temperature on the first day after operation went as high as 98.6°F. Afterward it ran on a normal line. Feeding was begun at once and was rapidly increased. The stitches were removed on August 24, and the patient left the hospital on August 31. The pathological report was as follows:

There is a tumor that has replaced the mucosa in one area and has extended downward through the muscularis mucosae. The tumor is composed of large cells, with big, often irregular, nuclei. Mitotic figures are numerous. The tumor is growing as groups and masses of cells, with occasional lumen formation. There is an extensive infiltration of lymphocytes, some plasma cells and a few polymorphonuclear leukocytes around the neoplastic cells. Microscopic diagnosis: Poorly differentiated, rapidly growing carcinoma.

The original section (Fig. 1) has been reviewed and there appears to be no doubt concerning the accuracy of the diagnosis.

Ever since the patient was operated on he has been in good health and hard at work as a machinist. At the time of the operation, he was forty-four years old, and so was I. I can tell him truthfully

MEDICAL PROGRESS

ENDOSCOPY*

EDWARD B. BENEDICT, M.D.†

BOSTON

THE recent advances in endoscopy may be reviewed under a variety of headings.

ANESTHESIA

Whalen¹ has reviewed the various sedatives and anesthetics that are useful in peroral endoscopy. In adults he advises 0.1 gm. of Nembutal at bedtime and again about half an hour before the operation. He also advises 16 mg. of morphine and 0.6 mg. of scopolamine. In children, an open capsule of Seconal Sodium placed in the rectum one hour before the examination is often sufficient to render the patient quiet and controllable. The toxic reactions from cocaine are counteracted by the use of one of the barbiturates for preanesthetic medication; 5 per cent cocaine is recommended. If general anesthesia is required, intravenous Pentothal Sodium is satisfactory. In cases in which there is spasm of the cricopharyngeus muscle, entrance to the esophagus has been easy after the use of curare, which is now on the market under the name Intocostin. Avertin is used infrequently because of the respiratory depression, the slow return of reflexes and the frequent necessity of supplementing anesthesia. Toxic effects from scopolamine may be counteracted by the use of 1.5 mg. of apomorphine.

BRONCHOSCOPY

Bronchitis

Holinger and Rigby² report 69 patients with fusospirochetal tracheobronchitis. Infections due to these organisms are usually associated with copious, foul expectoration, lung destruction and abscess formation or extensive bronchiectasis. The clinical features of fusospirochetal tracheobronchitis resemble those of pulmonary tuberculosis, including cough, loss of weight, fatigue, occasional hemoptysis and night sweats. The bronchoscopic findings consist simply of chronic bronchitis. The mucosa is injected, and a small amount of mucopurulent secretion may be present. The principal therapeutic agents are the arsenicals or autogenous vaccines, which may be employed, and bronchoscopic aspiration is used to relieve bronchial obstruction.

Bronchiectasis

In a study of the etiology of bronchiectasis, Olsen³ studied 85 patients who had congenital dextro-

cardia. Fourteen of these patients also had bronchiectasis. The frequency with which bronchiectasis accompanies visceral transportation lends support to the theory of the congenital origin of many cases of the disease. A consideration of the evidence in favor of both theories of the origin of bronchiectasis — viewed as congenital and as acquired — indicates that both congenital and acquired components enter into the production of most cases of the disease.

Rilance and Gerstl⁴ have reported a series of tuberculous patients in whom bronchiectasis assumed a place of major importance in the evolution of the pulmonary lesion and the development of the terminal pathologic condition. Bronchiectasis secondary to tuberculosis has repeatedly been demonstrated in tuberculous patients. Few of these patients, however, exhibit any significant symptoms due to the complication, and it seems likely that in the majority of them bronchiectasis is merely a benign bronchial dilatation not associated with abnormality of bronchial function. A minority appear to develop a true suppurative bronchiectasis that many times, both in severity of symptoms and in the resultant disability, overshadows the tuberculous parenchymal disease. It seems justifiable to assume a different etiologic basis for the two types of bronchiectasis. A series of 47 patients with significant degrees of bronchiectasis in association with tuberculosis was studied. Twelve patients came to autopsy; 35 were studied by bronchography. The clinical picture and the appearance of the x-ray films of these patients demonstrated the marked similarity that sometimes exists between the manifestations of tuberculous bronchiectasis and those due to active pulmonary tuberculosis. These authors believe that the symptoms of suppurative bronchiectasis secondary to pulmonary tuberculosis may so closely simulate those of active tuberculosis that errors in differentiation may readily be made. Occasional patients, not cognizant that they have had tuberculosis in the past, present themselves for the first time with symptoms due to a suppurative bronchiectasis that may readily be mistaken for active pulmonary tuberculosis. Suspicion of the presence of tuberculous bronchiectasis should be aroused when patients show the clinical symptoms usually interpreted as evidence of active tuberculosis, in association with either a persistently negative sputum or an x-ray picture that by itself would be interpreted as a healed tuberculous lesion. When all three conditions prevail, the evidence suggesting bronchiectasis is extremely strong. The authors

*From the Massachusetts General Hospital.

†Instructor in surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital.

be settled by peritoneoscopy. This procedure is a real contribution. If Dr. Benedict or Dr. Wallace finds by peritoneoscopy that the liver or peritoneum is involved, we may save that particular patient a needless exploration. In Parsons's first group of patients, exploratory laparotomy alone in the inoperable group gave an operative mortality of 25 per cent, so that this procedure is not so innocuous as one might think, whereas peritoneoscopy carries an extremely low mortality. Of the first group of 20 cases that Dr. Benedict peritoneoscoped, and in which he saw no reason why the lesions should not be removed, eighteen of the latter proved to be resectable. Only adherence to the pancreas is not made obvious by this particular procedure.

The last point that I should like to make is the question of the differential diagnosis of ulcer and cancer of the stomach. It was of considerable importance to us to find that on analyzing a ten-year group of patients with a diagnosis of ulcer of the stomach in our hospital, 14 per cent of them finally proved to have cancer. Patients with apparently benign lesions from a clinical standpoint, with high gastric acidity and typical ulcer pain, were symptomatically relieved on an ulcer regimen in the hospital and finally proved to have cancer. Frequently enough the roentgenologist would say that the ulcer was healing, or was no longer present, after a month's treatment, and on occasion the gastroscopist would find that he could no longer see the crater of the ulcer — only to have such a patient return in three to twelve months with an inoperable cancer of the stomach.

It certainly is worthy of consideration on the basis of this experience to revise our previous ideas concerning gastric ulcer. We should not consider gastric ulcer and duodenal ulcer in the same light. We have not studied our patients sufficiently to say whether the gastroenterologists can relieve as high a percentage of benign gastric ulcer by their conservative methods as they can of duodenal ulcer. Other reports from other clinics, however, stated definitely that the conservative method of treatment of gastric ulcer is unsatisfactory in at least 50 per cent of the patients. This is certainly 30 per cent less than the satisfactory results obtained by conservative methods of treatment of duodenal ulcer. When one adds this factor to the fact that gastrectomy for gastric

ulcer is infinitely a safer procedure than gastrectomy for duodenal ulcer, because in gastric ulcer the duodenum is normal and the treatment of the duodenal stump presents no hazard, — together with the difficulty in ruling out cancer, — it seems to me that we should be more radical in our attitude about gastric ulcer. My conception is that we should consider gastric ulcer fundamentally a surgical lesion, and duodenal ulcer primarily a medical lesion.

DR. CHARLES L. LARKIN, Waterbury, Connecticut: I do not wish to detract from Dr. Lund's operation or his ability to remove cancer of the stomach, but in view of the recent work of Dr. Green, the pathologist at the New Haven Hospital, I raise the question whether there is not a possibility that the tumor that was removed by Dr. Lund was not a cancer of the stomach.

Dr. Green has, as you probably know, been transplanting all suspected cancers that have been removed at his hospital into the anterior chamber of a rabbit's eye. He believes that every real cancer will transplant 100 per cent and that if it is not a cancer it will not transplant. In other words, he thinks that simple microscopical examination is not enough to prove that a cancer is a real cancer. He believes the real test is the biologic test.

It is quite probable that the tumor that Dr. Lund removed would not have proved to be a cancer by the biologic test, although microscopically it is typical.

DR. LUND (closing): There was no note on the lymph nodes. I should like to have had an examination of them.

I am sorry to say that I have not kept a record of all the cancers of the stomach I have operated on. I had one patient who lived for over fifteen years, but in most of my cases there were recurrences in three to five years or even before.

In regard to the tumor's not being a cancer, the patient had the proper chemical content of the stomach and a hard, ulcerated, proliferating tumor, with grossly positive nodes. You saw the section. Dr. Mallory reported carcinoma ventriculi, and Dr. Parker wrote the report that I read to you — so, in my opinion, this was a cancer, and I hope that they won't take it away from me.

faithfulness of the patient in carrying out the prescribed postural drainages, and in part on whether the good effects of aeration and of whatever reduction in infection of the bronchial mucosa occurs as a result of the improved drainage predominate over a recurrence of the mucosal swelling, which presumably may occur as a secondary reaction to the drugs that were used to shrink the mucosa. Experience has shown that, in a few cases, one bronchoscopic treatment removes all the particularly distressing symptoms for an indefinite period of time. In a greater number of cases no relief of symptoms occurs, and in rare cases the symptoms are made worse through an acute attack of pneumonitis. In a majority of patients a satisfactory improvement takes place, but in the course of a week, several weeks or months a relapse occurs, calling for another bronchoscopic treatment. In patients who are indefinitely relieved by one bronchoscopic treatment, or who are not relieved at all, further treatments are obviously not indicated. In the other patients, repeated bronchoscopies are indicated at whatever intervals — five days, several weeks or months — the circumstances require.

Foreign Bodies

Hartley⁸ has discussed a case in which a 10-cm. packing nail remained in the bronchus for thirteen years and was discovered accidentally during a routine x-ray examination of the thorax. For two years after aspirating the nail the patient had no symptoms referable to the chest. Eleven years later, however, he was admitted to the hospital because of fever and pain in the right side of the chest, and x-ray examination showed pneumonitis and pleural effusion, which cleared up spontaneously. The nail was not removed. In contrast to this the author cites the case of a boy four and a half years old who had persistent, violent cough for a two-year period owing to the presence of a wood screw in the left lower lobe of the bronchus. This bears out the well-known dictum that metallic foreign bodies cause much less disturbance than do vegetable ones.

Adenoma

Lowry and Rigler⁹ have reported a clinical and roentgenologic study of 7 cases of adenoma of the bronchus. They note the important fact that there is often extension of the tumor through the bronchial wall, with formation of an extrabronchial mass that may be larger than the intrabronchial portion. They emphasize the fact that although adenoma of the bronchus almost always remains benign so far as lethal metastasis is concerned, its effects on the lung are extremely serious and in many cases ultimately cause death. They also stress the fact that differentiation of benign from malignant tumors of the bronchi is not always possible from the bronchoscopic biopsy material alone. In one of the cases reported the adenoma existed for thirteen and a half

years and terminated with metastases to the opposite lung. In a second case the more usual solid form of the neoplasm was at first mistaken for a so-called "oat-cell carcinoma." The opinion of some investigators that bronchial adenoma is always a benign tumor is rejected. Because of the potentially malignant characteristics, early lobectomy or pneumonectomy is considered the treatment of choice.

Laff and Neuburger¹⁰ also stress the potentially malignant character of neoplasms diagnosed as bronchial adenomas manifested in their invasive growth — extrabronchial extension — and their ability to produce late metastases. Their histologically benign appearance is not incompatible with biologically malignant behavior.

Moersch¹¹ in discussing the diagnostic abnormalities of bronchiogenic carcinoma refers to adenoma of the bronchus, stating that pathologists differ whether the tumor should be regarded as a benign lesion or as one of a low degree of malignancy. Adenoma of the bronchus has a tendency to recur, and cases have been reported in which the adenoma has infiltrated and involved the mediastinal lymph nodes. At present, Moersch believes that if the tumor is pedunculated and is situated in one of the main stem bronchi, where it can readily be reached through a bronchoscope, it is best treated by bronchoscopic means. All the patients in this category whom he has treated bronchoscopically are still living and well. If, on the other hand, the tumor is situated where it cannot readily be reached bronchoscopically, or if it tends to infiltrate through the wall of a bronchus, or if much secondary pulmonary suppuration is present, Moersch believes that the condition is best handled by surgical means.

Carcinoma

In a recent article Blake¹² discusses the relation of chronic irritation to carcinoma. In the case reported, a chronic irritating factor — namely, a metal crucifix — was present in the bronchus for a number of years, with subsequent development of primary bronchiogenic carcinoma at the sight of the irritant. The crucifix did not cast a demonstrable shadow in the x-ray film. On bronchoscopy the right middle lobe bronchus was almost completely occluded by a granular mass 1 cm. from the orifice; a preliminary diagnosis of bronchiogenic carcinoma of the right middle lobe bronchus was made. A biopsy was performed, and the tissue removed was considerably larger than anticipated. Pathological examination of the material revealed a crucifix measuring 4 by 7 mm. embedded in the tissue, and a diagnosis of carcinoma was made. Exploratory thoracotomy was done, and revealed an inoperable anaplastic carcinoma of the right middle lobe. The carcinomatous tissue was found to involve the pericardium, the great vessels and mediastinal lymph

point out certain characteristics of tuberculous bronchiectasis that appear to differentiate it from the nontuberculous type.² Following the instillation of lipiodol into the bronchial tree, gross distortion and abnormal angulation of the bronchi, changes not usually found in cases of nontuberculous bronchiectasis, were frequently seen. Cystic bronchiectatic cavities, located in the shrunken upper lobe, appeared to simulate in every respect the usual roentgenographic appearance of chronic tuberculous cavities. The assumption that these bronchiectatic cavities were in reality re-epithelialized tuberculous cavities seems to be supported by the pathologic findings reported in one case.

In studying the treatment of bronchiectasis, Stacey⁵ reports that sulfathiazole may be applied locally to the tracheobronchial tree by inhalation of nebulized solutions of its sodium salt and that its use in a small series of cases of bronchiectasis has resulted in distinct benefits. The first 3 patients reported were suffering from acute infections, and in these the improvement was rapid and dramatic. No systemic reactions were noted, and no untoward local effects resulted from the treatments.

Oatway⁶ reports the use of sulfadiazine, sulfamerazine and sulfathiazole in 48 cases with purulent bronchial secretion. The diagnosis was chronic bronchitis in 11 cases, bronchial asthma with bronchitis in 11, and bronchiectasis in 16. The author is concerned chiefly with the 16 cases of bronchiectasis. The symptoms had persisted for one to twenty-five years. The daily volume of sputum varied between 20 and 800 cc. Administration of sulfonamides by mouth was found regularly effective in all cases of simple, uncomplicated bronchiectasis. The sputum was reduced in all cases, with an average decrease of 62 per cent. In the presence of atelectasis and putrid secretions the sulfonamides were much less efficient than they were in simple bronchiectasis. Tolerance was about as expected except in cases known to be clinically allergic. Oatway states that there is no reason to believe that the structure of the bronchiectatic lesion changes, although its progress may be prevented by sulfonamide treatment. It is recommended that sulfonamides be used in nonsurgical cases and for preoperative therapy. They should be combined with postural drainage, bronchoscopic aspiration, climatotherapy and treatment of the sinuses.

According to Alexander,⁷ the safety of pulmonary lobectomy has solved the problem of treatment for approximately half the bronchiectasis patients. Postural drainage is the most valuable of the nonsurgical therapeutic measures, but it is usually employed inefficiently. Every bronchiectatic patient should have at least one bronchoscopic examination, not only because some otherwise undetectable, important intrabronchial lesion may be discovered but also because the aspiration of secre-

tions and the chemical shrinkage of the bronchial mucosa often bring about improvement in the symptoms, which in occasional cases—notably in children but also in adults—is astonishing. Bronchoscopy is also of great value in preventing the development of bronchiectasis in early cases of pneumonitis of so-called “unresolved pneumonia.” The ordinary bronchoscopic treatment, in which a few of the secretions are aspirated and the mucosa is treated for only a few moments, is of little value. An effective treatment, which should be immediately preceded by a postural drainage that may occupy from fifteen to thirty minutes, requires that the bronchi containing secretions be repeatedly aspirated until all free secretions have been removed, both before and after the mucosa has been shrunken and the patient has repeatedly coughed on command, and that equal parts of 2 per cent pontocaine and 1:1000 epinephrine solutions, or other shrinkage drugs, be directly applied, step by step, to all parts of the mucosa that are swollen, the excess of the solution in the gauze pledgets being squeezed into those bronchi of the affected parts of the lung that are too small to be directly reached by the pledgets, or a small amount of the solution being injected into these bronchi. The effect of this treatment is to empty and open the choked bronchi, most of which, including the bronchiectases themselves, are distal to the field of bronchoscopic vision. The small bronchi in the peripheral portion of the bronchiectatic lobes cannot be reached by the bronchoscopic aspirator, but they can be at least partially emptied of secretions by voluntary coughing after all secretions proximal to them have been aspirated. Air enters more and more deeply into the lung as the secretions are aspirated and coughed from the bronchopulmonary areas that had been drowned in secretions.

Alexander believes that aeration of the peripheral portions of the affected lobes is the most important objective of bronchoscopic treatment. Aeration of the small bronchi and alveoli is the most effective means of aiding the patient to evacuate additional secretions by coughing, both during and following bronchoscopy. Deep breathing and coughing at fifteen-minute to sixty-minute intervals during waking hours for one or two days after a bronchoscopic treatment and the faithful carrying out of postural drainages indefinitely after bronchoscopy are obviously helpful in maintaining aeration and maximal evacuation of secretions. Evidence that a choked portion of a lung has been drained and aerated is often furnished by the change from dullness to resonance, from distant or almost absent breath sounds to distinct breath sounds and from few or no rales to many rales, as a result of a particularly effective bronchoscopic treatment, and sometimes solely as a result of postural drainage. The length of time during which aeration and drainage are maintained probably depends in part on the

heart and the opposite lung should be essentially normal. Probably few patients beyond sixty-five years of age are suitable for operation, although occasionally patients up to seventy years of age have been successfully operated on. Age alone does not necessarily contraindicate surgical intervention provided that the patient's general condition otherwise warrants it. He adds that, unfortunately, carcinoma of the lung tends to metastasize early and widely. In the series studied by Tinney,¹⁵ metastatic lesions had been found in almost every part of the body. Every attempt to rule out the presence of metastatic carcinoma should be made. Involvement of nerves, such as the recurrent laryngeal or phrenic nerve, involvement of the brachial plexus or any indication of nerve injury usually means inoperability, as does also pleural effusion, particularly if it is bloody. The patient should not be denied thoracic exploration if a reasonable chance exists that the lesion can be removed. Too often it is found at the time of operation that the lesion has spread beyond operable limits. The resectability rate at the time of thoracic exploration, however, is about the same as that in cases in which exploration is performed for carcinoma of the stomach.

Pohle and Siris¹⁸ believe that there is no question regarding the palliative value of cautiously applied x-ray therapy in the treatment of carcinoma of the bronchus. In rare cases, even in the presence of metastases, a five-year survival may be achieved.

Fermont¹⁹ reports a seven-year cure in a case of carcinoma of the bronchus treated by radon seeds inserted through the bronchoscope. The growth was found by bronchoscopy to be obstructing the dorsal division of the bronchus of the right lobe. Biopsy showed squamous-cell carcinoma. Six and a half years after the treatment, the patient was readmitted, at which time bronchoscopy showed a slight general constriction of the bronchus of the right lower lobe at the level of the middle-lobe orifice. Biopsy showed no evidence of growth. The patient improved on conservative treatment and was able to resume his work. I cannot help wondering in this case whether the tumor was not in all probability an adenoma, rather than a carcinoma, for it has been noted elsewhere in this review, as well as previously, that sometimes a pathologist is unable to make the differential diagnosis between adenoma and carcinoma on a small bronchoscopic biopsy.

Rienhoff²⁰ has evaluated the present status of primary carcinoma of the lung. In his experience, second to the roentgenogram in importance in yielding information that is helpful in arriving at a definite diagnosis is bronchoscopy. In fact, either by direct vision or biopsy or both, a positive diagnosis of primary carcinoma of the lung can be made only in this manner. In 61 per cent of the patients in this series a bronchiogenic carcinoma was seen by this method and a positive biopsy specimen was

secured. In 39 per cent the bronchoscopy was negative. He quotes Graham as having been able to establish a positive diagnosis in 75 per cent of the cases in his series and states that Ochsner believes that positive bronchoscopy parallels hilar involvement in 70 to 85 per cent of cases. A pulmonary growth in the periphery or even hilar lesions confined to the upper lobes may be beyond the vision of the bronchoscopist. Valuable information can be elicited by bronchoscopy even when the growth cannot be seen, such as fixation or deformity, or both, owing to pressure on any visible portion of the bronchial tree. The presence of blood or purulent discharge from certain bronchi serves as a lead. In this series of cases there were no untoward results during or after bronchoscopies, and in the hands of experts Rienhoff believes that the patients have little if any discomfort. In conclusion he states that primary carcinoma of the lung, otherwise a fatal disease, can be satisfactorily treated by surgical removal of the entire organ. Surgical measures short of total pneumonectomy are not efficacious. Postoperative mortality and longevity are at least as good as, if not better than, the postoperative results following the surgical treatment of carcinoma of other organs.

Tuberculosis

Of 115 cases of active pulmonary tuberculosis studied by Huang²¹ at autopsy, 43 per cent showed evidence of tracheobronchial tuberculosis. This author believes that all bronchial tuberculosis is secondary to pulmonary tuberculosis. Direct implantation of tubercle bacilli from open cavities of the lungs to the mucous membrane or mucous glands seems to be the most plausible explanation for the majority of cases. Tuberculous ulceration is the predominating lesion of the respiratory tract in fatal cases.

Salkin, Cadden and Edson²² examined bronchoscopically 622 cases of pulmonary tuberculosis. Ten per cent showed a tuberculous lesion on the first examination, and another 5 per cent eventually showed positive bronchial findings. The cases with a positive sputum and a cavity had an incidence three times as high as that of those with a negative sputum and no cavity. Tuberculosis of the lower lobe showed three times as much bronchitis as did that of the upper lobe. This phenomenon may be due to the greater endoscopic visibility of the lower-lobe bronchus and the stagnation of positive sputum there. One can expect a greater incidence of tracheobronchial tuberculosis in cases with laryngeal tuberculosis, and the reverse is also true. In over two thousand bronchoscopies in this study, only 1 case showed a spread of the disease that might be attributed to the procedure. Three or 4 per cent of the cases showed a drop in a previously existing fever, apparently owing to the greater ease of expectoration and improved aeration. Quite a number

nodes. Postoperative convalescence was uneventful. The patient did not give any preliminary history of a foreign body, but following the biopsy, further questioning revealed that about six years previously he had lost a small metal crucifix, which he thought that he had swallowed.

Fisher¹³ states that carcinoma of the trachea is rare. It usually arises in the lower third of the trachea and is of the squamous-cell type. It is a highly malignant growth that develops insidiously. The diagnosis of tracheal neoplasm can be made only by direct tracheoscopy and removal of a piece of the tissue for microscopic study. There seems to be only one satisfactory type of treatment in these cases. This consists of electrocoagulation of the growth through the bronchoscope, with the tumor under direct vision. The electrocoagulation should be followed by irradiation of the tumor with roentgen rays of high voltage.

Pierson¹⁴ reports a case of primary carcinoma of the trachea treated with radium. A man of sixty-one who had intermittent bouts of severe cough, dyspnea, suffocation and moderate hemoptysis for three years was found to have a primary adenocarcinoma of the trachea. An attempt to prove its histogenic origin from aberrant thyroid tissue by the use of radioactive iodine was unsuccessful. After removal of as much as possible of the tumor through the bronchoscope, the remnant was treated by radium applied within the trachea. Two years after treatment there were no subjective or objective evidences of tumor.

In a symposium on bronchiogenic carcinoma, Tinney¹⁵ discusses the clinical features, remarking that, unfortunately, bronchiogenic carcinoma does not have characteristic symptoms. The symptoms are the same as those produced by any pulmonary inflammatory disease and depend essentially on the size and location of the tumor. Cough was an early symptom in 81 per cent of the cases in Tinney's series. Dyspnea in cases of bronchiogenic carcinoma is caused either by obstruction of the bronchial lumen and atelectasis or by development of pleural effusion. When dyspnea is associated with wheeze, an incorrect diagnosis of asthma is often made. Hemoptysis occurred in 53 per cent of the cases. Because of hemoptysis a number of patients were erroneously thought to have pulmonary tuberculosis. Pain occurred in 54 per cent of the cases. Loss of weight was noted in 71 per cent but is of no significance for early diagnosis. Although hoarseness was noted in only 8 per cent of the cases, it is an important symptom, because it means that the lesion is inoperable, having spread to the mediastinum, with involvement of the recurrent laryngeal nerve. There were no symptoms referable to the respiratory system in 5 per cent of the cases. The lesions were discovered in this group during a general physical examination that included a roentgenogram of the thorax. In 70 per cent of

the cases, — those in which an adequate follow-up study was available, — the average duration of life after the diagnosis was established was six months. The average duration of life from the onset of symptoms was fourteen and a half months. This deplorable delay in diagnosis is the most significant factor in the poor prognosis of bronchiogenic carcinoma. In this series the prognosis was not influenced by the type or grade of tumor.

Moersch¹¹ discusses the diagnostic aspects of bronchiogenic carcinoma, pointing out that a negative roentgenogram of the thorax does not rule out cancer of the lung. He therefore believes that it is important to remember that if a patient gives a history suggestive of carcinoma of the lung, even though the physical findings and roentgenograms of the thorax are essentially negative, further diagnostic procedures are justified. Bronchoscopy is one of the most important aids to diagnosis of carcinoma of the lung and offers the easiest and probably the most accurate method of early diagnosis. In 92 per cent of the cases in which bronchoscopy was performed, the diagnosis was made from tissue obtained through the bronchoscope.

Brindley¹⁶ reports on the surgical aspects of bronchiogenic carcinoma, giving the results of pneumonectomy in 43 cases and lobectomy in 2. Seven patients (16 per cent) died in the first twenty-four hours after operation; 7 additional patients died in the hospital after the operation. One patient died three months after the pneumonectomy was performed. One patient is known to have had a recurrence of the tumor in the pleura nine months after operation. No correspondence or further examination was obtained in 4 cases. All the other patients were alive and without known recurrence of the lesion when last heard from or at the time of their last examination.

In a discussion of this symposium on bronchiogenic carcinoma, Clagett¹⁷ notes that improved results from the surgical treatment of carcinoma of the lung must come — as they must for carcinoma in all locations of the body — from earlier diagnosis of the disease. Competent surgeons should not hesitate to perform an exploratory operation on the thorax. During the summer of 1943, Clagett performed pneumonectomy in at least 5 cases in which a positive diagnosis was not made beforehand, and in every one the suspected carcinoma was found and the lesion was removed. If he had awaited a positive diagnosis in these cases, the lesions would have become inoperable. He states that it is impossible to lay down any hard and fast rules to govern indications for thoracic exploration in cases of proved or suspected carcinoma of the lung. There should be roentgenographic and bronchoscopic evidence of a pulmonary lesion, and every attempt should be made to rule out other pulmonary conditions, such as lung abscess, bronchiectasis and tuberculosis. The patient should be in good general condition; the

Bronchoscopy in the Armed Forces

In a report on the trends and practices in thoracic surgery in the Mediterranean theater, Churchill²⁵ has found bronchoscopic or catheter tracheo-bronchial aspiration increasingly useful to clear the respiratory passages of blood and secretions. Unless this is done, he says, oxygen administration and transfusion are of little avail.

Postoperative Use of the Bronchoscope

Garlock²⁶ emphasizes the importance postoperatively of employing bronchoscopy to relieve the patient of tenacious secretions. He considers that it is often a lifesaving procedure.

Postlobectomy Lobar Collapse

Sampson and Collis²⁷ believe that bronchoscopy is important in postlobectomy lobar collapse. In practice they have found that only one bronchoscopy is required in adults, although recollapse may occur in children, necessitating further instrumentation. It was found that even on the first or second postoperative day these patients stood bronchoscopy without being upset; in fact, many immediately felt better. The procedure was always done in the operating room under a local anesthetic. By laying the patient on the unaffected side the bronchoscope could be introduced through the side of the mouth into the affected lung with remarkable ease. In fact, it was these authors' experience that it is easier to use the bronchoscope on these patients than on the usual run of patients. This is thought to be due to the greater ease with which they can relax. Sampson and Collis conclude that from several aspects postlobectomy lobar collapse is a serious complication; that it is due to the obstruction of the bronchi with pus in association with certain mechanical alterations in the shape of the bronchial tree after lobectomy; that the longer this pus is left plugging the bronchi, the deeper it will pass into the lung and the more permanent will be the condition; that once collapse occurs it should be treated immediately by bronchoscopic aspiration, the results of which are highly satisfactory; and that postural measures give rise to some hope of reducing the incidence of the condition.

Lung Abscess

Brantigan and Looper²⁸ studied 122 cases of lung abscess, collecting from the literature 34 cases of patients who had received primary lobectomy for lung abscess. There were 7 deaths. The technic of Churchill^{29, 30} was used. Preoperative preparation included diet, bronchoscopic drainage, chemotherapy and blood transfusion.

Hemoptysis in Mitral Stenosis

Ferguson, Kobilak and Deitrick³¹ believe that mitral stenosis causes dilatation of the bronchial

veins in the submucosa of the larger bronchi as a result of the establishment of a collateral flow through them. In mitral stenosis, when infarction and acute pulmonary edema are not present, hemoptysis is probably due to bleeding from these dilated veins. Eleven cases of rheumatic heart disease studied by a special method of injection of particulate matter into the pulmonary veins indicated the presence of direct venous connections between the bronchus and pulmonary veins in men of all ages.

Agenesis of Lung

Valle and Graham³² report a case of agenesis of the lung proved during life by exploratory operation, and another case not proved but with an almost certain diagnosis. In the first case, bronchoscopy showed a normal larynx and a trachea twisted and distorted and shifted toward the left. The left main stem bronchus was completely obstructed 2 cm. below the carina. A blind pocket at the end of this bronchus appeared to be covered with epithelium, and there was no definite evidence of tumor. The right bronchial tree was normal. Thoracotomy showed that the only vestige of the left lung was a short bronchial stump with no lung tissue. The thymus gland was absent. No abnormalities were noted, and the chest was closed. In the second case, the trachea was displaced to the left. The right bronchial tree was seen to be normal but the left main bronchus was completely obstructed about 1 cm. below the carina. In a discussion of the 38 proved cases reported in the literature, Valle and Graham say that bronchoscopic studies will reveal a block of the main stem bronchus a short distance from the carina provided a rudimentary main stem bronchus is present on the affected side. In the literature most of the cases were diagnosed after death, but this is probably due to the fact that the majority were reported before the bronchoscope and bronchograms were so widely used, or used at all, in the diagnosis of chest lesions. At present, exploratory thoracotomy, which can be performed quite easily and without too much risk for the patient, is a possible means of positively diagnosing this condition. The authors give a valuable table of the findings in these 38 cases. It is worthy of note that both their patients are still alive. One case, that of a forty-one-year-old woman, was proved by an exploratory thoracotomy after a clinical diagnosis had been made of massive atelectasis of the left lung due to complete block of the left main bronchus. The other case, that of a five-year-old boy, is presumed to have been agenesis of the lung since the physical examination showed asymmetry of the chest, absence of breath sounds and flatness to percussion on the left side. Also, the x-ray picture showed complete opacity on the left with displacement of the trachea toward that

of patients asked for another bronchoscopy because they thought that it facilitated expectoration, lessened cough and improved breathing. The use of local therapy in bronchitis is one of the most debatable points of the entire subject. The experience of these authors leads them to believe that local treatment is of value, but one must remember that about three fourths of all cases heal spontaneously if the disease in the parenchyma is controlled. Treatment should be especially applied to the remaining patients, who do not do well when the parenchymal lesion is inactivated or when such complications occur as an undesirable stenosis, an accessible focus of hemorrhage, severe cough, difficulty in expectoration or attacks of dyspnea. Cases with tracheobronchial tuberculosis show a severer clinical course and have a poorer prognosis than do those with normal bronchi.

In contrast to the findings of the above authors, Radner²³ has noted a number of postbronchoscopic reactions in pulmonary tuberculosis. He concludes as follows:

The subject of tuberculous tracheobronchitis is of tremendous interest to the phthisiologist and thoracic surgeon. The trend toward routine bronchoscopic examination of all patients admitted to the sanatorium is not without its disadvantages. Limitation of bronchoscopy to the indications described will suffice to take care of almost all cases requiring treatment. Eleven cases have been collected from the American literature in which spread of disease following bronchoscopy is mentioned. Not in all instances did the authors feel definitely that bronchoscopy was directly responsible for the spread. In a study of one hundred and eighty-three bronchoscopic examinations made on patients with pulmonary tuberculosis the following findings were obtained, indicating that bronchoscopy is not an innocent procedure: (1) Eighteen bronchoscopic examinations were followed by immediate post-bronchoscopic fever, to which little significance can be attached. (2) Twenty-six bronchoscopic examinations were followed by a secondary rise in temperature, appearing between the tenth and sixteenth postbronchoscopic day, lasting fourteen to twenty-one days. (3) Twenty-one bronchoscopies were followed by minimal infiltrative spread as seen on roentgen films. (4) Five bronchoscopic examinations were followed by atelectasis of a lobe or lung. In this series, the number of patients who developed fever and spread of lesions following bronchoscopy is beyond explanation by coincidence. As a result of these findings it is suggested that: (1) Patients bronchoscoped prior to thoracoplasty should have their examination preferably three weeks in advance with a new roentgen film of the chest before surgery. This will eliminate some of the post-operative spreads that may be seen following thoracoplasty which are unjustifiably attributed to surgery. (2) The interval between bronchoscopic examination or treatments should not be less than six or eight weeks to allow for subsidence of any reaction resulting from previous treatments. (3) The disturbance of the cough reflex is very likely associated with the febrile reaction and extension of disease reported above. To minimize this, prebronchoscopic medication should preferably be limited to short-acting drugs and intratracheal anesthesia avoided whenever possible.

Davies²⁴ in a discussion of the treatment of tracheobronchial tuberculosis states that the aim of local treatment is twofold: first, to promote the healing of ulcerations in the tracheobronchial tree; and second, to prevent or minimize stenosis. He believes that the silver nitrate cautery aids in the healing of tuberculous ulcers in the human bronchi and

trachea by preparing the ulcer base to receive and support the ingrowing epithelium. This may perhaps be accomplished by reducing granulations and combating secondary infection. He does not believe that it has anything to do with the tuberculous nature of the lesion. Since silver nitrate has been widely and successfully used for many years to promote healing of dirty, granulating, superficial ulcerations in other parts of the body, it is not surprising that it should be effective in the treatment of similar lesions in the tracheobronchial tree. The epithelialization of tracheobronchial ulcers is important in that it removes one and often the only source of bacilli in the sputum, thus preventing bronchiogenic dissemination of tuberculosis and further bronchial or tracheal infection by implantation. It is also evident that epithelialization prevents a further increase in the size and extent of the ulcer. This may be helpful in preventing a localized ulcer from eventually involving the whole circumference of the bronchial lumen. In the bronchus, as in other hollow organs, circumferential ulceration is likely to be followed by serious stenosis, because of the concentric contraction of the fibrous tissue that is laid down as part of the repair process. It is Davies's opinion, however, that in 19 of his 26 cases local therapy was of considerable importance. In 2 of the remaining 7 cases, which were seen early in the course of the study, the local therapy employed was grossly insufficient by his present standards, only 10 per cent silver nitrate having been used, and that at intervals of a month or six weeks. Those collected cases in which local therapy was not used showed 31 (26 per cent) of 121 patients dead and 13 cases (11 per cent) classified as "healed," "well" and so forth. Combination of Davies's results with those collected from the literature in which local therapy was used shows 83 (39 per cent) of 215 cases "arrested," "healed" or "well" and 29 patients (13 per cent) dead. There is less than one chance in two thousand, considering arrested cases, and less than one chance in two hundred, considering deaths, that such a difference in results is solely accidental. The author advises the following treatment: complete bed rest in a sanatorium and a diet adequate in all essentials; relief of symptoms by a warm, humid atmosphere, adequate fluid intake, postural drainage and the use of expectorants, antispasmodics and barbiturates as necessary; persistent bronchoscopic cauterization of all accessible ulcerated lesions at biweekly intervals, preferably with a 30 per cent solution of silver nitrate; use of collapse therapy if the parenchymal lesion by itself demands collapse or if a main or lobar bronchus is seriously obstructed and if the obstruction cannot be promptly relieved; complete thoracoplasty as the procedure of choice if collapse is indicated; and in a few exceptional cases, lobectomy, pneumonectomy or open-cavity drainage when more conservative measures have failed.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Special Meeting, January 31, 1945

A SPECIAL meeting of the Council of the Massachusetts Medical Society was called to order at 10:30 a.m. in John Ware Hall, 8 Fenway, Boston, on Wednesday, January 31, 1945, by the president, Dr. Elmer S. Bagnall, Essex North; 207 councilors were present (Appendix No. 1).

The record of the meeting held on October 4, 1944, as published in the *New England Journal of Medicine*, issue of December 21, 1944, was presented by the Secretary. On a motion by Dr. John B. Hall, Norfolk, and a second by Dr. David Cheever, Suffolk, the record was approved by vote of the Council.

REPORT OF EXECUTIVE COMMITTEE

This report was presented by the Secretary. He said that the committee had reviewed a "basic general plan for a Massachusetts program for the care of children with acute rheumatic fever" as presented by the Committee on Public Health. He added that this plan was presented in detail in the circular of advance information, which had been sent to each councilor. He said that the committee recommended the approval of this report provided certain qualifications which had to do with those permitted to act as consultants under the plan be deleted. These qualifications were represented by the following words which appeared in that part of the report which referred to this subject: "who are certified by or eligible for certification by the boards of their respective specialties."

The Secretary spoke of a communication which the committee had received from Dr. Jacob Fine, in which the latter sought to have adopted the following amendment to the by-laws of the Massachusetts Medical Society:

Chapter V, Section 2b, is hereby amended to read as follows:

The Secretary of a District Society shall receive an application from a graduate of a discontinued medical school, a foreign medical school after the year 1933 or any medical school not approved by the Council only when the applicant has possessed a license to practice medicine in the United States or its territories for at least five years. A graduate of a foreign medical school on the approved list of the National Board of Medical Examiners prior to 1934 may apply for membership to the secretary of a district society if he has possessed a license to practice medicine for a minimum of five years.

He called attention to Dr. Fine's argument in support of this proposal as it appeared in the circular of advance information (Appendix No. 2).

In connection with the administrability of the proposed amendment the Secretary read the following letter from Mr. Everett S. Elwood, executive

secretary of the National Board of Medical Examiners:

Dear Dr. Tighe:

The only list of the European medical schools that the National Board ever had has been the list prepared by the Examining Board in England. As you know, there has never been an appraisal of the medical schools in Europe by any accredited agency in this country. Dr. Rappleye, dean of the Columbia University Medical School, brought back some information about the so-called "extramural schools" of Scotland and Ireland which indicated that they were not up to the standards set for the approved schools in this country and we therefore discontinued accepting their graduates after 1939, as the enclosed resolution will show. With this exception, our board has used the list of schools that were approved for admission to the examinations of the English Board, and until we stopped admitting graduates from the Continental schools of Europe we admitted to our examinations those whose credentials were satisfactory, if they had completed their work satisfactorily in a European school on the list of the English Board.

Your letter asks for a list before 1934. I enclose an extra copy, that we had on hand, of the pamphlet gotten out by the English Board in 1934. If I knew the particular school or schools to which you refer I could probably reply more satisfactorily.

Very sincerely yours,
EVERETT S. ELWOOD, *Executive Secretary*
National Board of Medical Examiners

December 21, 1944

The Secretary added that the committee unanimously recommended that the Council disapprove Dr. Fine's amendment. He moved the adoption of this recommendation. The motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

The Secretary spoke of a communication which had been received by the committee from Dr. Sidney C. Wiggin in which the latter requested that the Massachusetts Medical Society set up a Section of Anesthesiology. He referred the Council to this letter as published in the circular of advance information. He said that the committee looked favorably on this petition and recommended to the Council that such a section be set up. He moved the adoption of the recommendation. This motion was seconded by Dr. Peirce H. Leavitt, Plymouth, and it was so ordered by vote of the Council.

The Secretary said that the committee had reviewed the report of the Committee on Public Relations and approved the recommendations contained in this report.

He said that the committee had reviewed the report of the Committee Appointed to Confer with the Massachusetts Hospital Association and recommended to the Council that this report be referred back to its source for clarification.

The Secretary said that the committee noted that the President had created a Committee on Council

side, and the bronchogram a complete block of the left main bronchus. A bronchoscopy was performed that confirmed these findings.

Lung Changes in Electric Arc Welders

According to Sander,³³ it has become generally recognized that both acute and chronic lung changes may occur when welders are exposed to highly concentrated fumes. Sander discusses 4 cases, stating that he has not found any remarkable degree of bronchitis in welders generally, even including those who have obviously had intense fume exposures.

I recently had the opportunity to do a bronchoscopy on a patient exposed to the fumes of electric arc welding and found a slight chronic bronchitis. Following bronchoscopy the patient was completely relieved of his former symptoms, namely, sensation of a lump and irritation in throat, cough, wheeze, dyspnea and choking. He was convinced that the bronchoscopy had cured him. It is my opinion, however, that elimination of welding fumes is the real reason that he feels so well at the present time.

Sander concludes as follows: Electric arc welding that is done in large rooms and where the fumes are not allowed to concentrate excessively near the breathing level does not cause any lung changes, even after many years of work. Excessive inhalation of concentrated fumes, especially in confined and unventilated spaces, may cause siderosis in the lungs in six to ten years. The siderosis so produced consists only of inert iron-pigment deposits in the lymphatics, without proliferation of fibrous tissue and without progressive changes after exposure is materially decreased. This siderosis does not predispose to tuberculosis or other lung infections, nor does it cause functional impairment of the lungs and therefore symptoms referable to the lungs. Acute irritative phenomena of the throat may occur with too prolonged confined work in dense clouds of fumes, but these appear to be transitory reactions leaving no residual impairment. Any respiratory involvement may be prevented in welding, even with the most confined and prolonged work, if proper precautions are taken, either by adequate exhaust ventilation, ventilated helmets or positive-pressure respirators.

(To be concluded)

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Special Meeting, January 31, 1945

A SPECIAL meeting of the Council of the Massachusetts Medical Society was called to order at 10:30 a.m. in John Ware Hall, 8 Fenway, Boston, on Wednesday, January 31, 1945, by the president, Dr. Elmer S. Bagnall, Essex North; 207 councilors were present (Appendix No. 1).

The record of the meeting held on October 4, 1944, as published in the *New England Journal of Medicine*, issue of December 21, 1944, was presented by the Secretary. On a motion by Dr. John B. Hall, Norfolk, and a second by Dr. David Cheever, Suffolk, the record was approved by vote of the Council.

REPORT OF EXECUTIVE COMMITTEE

This report was presented by the Secretary. He said that the committee had reviewed a "basic general plan for a Massachusetts program for the care of children with acute rheumatic fever" as presented by the Committee on Public Health. He added that this plan was presented in detail in the circular of advance information, which had been sent to each councilor. He said that the committee recommended the approval of this report provided certain qualifications which had to do with those permitted to act as consultants under the plan be deleted. These qualifications were represented by the following words which appeared in that part of the report which referred to this subject: "who are certified by or eligible for certification by the boards of their respective specialties."

The Secretary spoke of a communication which the committee had received from Dr. Jacob Fine, in which the latter sought to have adopted the following amendment to the by-laws of the Massachusetts Medical Society:

Chapter V, Section 2b, is hereby amended to read as follows:

The Secretary of a District Society shall receive an application from a graduate of a discontinued medical school, a foreign medical school after the year 1933 or any medical school not approved by the Council only when the applicant has possessed a license to practice medicine in the United States or its territories for at least five years. A graduate of a foreign medical school on the approved list of the National Board of Medical Examiners prior to 1934 may apply for membership to the secretary of a district society if he has possessed a license to practice medicine for a minimum of five years.

He called attention to Dr. Fine's argument in support of this proposal as it appeared in the circular of advance information (Appendix No. 2).

In connection with the administrability of the proposed amendment the Secretary read the following letter from Mr. Everett S. Elwood, executive

secretary of the National Board of Medical Examiners:

Dear Dr. Tighe:

The only list of the European medical schools that the National Board ever had has been the list prepared by the Examining Board in England. As you know, there has never been an appraisal of the medical schools in Europe by any accredited agency in this country. Dr. Rappleye, dean of the Columbia University Medical School, brought back some information about the so-called "extramural schools" of Scotland and Ireland which indicated that they were not up to the standards set for the approved schools in this country and we therefore discontinued accepting their graduates after 1939, as the enclosed resolution will show. With this exception, our board has used the list of schools that were approved for admission to the examinations of the English Board, and until we stopped admitting graduates from the Continental schools of Europe we admitted to our examinations those whose credentials were satisfactory, if they had completed their work satisfactorily in a European school on the list of the English Board.

Your letter asks for a list before 1934. I enclose an extra copy, that we had on hand, of the pamphlet gotten out by the English Board in 1934. If I knew the particular school or schools to which you refer I could probably reply more satisfactorily.

Very sincerely yours,

EVERETT S. ELWOOD, *Executive Secretary*
National Board of Medical Examiners

December 21, 1944

The Secretary added that the committee unanimously recommended that the Council disapprove Dr. Fine's amendment. He moved the adoption of this recommendation. The motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

The Secretary spoke of a communication which had been received by the committee from Dr. Sidney C. Wiggin in which the latter requested that the Massachusetts Medical Society set up a Section of Anesthesiology. He referred the Council to this letter as published in the circular of advance information. He said that the committee looked favorably on this petition and recommended to the Council that such a section be set up. He moved the adoption of the recommendation. This motion was seconded by Dr. Peirce H. Leavitt, Plymouth, and it was so ordered by vote of the Council.

The Secretary said that the committee had reviewed the report of the Committee on Public Relations and approved the recommendations contained in this report.

He said that the committee had reviewed the report of the Committee Appointed to Confer with the Massachusetts Hospital Association and recommended to the Council that this report be referred back to its source for clarification.

The Secretary said that the committee noted that the President had created a Committee on Council

Rules. He reported that the Executive Committee approved of this act of the President and recommended that the Council do likewise. He moved the adoption of this recommendation. This motion was seconded by Dr. Guy L. Richardson, Essex North, and it was so ordered by vote of the Council.

He said that the Executive Committee had reviewed the report of the Committee on Council Rules and approved the recommendations contained therein, seeing in these recommendations a means of shortening, facilitating and making more orderly the conduct of the business of the Council.

He said the Executive Committee had reviewed the report of the Committee on Maternal Welfare and approved it.

He next reported on the questionnaire concerning the establishment of a Postwar Loan Fund for the use of those of our members after their retirement from the armed services. He said that 4609 questionnaires of the following character were sent out:

THE POSTWAR LOAN FUND

1. The only objective of the Postwar Loan Fund is to make available immediate financial assistance to those members of the Massachusetts Medical Society who, having served in the present World War, on separation from the service, are in need of temporary financial aid.

2. To establish this fund it is proposed to levy an assessment on all those members of the Society not privileged to serve in the armed forces during this War. While the amount of the levy and its duration will be determined by the Council of the Massachusetts Medical Society, the Committee on Postwar Loan Fund has recommended that this fund be raised by an assessment of \$10.00 on all the members heretofore described. It is to be understood that this assessment will have the same force as any assessment authorized by the Council in accordance with the by-laws of the Society.

3. The procedure of application to the fund will be simple and will entail no endorosees. The interest charge will be nominal. It will also be confidential between the applicant and a committee, to be appointed by the President.

4. In establishing such a plan we shall be privileged to serve those of our members who are serving us during these trying days.

5. Please indicate your opinion with reference to this fund on the space below, and mail it immediately, certainly on or before December 10, 1944.

PLEASE RETURN THIS BALLOT

I ☐ do
☐ do not approve of the Postwar Loan Fund.

Name

District

No unsigned ballots will be counted. Your ballot is confidential.

He added that 1897 post cards had been returned: 1457, or 76.8 per cent, approved, 374, or 19.7 per cent, disapproved, and 66 were blank.

The Secretary, in continuing to refer to this matter, said that the Executive Committee noted that, in the report originally offered by the Committee on Postwar Loan Fund, no recommendations were made as to the final disposition of the monies raised under these auspices.

There were those, he added, who thought that such funds, after they had served the original purpose for which they had been gathered, might be used to set up in the Society a permanent benevolent fund for the purpose of easing the burden of those of the fellows, or of their dependents, who had fallen on evil times.

He said that the use of the Society's funds as a means of financing the enterprise proposed by the

Committee on Postwar Loan Fund was also discussed and that, although no conclusions were arrived at by the Executive Committee in these matters, it recommended to the Council that the report originally offered be referred back to the Committee on Postwar Loan Fund for recommendations with regard to them.

The Secretary said that the Executive Committee reviewed the report of the Committee on Finance and approved it subject to certain corrections, which had since been made.

He said that the Executive Committee reviewed the report of the Committee on Postwar Planning and approved it.

He said that the Council, at its meeting February 5, 1941, authorized a change in the type of diploma which is issued to those who become members of the Massachusetts Medical Society. This authorization assumed that the supply of diploma forms then on hand be used until exhausted, which point was about to be reached.

The Executive Committee had inspected the new diploma and did not believe that it represented an improvement on the old one. It was thought that the new form was not well balanced as a document and that it was devoid of artistic merit. The Executive Committee therefore recommended that the Council rescind its action of February 5, 1941, and that the old form be continued. The Secretary moved the adoption of this recommendation. This motion was seconded by Dr. Leavitt, and it was so ordered by vote of the Council.

He added that the committee had approved of certain *ad interim* appointments made by the President.

He moved the adoption of the report as a whole. This motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

REPORTS OF STANDING COMMITTEES

Committee on Publications — Dr. Richard M. Smith, Suffolk, chairman.

This report (Appendix No. 3) was offered by the chairman, who expressed the committee's great sense of loss in the death of Dr. William B. Breed.

He said that the committee had invited Colonel Walter Bauer, medical consultant to the Eighth Service Command, to deliver the Shattuck Lecture and that the latter had accepted subject to exigencies of military duty.

He added that the committee recommended that a directory of the fellows of the Society be published in 1945, that the issue be limited to 500 copies and that not more than \$1500 be appropriated for this purpose.

Dr. Smith bespoke the committee's deep appreciation of the efficient manner in which the affairs of the *Journal* had been handled by the editor, Dr. Robert N. Nye. Miss Davies, the assistant editor,

and her assistants were also commended in the report.

Dr. Smith said that, during 1944, 6109 new "outside" subscriptions had been added and that this figure was 42 per cent greater than that of 1943. He said that 4221 of these were regular, and that 1888 were student subscriptions. He said that there were many cancellations but that the net increase was 2394 regular, and 357 student. He added, as being specially noteworthy, the fact that of the 1531 student subscriptions that had expired, 674 had been renewed at the full rate.

He said that, as of December 31, 1944, the *Journal* had 14,885 subscribers and that this did not include 337 copies that were sent once each month to the members of the New Hampshire Medical Society.

He said that the operations of the *Journal* during 1944 resulted in a net loss of \$7937, which is partly balanced by an appropriation of \$7900 from the Society. He added that the net cost to each member in 1944 was \$1.81 as compared with \$1.30 in 1943, and that this was so because of increased costs of printing and binding.

Dr. Smith said that 194 manuscripts had been considered by the Editorial Board during the year and that 151 were accepted. He added that the committee believed that a cut in pagination was more desirable than the acceptances of papers that do not meet the standards set by the board. He said that shortage of paper continues to represent a problem.

He spoke of the fact that a change had been made a year ago in the firm responsible for printing. It was hoped that this would overcome some of the difficulties that had been present in previous years. The problems, however, are still present, he added.

Dr. Smith spoke of a survey that had been conducted among the subscribers outside of Massachusetts for the purpose of determining the most popular features of the *Journal*. Those approached in this survey were also asked if they would subscribe to the progress reports if the latter were printed as a quarterly publication. Subscribers in Connecticut, Ohio, Texas, Oregon and Washington were polled. The majority indicated approval of the *Journal* because of its total content. The response to the question concerning the quarterly publication of the progress reports appeared to indicate that this would be a successful undertaking.

Dr. Smith said that the revenue from advertising during 1945 promises to be larger and that the net cost to the Society should be lower.

He added, finally, that the accounts of the *Journal* had been audited and found to be in order.

During the course of this report Dr. Smith showed a slide to illustrate certain facts contained in the report.

Dr. Smith moved the acceptance of the report and the adoption of the recommendations. This motion

was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

Committee on Arrangements — Dr. Roy J. Heffernan, Norfolk, chairman.

This report, which was offered by Dr. Heffernan, is as follows:

The Committee on Arrangements has held a number of meetings throughout the fall and early winter. As a result of these conclaves a varied and interesting program has been arranged for the annual meeting on May 22, 23 and 24, at the Hotel Statler, Boston.

We have been particularly fortunate in securing the active co-operation of the medical departments of the United States Army. Three of our speakers are from the Surgeon General's office, and another is the director of the Army Pathological Museum. We feel that the program will be of interest to all the members of our society but particularly to the general practitioner, for whom it is pre-eminently planned.

The sale of space to technical exhibitors has exceeded all previous records. Ten thousand, six hundred and twenty dollars' worth of space have been sold, and over \$6451.50 is now in the hands of your treasurer. This splendid achievement is due almost entirely to the energetic efficient management of this department by Mr. Robert Boyd.

Your committee is, of course, aware of the recent ruling of the O. D. T. forbidding meetings not connected with the war effort. We have a strong conviction, however, that our annual meeting is justified in view of our close co-operation with the armed services and other governmental agencies, and because the need for postgraduate instruction and demonstration is greater at this time than ever before. In due time we shall apply for permission to hold the meeting in its regular form, and our future activities will be governed by the result of that application.

Dr. Heffernan moved the adoption of the report. This motion was seconded by Dr. Hall, and it was so ordered by vote of the Council.

Committee on Ethics and Discipline — Dr. Ralph R. Stratton, Middlesex East, chairman.

No report.

Committee on Medical Education — Dr. Robert T. Monroe, Norfolk, chairman.

No report.

Committee on Membership — Dr. Harlan F. Newton, Suffolk, chairman.

No report.

Committee on Public Health — Dr. Roy J. Ward, Worcester, chairman.

Dr. Ward offered the report (Appendix No. 4) as it appeared in the circular of advance information and moved the approval of the rheumatic-heart-disease program as submitted therein. This motion was seconded by Dr. Leroy E. Parkins, Suffolk.

Dr. Donald Munro, Suffolk, moved as an amendment the adoption of the recommendation of the Executive Committee. (This called for the approval of the report provided the following phrase was deleted: "who are certified by or eligible for certification by the boards of their respective specialties.") This amendment was seconded by Dr. Richardson.

Dr. Helen S. Pittman, Suffolk, asked why the Executive Committee recommended the deletion of this phraseology.

Dr. Munro replied that such boards were not sufficiently established in the eyes of the public at large and particularly in the eyes of the general practitioner, who sees the majority of the cases of rheumatic heart disease, to warrant limiting the choice of consultants to this group.

The amendment was adopted by vote of the Council.

Dr. Ward's motion to adopt the report, as amended, was likewise ordered by vote of the Council.

Dr. Ward said that Chapter VII, Section 11, of the by-laws of the Massachusetts Medical Society state that the Committee on Public Health "shall foster the knowledge of the prevention and treatment of disease by any appropriate measures." He added that, under this definition, his committee had felt justified in entering into a study of the matter of transfusions and that with this end in mind the following subcommittee had been appointed: William Dameshek, chairman, Geoffrey Edsall, William Freeman, Charles A. Janeway, George L. Schadt, George MacIver, Joseph Ross and Benjamin F. Andrews.

Dr. Ward submitted the following report issued by the subcommittee:

The first meeting of the Subcommittee on Transfusions of the Committee on Public Health was held on Wednesday, January 24, and was attended by Drs. William Dameshek, chairman, Geoffrey Edsall, William Freeman, Charles A. Janeway and Elmer S. Bagnall.

It was the opinion of the committee that a review of the transfusion situation in the Commonwealth was greatly to be desired, with particular reference to reactions, methods of typing and cross matching, the types of personnel involved and so forth. Having once obtained a general idea of these data by means of questionnaires, it might then be desirable for the Society to participate in an educational campaign, preferably with the collaboration of the Massachusetts Department of Public Health.

Educational features might include a rather detailed instruction booklet for use by hospital physicians and technicians, systematically conducted talks by lecturers familiar with the subject, and short one-day or two-day refresher courses for technicians, the latter perhaps with the collaboration of the Commonwealth Fund and the Commonwealth.

Dr. Edsall, representing the Department of Public Health, expressed his great interest in the objectives of the committee and welcomed its possible collaboration, particularly with respect to revision of the present regulations regarding transfusions, the standardization of typing serums and so forth. He believed that new regulations respecting transfusions and new developments relating to inspection and standardization of typing serums might well be a collaborative venture between the Massachusetts Department of Public Health on the one hand and the Massachusetts Medical Society, through this special subcommittee, on the other.

It was finally concluded that this committee might function in these four fields: the collection of information regarding transfusions, blood grouping tests and transfusion reactions; education of physicians and technicians by appropriate means; the development of facilities relating to typing serums and so forth; and the standardization of regulations relating to transfusions. All these functions might be made in collaboration with the Department of Public Health.

An appropriation of \$200 would probably be sufficient to defray printing and mailing costs, particularly for the proposed questionnaire.

Dr. Ward moved that, with the approval of the Committee on Finance, \$200 be added to the budget of the Committee on Public Health to provide for clerical help and postage for making this study. This motion was seconded by Dr. Richardson.

Dr. George Leonard Schadt, Hampden, was recognized by the chair. He prefaced his remarks by assuring the Council that there was nothing personal in what he was about to say. He pointed out that this matter was presented to the Council in October and defeated. He expressed surprise on the receipt of a letter from Dr. Ward saying that he, Dr. Schadt, had been appointed to a subcommittee of the Committee on Public Health which subcommittee would consider the matter of transfusions. He added that what he had to say might therefore be considered in the nature of a dissenting minority report.

He thought the setting up of a subcommittee by a committee of the Society in a matter that had been turned down by the Council was establishing a curious precedent. He expressed the thought that this was work that the Massachusetts Department of Public Health, and not the Massachusetts Medical Society, should engage in.

Dr. Dameshek explained that, during the luncheon period at the October meeting of the Council, Dr. Ward had approached him and suggested that the Committee on Public Health was interested in this sort of thing and further suggested developing a subcommittee of his committee to look into this matter. He said such a subcommittee was established. He said that he was at a loss to understand the reaction against this sort of subcommittee. He expressed it as his belief that the Massachusetts Medical Society should be concerned with better practices and with the education of physicians. He added that the Society should likewise be concerned with the development of new technics in hospitals and with more or less supervision of these technics.

He thought such a subcommittee could gather information concerning the preliminary steps that should be used to safeguard transfusions, that the committee might draw up standards that could be used to further safeguard this procedure, that these standards might be set forth in a booklet and that talks and refresher courses to physicians and technicians might further supplement the program.

He expressed the hope that the motion would prevail.

At that point, Dr. Charles E. Mongan, Middlesex South, asked two questions: "Is the transfusion of blood from one person to another a public-health function, and what is public health? Where does public health end and private health begin?" The President answered by saying that the questions flattered him.

Dr. Mongan moved that the matter be laid on the table. The motion was seconded by Dr. Lester M. Felton, Worcester, and it was so ordered by vote of the Council. This action was accomplished by a show of hands — 84 for the motion and 71 against.

Committee on Society Headquarters — Dr. Frank R. Ober, Suffolk, chairman.

This report (Appendix No. 5) was offered by Dr. Ober, who pointed out that more room will be needed for the facilities of the Society — notably for the information bureau and, as pointed out in Dr. Smith's report, for the *Journal*.

Dr. Ober moved the adoption of the report. This motion was seconded by Dr. Hilbert F. Dav, Middlesex South, and it was so ordered by vote of the Council.

Committee on Medical Defense — Dr. Arthur W. Allen, Suffolk, chairman.

No report.

Committee on Finance — Dr. Francis C. Hall, Suffolk, chairman.

This report (Appendix No. 6), as published in the circular of advance information and representing the budget for the year 1945, was presented by Dr. Hall, who moved its adoption. This motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

Committee on Industrial Health — Dr. Dwight O'Hara, Middlesex South, chairman.

No report.

REPORTS ON STATE-WIDE COMMITTEES

Committee on Legislation — Dr. William E. Browne, Suffolk, chairman.

Dr. Browne announced that the holding of the Council meeting a week ahead of schedule had made a written report impossible.

Dr. Browne stated that Mr. Charles Dunn had been retained as counsel and that no contract had been entered into by the committee in this connection. He added that this left the committee free to make a change if it saw fit. He said that the committee was endeavoring to get the name of the family physician of each member of the Legislature and that some progress had been made in this direction.

Dr. Browne then spoke of Bill 261. He explained that this bill provided for a system of sickness insurance for those employed in industry. He added that the proposal would be compulsory from the standpoint of the employer and voluntary on the part of the employee and that the system thus set up would be administered by the Industrial Accident Board. He said that he had been informed by counsel that this bill was not in conflict with the

Blue Shield. He said that the committee was not prepared to advise with regard to this bill but that "by the time it comes up for discussion in the Senate and House, we shall know more about it and we trust that any action we may take will be worth while."

Dr. Browne next spoke of a bill sponsored by Dr. Leavitt, of Brockton. This bill, he added, had to do with the powers vested in medical examiners in the matter of autopsies. The proposed bill places the determination whether or not an autopsy shall be performed in the hands of the medical examiner. Dr. Browne said the committee approved the bill.

He spoke of a bill that would make cancer a reportable disease. He said that, although the bill was not without certain objections, he thought his committee would approve of it.

Dr. Browne next referred to House Bills 415 and 416 introduced on the petition of Dr. H. Quimby Gallepe. He said that, at its meeting held earlier in the day, the committee had voted to recommend to the Council disapproval of these bills. He explained that Bill 415 would forbid anyone to take the examinations given by the State Board of Registration in Medicine more than three times. He moved the adoption of this recommendation. This motion was seconded by Dr. Felton.

Dr. H. Quimby Gallepe, Middlesex South, explained reasons behind the two bills introduced by the Board of Registration in Medicine. He said that they were written by Dr. John Spellman for the purpose of obviating the practice of political pressure, which practice had placed past boards in trouble, and for the purpose of getting rid of those who obviously could never qualify. He said that only 40 per cent of those who took the examination in November passed and that the 60 per cent who failed comprised those who had taken the examination "over and over and over again." He said that Bill 416 would give the Board the right to examine a doctor whose license had been revoked and who had been away from the practice of medicine for a considerable time.

He added that Bills 415 and 416 were not important at the moment and that the Board would gladly set them aside if it could get complete support for the more important bills that were before the Legislature. He explained that the latter bills would tear down the Medical Practice Act and that, if their proponents were successful, Massachusetts would go back even beyond the unenviable position that she occupied previous to 1936. Finally, he urged the Council's support in defeating the bills introduced by the chiropractors, the osteopaths and those who favor substandard schools.

Dr. Browne agreed that the bills introduced by the Board might be considered at a later time.

Dr. Daniel B. Reardon, Norfolk South, said that his district was meeting with the legislators from that area on Thursday evening. He recommended this procedure to other districts.

Dr. Helen S. Pittman, Suffolk, asked why the Executive Committee recommended the deletion of this phraseology.

Dr. Munro replied that such boards were not sufficiently established in the eyes of the public at large and particularly in the eyes of the general practitioner, who sees the majority of the cases of rheumatic heart disease, to warrant limiting the choice of consultants to this group.

The amendment was adopted by vote of the Council.

Dr. Ward's motion to adopt the report, as amended, was likewise ordered by vote of the Council.

Dr. Ward said that Chapter VII, Section 11, of the by-laws of the Massachusetts Medical Society state that the Committee on Public Health "shall foster the knowledge of the prevention and treatment of disease by any appropriate measures." He added that, under this definition, his committee had felt justified in entering into a study of the matter of transfusions and that with this end in mind the following subcommittee had been appointed: William Dameshek, chairman, Geoffrey Edsall, William Freeman, Charles A. Janeway, George L. Schadt, George MacIver, Joseph Ross and Benjamin F. Andrews.

Dr. Ward submitted the following report issued by the subcommittee:

The first meeting of the Subcommittee on Transfusions of the Committee on Public Health was held on Wednesday, January 24, and was attended by Drs. William Dameshek, chairman, Geoffrey Edsall, William Freeman, Charles A. Janeway and Elmer S. Bagnall.

It was the opinion of the committee that a review of the transfusion situation in the Commonwealth was greatly to be desired, with particular reference to reactions, methods of typing and cross matching, the types of personnel involved and so forth. Having once obtained a general idea of these data by means of questionnaires, it might then be desirable for the Society to participate in an educational campaign, preferably with the collaboration of the Massachusetts Department of Public Health.

Educational features might include a rather detailed instruction booklet for use by hospital physicians and technicians, systematically conducted talks by lecturers familiar with the subject, and short one-day or two-day refresher courses for technicians, the latter perhaps with the collaboration of the Commonwealth Fund and the Commonwealth.

Dr. Edsall, representing the Department of Public Health, expressed his great interest in the objectives of the committee and welcomed its possible collaboration, particularly with respect to revision of the present regulations regarding transfusions, the standardization of typing serums and so forth. He believed that new regulations respecting transfusions and new developments relating to inspection and standardization of typing serums might well be a collaborative venture between the Massachusetts Department of Public Health on the one hand and the Massachusetts Medical Society, through this special subcommittee, on the other.

It was finally concluded that this committee might function in these four fields: the collection of information regarding transfusions, blood grouping tests and transfusion reactions; education of physicians and technicians by appropriate means; the development of facilities relating to typing serums and so forth; and the standardization of regulations relating to transfusions. All these functions might be made in collaboration with the Department of Public Health.

An appropriation of \$200 would probably be sufficient to defray printing and mailing costs, particularly for the proposed questionnaire.

Dr. Ward moved that, with the approval of the Committee on Finance, \$200 be added to the budget of the Committee on Public Health to provide for clerical help and postage for making this study. This motion was seconded by Dr. Richardson.

Dr. George Leonard Schadt, Hampden, was recognized by the chair. He prefaced his remarks by assuring the Council that there was nothing personal in what he was about to say. He pointed out that this matter was presented to the Council in October and defeated. He expressed surprise that he, Dr. Schadt, had been appointed to a subcommittee of the Committee on Public Health which subcommittee would consider the matter of transfusions. He added that what he had to say might therefore be considered in the nature of a dissenting minority report.

He thought the setting up of a subcommittee by a committee of the Society in a matter that had been turned down by the Council was establishing a curious precedent. He expressed the thought that this was work that the Massachusetts Department of Public Health, and not the Massachusetts Medical Society, should engage in.

Dr. Dameshek explained that, during the luncheon period at the October meeting of the Council, Dr. Ward had approached him and suggested that the Committee on Public Health was interested in this sort of thing and further suggested developing a subcommittee of his committee to look into this matter. He said such a subcommittee was established. He said that he was at a loss to understand the reaction against this sort of subcommittee. He expressed it as his belief that the Massachusetts Medical Society should be concerned with better practices and with the education of physicians. He added that the Society should likewise be concerned with the development of new technics in hospitals and with more or less supervision of these technics.

He thought such a subcommittee could gather information concerning the preliminary steps that should be used to safeguard transfusions, that the committee might draw up standards that could be used to further safeguard this procedure, that these standards might be set forth in a booklet and that talks and refresher courses to physicians and technicians might further supplement the program.

He expressed the hope that the motion would prevail.

At that point, Dr. Charles E. Mongan, Middlesex South, asked two questions: "Is the transfusion of blood from one person to another a public-health function, and what is public health? Where does public health end and private health begin?" The President answered by saying that the questions flattered him.

He moved the adoption of this recommendation. This motion was seconded by Dr. Cheever and it was so ordered by vote of the Council.

The second was as follows:

The secretary of the Society should instruct and encourage the executive secretary of the Society to familiarize himself with medical publicity.

Dr. Hornor moved the adoption of this recommendation. This motion was seconded by Dr. George J. Connor, Essex North, and it was so ordered by vote of the Council.

Dr. Hornor said that it was the unanimous opinion of the committee that the expense involved in the second recommendation should be charged to administration. He added that it was also the unanimous opinion of the committee that publicity for the annual meeting was the responsibility of the Committee on Arrangements.

Dr. Hornor moved the discharge of the Subcommittee to Look into the Matter of Better Publicity for the Massachusetts Medical Society. This motion was seconded by Dr. Richardson and it was so ordered by vote of the Council.

Dr. Hornor in offering the third recommendation reported the approval by the Committee on Public Relations of the following motion:

That the Committee on Public Relations of the Massachusetts Medical Society report to the Council of the Massachusetts Medical Society that this committee is in favor of finding and expanding common grounds of agreement with representative groups of the public and that a committee be appointed by the President with the end in mind of creating a better general understanding of the problems involved in good medical care.

He moved the adoption of the recommendation contained in this motion. This motion was seconded by Dr. Richardson, and it was so ordered by vote of the Council.

On behalf of the Committee on Public Relations Dr. Hornor moved the adoption of the fourth recommendation, which is as follows:

The Committee on Public Relations, recognizing the Society's obligation to further education of the public in regard to medicine, recommends to the Council that the president of the Society appoint a special committee, containing representatives of the Committee on Public Relations, Committee on Ethics and Discipline, Committee on Publications, Committee on Public Health and any others that he desires, to further the education of the public in regard to medical questions, particularly through popular magazines.

This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Hornor said that the following questions concerning industrial accidents had been referred to a subcommittee headed by Dr. Ellison:

The abuse of the rules that an injured employee may have the services of a physician of his own choice.

The question of the correct charge by a doctor to a patient he treated, the case having previously been declined by the Committee on Ethics and Discipline.

The question of simplified insurance forms, which was brought to the attention of the committee by the Norfolk District Medical Society.

Dr. Hornor said that the committee had reviewed the report of the Committee Appointed to Confer with the Massachusetts Hospital Association and approved the recommendations contained in that report.

Dr. Hornor moved the adoption of the report as a whole. This motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

Subcommittee (of the Committee on Public Relations) to Meet with the Medical Advisory Committee of the Industrial Accident Board—Dr. Daniel J. Ellison, Middlesex North, chairman.

This report (Appendix No. 8) was offered by Dr. Ellison. He said that, although his committee had been originally appointed to confer with the Medical Advisory Committee of the Industrial Accident Board, it had been directed by the Committee on Public Relations to take up directly with the board certain problems that had arisen.

He said that the first problem had to do with a complaint that certain insurers and employers were in fact compelling injured employees to submit to treatment at the hands of surgeons and at hospitals not of their own choice and that such employers even went so far as to discharge the injured workman if he did not acquiesce.

He added that Mrs. Tousant, chairman of the Industrial Accident Board, had informed him that if any doctor knows of such a case and will present all the facts in writing to her, including the date of the accident, the name of the employee and of the foreman, nurse or other person engaging in the illegal action, she will promptly put a stop to it. He pointed out that it must be obvious that the chairman of the board could not act on mere gossip.

The second problem had to do with a person who allegedly sustained a hernia in the course of his employment. The insurance company denied responsibility, and the injured workman privately contracted with a doctor of his own choice for the repair of the hernia. Under the contract the doctor charged the workman \$250, out of which amount the doctor agreed to and did pay the hospital bill. Subsequently, the Industrial Accident Board found that the insurance company was liable. The plaintiff then tried to recover the \$250 that he had expended. Dr. Ellison said that his committee agreed with Mrs. Tousant that the insurer should be liable only for the amount usually allowed by the board as compensation for the surgeon and hospital in an uncomplicated case of this kind.

Dr. Ellison said that the Industrial Accident Board was being greatly disturbed by a problem that was becoming widespread, especially in Boston. A workman is said by a physician to have sustained an industrial hernia. The workman is forthwith sent into some private hospital and operated on. No records or very sketchy records are kept. There is no proof that a herniotomy has been done. There

Dr. Richard Dutton, Middlesex East, asked whether, if the Approving Authority was now in effect, it applied to all candidates eligible for examination. Dr. Gallupe explained that those who entered a medical school after January 1, 1941, must graduate from an approved school. Otherwise, they are not permitted to take the examination leading to licensure in Massachusetts. In addition he pointed out that such graduates are not permitted to practice medicine anywhere in the United States. He said that the effective date of the present law was originally January 1, 1939, and that it was amended so as to give the substandard schools two years' additional grace. He pointed out that there was a bill before the Legislature that would further postpone the effective date of this law until three years after the close of the present war.

Dr. Paul J. Jakmauh, Norfolk, moved as an amendment to Dr. Browne's motion that the committee be instructed to ask leave to withdraw these bills and therefore give the committee further time to study and present the matter to us. This amendment was seconded by Dr. Merrill C. Sosman, Suffolk.

The President called for the vote on this amendment, but before it could be completed Dr. Browne moved that the matter be tabled. This motion was seconded by Dr. Leavitt.

Dr. Humphrey L. McCarthy, Norfolk, asked if, in the event that this motion prevailed, it would mean that the Council took no action on these bills. He was informed by the President that that was his conception of the situation. Dr. McCarthy pointed out that the Committee on Legislation voted unanimously to oppose these measures. He added that it was his belief that the chairman of that committee should not instigate their being tabled.

At that point Dr. Leavitt suggested that Dr. Browne withdraw his amendment saying that he, Dr. Leavitt, would make the same amendment on Dr. Browne's withdrawal. He expressed the thought that this might be a more seemly way to present this type of motion to the Council.

Dr. Browne did not acquiesce. He thought that there was merit in not having the Council go on record as opposed to matters that it might deem wise to favor in the future.

At that point the President said, as a means of clearing the air, that he would entertain a motion of support for the Committee on Legislation. Dr. Schadt so moved. This motion was seconded by Dr. Leavitt, and it was so ordered by vote of the Council.

Dr. Browne next referred to a bill introduced by a chiropodist, which would permit chiropodists to use a hypodermic syringe in the course of their professional activities. He said that his committee had opposed this bill and that it had been withdrawn after a hearing before the Committee on Public Health of the Legislature.

Dr. Browne next grouped several bills that would

further postpone the operative date of the Approving Authority. These bills would, he added, delay the operative date from one to three years after the termination of the present war. He said that the committee opposed the bills.

Dr. Browne next referred to a bill that would create a State University Medical School.

Dr. Browne spoke of a plan to form a committee of fifty-four to be made up of the president and two others from each district society. He said that this plan included the thought that eighteen of this number might wait on the Governor in case any of the bills, referred to as being opposed by the committee, should get to him for his signature, and explain why he should not sign them.

Dr. Browne expressed his thanks for the help that he had been given by Dr. Charles E. Mongan. He also spoke of the importance of having our members present at the hearings on these bills. He quoted a member of the Committee on Public Health as saying that the objectionable bills had a 50 per cent chance of going through.

He referred to the so-called "Chiropractic Bill" and said that, in this connection, the committee stood for one single standard, which all should meet if they would practice the healing art.

Dr. Browne moved that the Council extend its thanks to Dr. Brainard F. Conley, former chairman of the Committee on Legislation, for the years he had effectively put into the legislative work. This motion was seconded by Dr. Walter H. Pulsifer, Plymouth, and it was so ordered by vote of the Council.

Dr. Browne moved the adoption of the report. This motion was seconded by Dr. Pulsifer, and it was so ordered by vote of the Council.

Dr. Browne said he made this motion subject to amending the report when it appeared in formal shape.

The Council adjourned at 2:00 p.m. for luncheon and reconvened at 2:45 p.m.

Committee on Public Relations—Dr. Albert A. Hornor, Suffolk, secretary.

This report (Appendix No. 7) was offered by Dr. Hornor.

In offering this report, Dr. Hornor said that the Committee on Public Relations had considered the question of policy to be followed in supplying advice to lay inquiries coming into a community about the selection of a family physician. He said that it was the opinion of the committee that all requests for information of this kind should be referred to the secretary of the respective district society.

He offered four recommendations, all of which he said had been approved by the Committee on Public Relations. The first was as follows:

In view of the probability of not getting an ideal man now, the Society should not try to hire a publicity agent at the present time.

hospital, as well as surgery and obstetrics. And I am sure that if we can move on that basis it will be a much healthier approach than what has occurred in some other sections.

I think that it should be drawn to your attention that in California, where they have only approached our present figures, or a little bit more, in a five-year period, and where they have not had the healthy relation of general goodwill that Massachusetts has experienced, the profession seems to be taking a definite step in co-operation with the governor to institute a program of compulsory health insurance. It behooves us to prove that a voluntary program can succeed, because if not, this may lead to a feeling on the part of the profession that no ultimate solution can be achieved other than compulsory health insurance.

The revision of the fee schedule by the specialists' group is progressing. Of course, it must be slow and should be accurate. Many men have given a good deal of time and thought to establishing a more adequate schedule, and it is my hope that after each group has completed its part, at least the chairman of each group will evaluate the conception of the value of the service of other groups in contrast with his own personal conception of the value of his own service. That certainly is a fair approach to the problem of getting an equitable base of compensation through all the groups.

There has been a change in the Board of Directors, owing to the untimely loss of the services of Dr. J. Harper Blaisdell. His place has been filled by Dr. Norman Welch, which gives representation in the Board of Directors of an internist, which means, of course, that if within this year we can move effectively in the problem of arranging for some medical care in the hospital his presence will contribute a great deal.

I think that we should think in terms of stabilizing our program. We have sought to eliminate problems and frictions and misunderstanding. There are, of course, innumerable "bugs," as in any new venture, that must be ironed out. The fee schedule is one on which we are putting a great deal of time. We have achieved a great deal more satisfactory contact with groups, so far as publicity is concerned, since we have the full-time services of Mr. Cunningham. He is trying to approach hospital staffs and to discuss the problems with them, and I hope that he will be given a welcome reception. He is also trying to interest other groups. Publicity is difficult. We do have plans, as you have noted, to get periodic records and statements into the *New England Journal of Medicine*. Beyond that it is difficult. The hired layman can contribute some time to this aspect, but, those of us who are serving you in trying to make this program roll are limited in our time, and we cannot indulge in much writing on the side regarding the meetings that we have to keep this thing going.

It should be kept in mind that there are channels through which you can move with reference to the corporation that you have established. Physicians have an effective control over this organization through the Executive Committee of the Society, the members of which, as you know, constitute the voting members of the corporation and are in contact with physicians all over the Commonwealth and sensitive to their opinions. The voting members at all times are free to send recommendations and memoranda to the Board of Directors, which, of course, would be seriously weighed. On any major departures in reorganization and extensions, as you remember, under the factors we call vital medical matters, the board is required to give thirty days' notification to the voting members, the Executive Committee, so that any radical action can be immediately held up until further consideration is given to it.

All in all, things seem to point to the fact that this year will prove that we have initiated a successful venture. I surely hope so.

Dr. McCann left the platform amid applause.

REPORTS OF SPECIAL COMMITTEES

Committee on Cancer — Dr. George A. Moore, Plymouth, chairman.

No report.

War Participation Committee — Dr. Guy L. Richardson, Essex North, chairman.

This report, which is as follows, was presented by Dr. Richardson:

The situation in Massachusetts regarding doctors' certificates for change of employment appears to be satisfactory to the War Manpower Commission. Thus far we have not been asked to review any of these certificates. In a letter to me under date of January 13, 1945, Mr. James G. Walsh, assistant state director, writes: "We would very much welcome your continued assistance to the War Manpower Commission throughout the Commonwealth and I wish to assure you that the announcement by this commission that medical certificates would be reviewed by your committee has been very helpful." At the present time there is no outstanding case which this office feels should be sent to you for review. In general, the doctors have co-operated exceedingly well. Again, let me thank you for your continued co-operation in this matter."

The Office of Price Administration has several times called on us for assistance. We have appointed local war participation committees to assist the ration boards in communities where there was need for such help. In some cities, physicians' committees to do this work had already been in operation and were of distinct benefit to the rationing plan.

Miss Elizabeth Golden, rationing specialist of the Office of Price Administration, makes the following statement: "Throughout the State the result of establishing these committees has been to reduce immediately the number of spurious requests for extra foods. Now that it is generally known that competent medical authorities are controlling the rations, doctors who heretofore have signed with little regard for what they are asking are more inclined to be careful and frequently deny requests for special indulgence." These committees are guided by the general directions on food rationing from the Medical Advisory Committee, under the chairmanship of Dr. Joseph Garland.

Doctors' prescriptions for heavy cream have steadily lessened. The War Food Administration now receives two or three a day instead of the one hundred a day formerly received. Only thirty-five of these prescriptions have been approved since August 1, 1944. Cream is not a rationed product, but the need to conserve fats is great. The publicity given by us in this matter has helped. Dr. Garland and his committee have done the real job.

In our October report to the Council we told you that we were gathering data on the adequacy of hospital care for emergency cases. In the main the response from the hospitals was excellent. One or two did not reply, and the replies from a few did not contain the information desired. To summarize the results: no problem in this respect appeared to exist in the Springfield and Worcester hospitals, all answering that no emergency patients were refused admission. These answers placed Springfield and Worcester with the smaller cities and towns, which were considered by us not to need this inquiry. The problem was thus narrowed to Boston. More than two thirds of the Boston hospitals admitted having to refuse admission to some or many emergency cases because of lack of personnel or beds.

On January 17, at our request, we held a joint meeting with the Committee Appointed to Confer with the Massachusetts Hospital Association, of which Dr. Walter Phippen is chairman. Ways and means to lessen the frequency of the refusal of emergency cases were considered. It was decided to seek further co-operation from physicians in agreeing to postpone admission of an elective case to allow admission of another physician's emergency case, to discriminate more carefully in labeling a case as an emergency (some hospitals have a committee of doctors to check the question of urgency) and to discharge patients from the hospital as early as possible.

It was voted to recommend to the Council that the Committee Appointed to Confer with the Massachusetts Hospital Association inform that association that we as physicians are fully cognizant of the immensity of their problem in these war years and that we believe they have fulfilled their obligations well, and further that we welcome

is even no proof that the man in fact did have a hernia. Dr. Ellison, in the name of his committee, recommended that a committee from the Society be appointed to study the problem and report at some future time to the Council. He moved the adoption of the recommendation. This motion was seconded by Dr. Hornor, and it was so ordered by vote of the Council.

Dr. Ellison next referred to a suggestion that had come from the Norfolk District Medical Society to the effect that industrial accident forms be shortened. Dr. Ellison pointed out that there were certain essential questions that must be answered on all forms of this kind. He added that when and if such a short form was developed he would gladly go back to the board with it.

Dr. Ellison completed his report by paying a very high tribute to Mrs. Tousant, chairman of the Massachusetts Industrial Accident Board.

Subcommittee (of the Committee on Public Relations) on Tax-Supported Medical Care—Dr. John J. Dumphy, Worcester, chairman.

This report, which is as follows, was offered by Dr. Dumphy:

The committee is aware that approximately 16,000,000 veterans on their return to civilian life are eligible to receive tax-supported medical care.

Recognizing our responsibility to help provide better care for veterans, we believe that the Committee on Legislation would do well to favor free choice of physician and hospital by veterans. This would permit these men to be cared for in their own communities.

Dr. Dumphy moved the adoption of the report. This motion was seconded by Dr. Connor, and it was so ordered by vote of the Council.

Subcommittee (of the Committee on Public Relations) on Postpayment Medical Care—Dr. Daniel J. Ellison, Middlesex North, chairman.

This report, which is as follows, was offered by Dr. Ellison:

One meeting of the enlarged committee has been held since the last session of the Council. At that time the principles of the plan were outlined in full by Mr. William McCarthy, vice-president of the National Shawmut Bank. On the motion of Dr. Bagnall, it was voted that the presidents enlarge their local committees to include one man from the several communities therein to act as liaison officers between the medical men and the local bank or banks. The various presidents have responded well to this request, and in many districts these committees are now functioning. It was thought that the members of the state committee might well act as chairmen of the local committees.

A second meeting of Dr. Bagnall and myself with Mr. McCarthy and Mr. John Mack, of the American Bankers Association, was held ten days ago to discuss ways and means of bringing this plan to the attention of the public. It was believed that this could be done by suggestions by the doctors to their patients. One method might well be a booklet put out by the Society extolling the benefits of the Blue Cross, Blue Shield and Blue Triangle. Another would be its being drawn to the attention of depositors as they transact business with banks, and still another, as certain forms of newspaper publicity. It is a fact that this is the only state that has possibilities of complete budget

payment for all medical care—the Blue Cross for hospital care; the Blue Shield for certain surgical, maternity and diagnostic care, and the Blue Triangle to cover the parts not included in the first two.

There is one feature of this plan that should again be brought to your attention. That is the phrase, "with recourse." When it was mentioned last, you men gave me a beautiful Bronx cheer. This was undoubtedly due to a misunderstanding. The amount of the face of the note is not to buy someone's wife a fur coat or pay money lost on the horses; it is money owed you.

It is the opinion of your committee that this plan is sound. At present most people pay their bills. The time will come, however, when we shall want to use this plan oftener. Let's get acquainted with it now by using it in the occasional case.

Dr. Ellison moved the adoption of the report. This motion was seconded by Dr. Richardson, and it was so ordered by vote of the Council.

Blue Shield

At that point, Dr. James C. McCann, Worcester, was called on for a report on the Blue Shield. He spoke as follows:

I shall make as brief a statement as I can, just so that you may know what is happening with reference to the Blue Shield. At present 88,000 subscribers are enrolled. In the month of January of this year, over 18,000 were enrolled. It took the whole first year to enroll 25,000 so that in this one month we have approximated what we accomplished in the first year.

As in all of this type of endeavor, one hits a point where there appears to be what you might call the snowball rolling, and we only hope that this marked increase in enrollment denotes the real expansion of the Blue Shield. We have also had progressive increase in the number of physicians who have signed up as participating physicians, the number at present being over 4000, which represents a large percentage of the actively practicing men who are still in the Commonwealth, due allowances being made, of course, for the men who are in the service.

Many of the names of nonparticipating physicians, when rechecked through the local committees and through the available information headquarters, are men who are in the service.

With regard to our finances, we are still in an extremely healthy position. As you know, the Commissioner of Insurance requires that 25 per cent be immediately placed aside for a growing reserve, and we are not free to use this money until it totals \$225,000. We have \$90,000 in that reserve at the present time, and with our growing enrollment, I hazard a guess that by July we shall have satisfied the requirements of the commissioner with reference to the total sum of the reserve. At that point, of course, we shall be freed from the restriction on returning the \$25,000 to the Society and it can be returned intact.

This means at the present time, with this required 25 per cent reserve, that we are running on a 75 per cent margin. That has interesting possibilities for the future, because, of course, our next move should be, as was outlined in the program that was accepted by the Society, the inclusion of medical care in hospitals. That program, I think, we should adhere to rigidly, because it is vital that that step be taken in order effectively to make all the men who are participating in the support of this project eligible for care of patients under this project.

All the men who have patients in the hospital under medical care at the present time are not participating, but have signed up simply on the basis of goodwill. From a restricted experience in New Jersey, which would have to be closely evaluated before it could be used as a base on which definitely to build and commit ourselves, medical services in the hospital have ranged on the financial side from 15 to 21 per cent. If we should have a similar experience, our premium rates, in view of the fact that 25 per cent will eventually be released, should be adequate to include a large proportion of the expense of medical care in the

tract all those things for which the hospital usually made a charge. He added that this left the matter squarely in the hands of the radiologist to make whatever arrangements he and the hospital could jointly agree on.

Dr. Hornor said that there evidently was a disposition on the part of radiologists to change certain practices that had grown up in this specialty and that in this spirit they had approached the Committee on Public Relations last summer so that they might have the help of the Massachusetts Medical Society in this purpose. He added that the Society should give them all the help it could.

Dr. John Fallon, Worcester, expressed the view that the matter should be further considered by the radiologists and the committee. He added that the inclusion of x-rays in the Blue Cross contract should not defer the Society from pursuing this subject further.

Dr. Bagnall said that the x-ray group had demonstrated and exercised more constructive thinking in the last year than it had in all the time that has elapsed since the start of the Blue Cross. He said that, in view of this fact, he believed the group should have been given more time. He added that he voted against the inclusion of x-ray in the contract when this matter was recently before the directors of the Blue Cross.

Dr. Howard F. Root, Suffolk, asked if, in the discussions on this subject, any consideration had been given to the possibility of separating the hospital from the professional costs. Dr. Bagnall said that Dr. Faxon could answer the question better than he.

Dr. Dameshek moved as an amendment the adoption of the recommendation of the Executive Committee.

Dr. Phippen was asked by the President if he would accept the amendment. He said that he was a little disposed not to accept the amendment. He believed the report should be voted on as presented. In support of this report he said that apparently brevity is not always conducive to clarity. The report as modified, he thought, was fairly clear. He added that what the committee intended to say in the second paragraph, the matter discussed by Dr. Faxon, was that a hospital should not exploit its x-ray department. He said that no one could question the fact that the radiologist furnishes medical service and that from the standpoint of this report nothing was said whether the Blue Shield or the Blue Cross should make provisions for x-ray. What the committee did say, he continued, was that, if either of them was going to take over the full professional service of the radiologist, the Blue Shield was the logical one to do it.

Dr. Faxon agreed with the President that the radiologist had begun to show a little constructive

thinking in the matter during the last year. He expressed the opinion that the problem could be solved by the hospitals and radiologists getting together on it.

Dr. Leavitt reiterated his belief that there seemed to be some sort of argument going on among the members of the x-ray society and that the latter should settle their own differences.

The amendment to refer this matter back to the committee for clarification was put and was lost.

The original motion was put by the chair, and so ordered by vote of the Council.

Committee on Postwar Planning—Dr. Howard F. Root, Suffolk, chairman.

This report (Appendix No. 9) was offered by the chairman. He said that Dr. Leroy Parkins had agreed to serve as secretary.

He announced that the committee had organized many subcommittees of the whole. These had to do with hospitals, postgraduate education, medical schools, Massachusetts Medical Society organization and medical economics.

The report quoted from the record of the Council meeting held on June 9, 1936, regarding approved recommendations for the establishment of local medical-service councils. Dr. Root said that twenty-three local health councils now exist and co-operate with the Massachusetts Central Health Council. He added that physicians should take more interest in them for the purpose of their greater activation and that additional councils should be organized. Dr. Root moved acceptance of this part of the report. This motion was seconded by Dr. Phippen, and it was so ordered by vote of the Council.

Dr. Root moved that the Council authorize the President to inform the president and secretary of each district society, the chairman of each health council, the superintendent or chairman of the staff and the chairman of the board of trustees of each hospital in the Commonwealth whose staff members are in community practice concerning the following resolution:

RESOLVED, That the Council of the Massachusetts Medical Society, having in mind the unusual problems of medical care to be presented now and in the postwar period, recommends (1) the formation of health councils where none exist, or when the present council is inactive, to be composed of physicians and dentists, hospital trustees, public-health specialists, educators, editors, employers and representatives of labor and groups concerned with the distribution of medical care, to consider and adopt further measures for extending medical services in the community and increasing preventive-health education both by local effort and through co-operation with state and federal bodies; (2) more active participation by physicians in the work of health councils already in active existence; and (3) that the Committee on Public Relations implement these recommendations in such manner as the committee deems most profitable.

This motion was seconded by Dr. Ohler, and it was so ordered by vote of the Council.

suggestions for added co-operation by the medical profession to the end that a real emergency be not refused admission.

Dr. Richardson moved the acceptance of the report and the adoption of the recommendation contained therein. This motion was seconded by Dr. Phippen, and it was so ordered by vote of the Council.

Committee on Rehabilitation—Dr. Joseph H. Shortell, Suffolk, chairman.

No response.

Committee Appointed to Confer with the Massachusetts Hospital Association—Dr. Walter G. Phippen, Essex South, chairman.

Dr. Phippen in reading the following report said it was somewhat different from that submitted to the Executive Committee and set forth in the pamphlet of advance information.

The Committee Appointed to Confer with the Massachusetts Hospital Association was invited to meet with representatives of the New England Roentgen-Ray Society and the Section of Radiology of the Massachusetts Medical Society on November 13, 1944. Those present at the meeting were Dr. Hugh F. Hare and Dr. George Levene, of the New England Roentgen-Ray Society, Dr. George Holmes, of the Massachusetts General Hospital, Dr. Merrill C. Sosman, of the Peter Bent Brigham Hospital, Dr. Stanley Wilson, of the Salem Hospital, and the committee (Dr. Walter G. Phippen, chairman, Dr. Elmer S. Bagnall, Dr. Edwin D. Gardner, Dr. John Fallon and Dr. Frederic Hagler).

A long and friendly discussion of the whole situation of the relation of the radiologist to the hospital and to the Blue Cross and Blue Shield ensued. The members of the committee thought that they could unanimously agree to the resolutions drawn up by the New England Roentgen-Ray Society and the Section of Radiology, and unanimously adopted by them on November 3, 1944, as follows:

The professional status of the radiologist in a hospital should be comparable to the status of other chiefs-of-service in that hospital.

It should be agreed that a hospital should not make excess profit from medical services. It is agreed that a hospital with the overhead necessary to maintain a medical service at a high standard should be reimbursed for the actual expenses of maintaining a department, with a fair share of overhead, investment of capital, maintenance and replacement of equipment.

If the Massachusetts Hospital Association agrees to these basic principles, fees can be reduced and the cost of medical care can be lowered.

The committee members were also of the opinion that the radiologist furnished medical service rather than hospital service and that therefore payment for his service should logically come under the Blue Shield rather than under the Blue Cross.

The committee was unanimous in voting to present this statement to the Executive Committee at its next meeting in the hope that it could support this resolution and present it to the Council for its approval.

Dr. Phippen moved the adoption of the report and the adoption of the resolution. This motion was seconded by Dr. Hornor.

Dr. Nathaniel W. Faxon, Suffolk, asked that the recommendation of the Executive Committee in connection with the matter be read. Dr. Leavitt read the recommendation as follows:

The Executive Committee recommends that this report be referred back to the committee for clarification.

Dr. Faxon said in general he was in accord with the report. He thought, however, as it referred to the profit made by hospitals, the word "undue" should be made to appear before the word profit. Speaking for one hospital, he said that he subscribed to the feeling that a great many radiologists have, namely, that hospitals should not make a large profit out of their profession and practice. He added that some hospitals will probably not subscribe to this view. He said that he also believed that members of hospital staffs should not profit unduly by the fact that they are members of such staffs.

Dr. Leavitt, in expressing the views of the Executive Committee in connection with this report, said that the committee was very much in the dark about what was actually going on. He added that the whole thing sounded as if there was an argument somewhere and that the committee thought that it should know more about the matter before it lent itself to the argument.

Dr. William A. R. Chapin, Hampden, expressed support for the Executive Committee's recommendation.

In confirmation of the point made by Dr. Leavitt, that there seemed to be an argument going on somewhere, he said he had talked with Dr. Jackson, whom he identified as "our radiologist at home," and that the latter said that he had attended the meeting of the radiologists at which these principles were adopted and that the arguments for and against were so mixed up that he, Dr. Jackson, could not make sense out of them.

Dr. Reardon asked if Dr. McCann could give the Council any information as to what was the practice with regard to x-rays in other state medical-service plans. Dr. McCann replied that in those plans that included x-rays a cash allowance was made, in most cases up to \$15.00. He added that the New Jersey plan did not include x-ray.

Dr. Faxon said that a substantial number of Blue Cross plans include x-ray as part of what is spoken of as hospital expense. He added that the Massachusetts Blue Cross was disposed to treat the radiologists as fair as possible and that this problem had been debated ever since Blue Cross started and was continuing to be debated at the present time. He finally said that he himself had not arrived at the answer.

Dr. Hornor pointed out that, so far as the inclusion of x-ray in the Massachusetts Blue Cross plan is concerned, it was an accomplished fact. Dr. Faxon said that although this was so it was with reluctance that such a policy had been established. He added that the Blue Cross had been trying to get this matter settled for three or four years and was not getting anywhere. He also said that, at the last meeting of the Blue Cross directors, the majority felt that it was the only thing to do.

Dr. Bagnall said that what the Blue Cross directors actually voted to do was to include in the con-

It was pointed out that the United States Public Health Service expects to get money to finance stated services in their hospital situations.

Former Governor Saltonstall has passed on to Governor Tobin the appointment of the committee which would be expected to study the whole situation, especially the ability of nonteaching hospitals to set up residencies.

The American Hospital Association is also devising a questionnaire to be sent to hospitals for a survey, conducted under Dr. Bachmeyer, with Dr. Norby as assistant director.

It is possible that the Army and Navy will take over refresher courses, so-called, and carry them on in Army, Navy or Veteran hospitals. Additional Veteran hospitals might well be built close to medical centers instead of in the country, as in prewar times.

It was pointed out that it was necessary to sort out these war medical graduates and select those worth teaching and not waste time on the others.

Lastly, it was suggested that an extern service might serve to take care of a great many of these returning veterans.

Dr. Faxon moved the acceptance of the report. This motion was seconded by Dr. Ober, and it was so ordered by vote of the Council.

Committee on Medical Information Bureau — Dr. Walter G. Phippen, Essex South, chairman.

This report, which was offered by Dr. Phippen, is as follows:

Since the last meeting of the Council, the Bureau of Clinical Information of the Massachusetts Medical Society has become a going concern. Invitations were sent to twenty-two hospitals in Greater Boston to meet with this committee on October 25, 1944. Twenty hospitals accepted and sent a representative to the meeting. All not only were co-operative and offered the co-operation of their hospitals but were enthusiastic about the project. The Bureau opened on November 15, 1944, with Miss Mary D. Gaston in charge as secretary. An announcement of this fact was sent out as follows: to the secretaries of every district medical society, with the request that it be read at the next meeting; to the secretaries of every state medical society in the United States; to the secretary of the American Medical Association; to the editors of every state medical journal, with the request that they print it; to the 240 hospitals in Massachusetts, with the request that they post it; to the editor of the *Journal of the American Medical Association*, with the request that he print it; to every Army (76) and Navy (20) hospital in Massachusetts, with the request that they post it; and to every member of the Massachusetts Medical Society with his bill for dues.

Seven hospitals sent us enough material concerning non-operative clinics, conferences, special rounds and so forth so that we could publish our first bulletin on November 20. This went to all the co-operating hospitals. By December 5, we had many requests for the bulletin and eleven hospitals had contributed material so that we issued a second bulletin, sending it to all the contributing hospitals and all who had requested it.

It was originally intended to issue the bulletins either every three or six months, but we found that most of the hospitals change their schedules every month. It was decided that we should issue the bulletin every month, and consequently the third number was sent out on January 2. It has proved to be very much desired, and we have had so many requests from physicians, hospitals, the Army, the Navy and many others, that the February mailing list will probably reach 180.

We have had many interesting letters from various parts of the Commonwealth. A particularly enthusiastic one came from Cape Cod, applauding the Bureau and asking for the bulletin. The Dispensary of the First Service Command also asked to be placed on the mailing list. Altogether we are much pleased with the reception accorded the bulletin.

In all, twenty-one hospitals and the Lahey Clinic now send us both operating lists and material for the bulletin. The demand for information concerning operations has not been so great as was expected, to date only about 75 such requests having been received. Contrary to expectations, most requests come between 11 a.m. and 5 p.m. Only one request came before 9 a.m., and only 2 after 5 p.m. It may be necessary to adjust our office hours.

The Bureau hopes to be of still greater usefulness in the future when it becomes better known. Particularly it anticipates a much broader usefulness when plans are perfected for postgraduate teaching for returning service men. It is anxious to co-operate with the national, state and local committees on postwar planning and stands ready to tabulate any information concerning internships, residencies and courses, and have it currently available for enquiring servicemen.

The committee begs your indulgence to continue on until the annual meeting.

Dr. Phippen moved the adoption of the report. This motion was seconded by Dr. Ober, and it was so ordered by vote of the Council.

Postwar Loan Fund Committee — Dr. George Leonard Schadt, Hampden, chairman.

This report (Appendix No. 10) was offered by Dr. Schadt who referred to the results of the questionnaire that had been sent to the members of the Society. Dr. Schadt made use of certain slides to illustrate the information gathered in this manner. He said that the questionnaire had been sent to 4600 fellows; 1916, or 41.6 per cent, had responded as of January 24, 1945. He added that this was an excellent return: 14 to 20 per cent being considered good. He said that 1484 members of the Society approved of the plan, that 380 disapproved and that there were 66 blanks. He said that the committee was inclined to look on this as a mandate to go through with the plan.

He said that there were three districts that showed disapproval — Bristol North, Franklin and Worcester North.

He pointed out that the report that was before the Council differed somewhat from that submitted in April, 1944; that this was principally by way of certain additions that had come about as the result of an analysis of the questionnaire by the committee.

At that point Dr. Schadt read the report in its entirety and the recommendations contained therein. He moved its acceptance. This motion was seconded by Dr. Richardson, and it was so ordered by vote of the Council.

Dr. Schadt moved the adoption of the first recommendation. This recommendation is as follows:

The Postwar Loan Fund Committee recommends that the Council of the Massachusetts Medical Society authorize the establishment of a postwar loan fund.

This motion was seconded by Dr. Chapin.

Dr. Parkins said that, while he was much in favor of helping people, he wondered if this was the way to go about it. He placed \$30,000 as the amount that would be raised under this plan. He thought this would be entirely inadequate. He expressed the thought that the money raised could be put

*Subcommittee (of Committee on Postwar Planning)
on Postgraduate Education — Dr. W. Richard
Ohler, Norfolk, chairman.*

This report, which is as follows, was offered by the chairman:

As a result of conferences with various people interested in the problem of postgraduate medical instruction and with full realization of the importance of the problem in this period, the Subcommittee on Postgraduate Education submits these objectives.

First, that this committee co-operate in every way possible with the subcommittees on hospitals and medical schools in the work of providing residencies or other opportunities for further hospital experience or instruction for returning doctors.

Second, that this committee gather information concerning opportunities for postgraduate work in Massachusetts and elsewhere in the country.

Third, that, in co-operation with the subcommittees on hospitals and medical schools, this committee provide or assist in providing a program of postgraduate refresher courses to be given both in Boston and in other parts of the Commonwealth for returning doctors and other interested physicians. That in so doing, this committee also co-operate with schools of public health, organized teaching clinics, the State Department of Public Health and other scientific state and federal agencies.

In order that progress be made as quickly as possible and with as little confusion as possible Dr. Ohler offered the following motion:

That the Council authorize the Subcommittee on Postgraduate Education to make available information regarding all opportunities for postgraduate medical instruction in co-operation with the Bureau of Clinical Information, and to institute a program for the extension of postgraduate medical instruction in the entire state, and, in so doing, to seek the co-operation of approved medical schools, schools of public health, teaching clinics, the State Department of Public Health and other state and federal agencies.

This motion was seconded by Dr. Schadt and it was so ordered by vote of the Council.

*Subcommittee (of Committee on Postwar Planning)
on Medical Schools — Dr. Charles F. Branch,
Suffolk, chairman.*

The report, which is as follows, was offered by Dr. Branch:

This committee has a preliminary report in which it would like to make some general observations on the part that medical schools may play in the planning of postwar courses, and would also like to offer a resolution that it believes is pertinent to postwar medical education in this state.

Under the heading of general observations we wish to point out that there are three general types of postgraduate opportunity that should be freely available for doctors returning from military service: resident training, which is entirely carried on in hospitals and is essentially a hospital problem, but in which the profession at large and the medical schools take part; fellowship opportunities for those wishing to qualify for teaching and investigative work in the preclinical sciences, which will be found largely in the medical schools; and refresher-type courses for those who have been recently graduated and may feel that they have been "short-changed" in their regular medical education.

In all these types of training the medical schools are anxious to participate as their resources permit, and are already making plans for such participation. It is pertinent to add, however, that the medical schools are still overloaded with their wartime commitments and cannot be expected to assume large new burdens of this sort until there is a substantial return of the teachers now on leave.

The matter to which we have addressed our resolution is one on which immediate action seems needed, else it be too late, and our returning fellows will face a profession which will continue to be annually diluted and weakened by graduates of unapproved medical schools.

WHEREAS, The standards of medical education in Massachusetts have been notoriously low for a long period of time, and

WHEREAS, A law providing for their improvement through the creation of an approving authority was placed on the statute books in 1936, and was amended in 1939, such amendment having been made in the interest of those upon whom the law was thought to work some hardship, and

WHEREAS, This amended law is now in operation and is presumably capable of elevating the educational standards of the Commonwealth; therefore be it

RESOLVED, That, in the interest of public health and the standards of medical education and medical practice, it is vitally important that the Massachusetts Medical Society immediately take an active part in maintaining and supporting the law as it now stands.

Dr. Leroy E. Parkins, Suffolk, moved the adoption of the resolution. This motion was seconded by Dr. Phippen, and it was so ordered by vote of the Council.

*Subcommittee (of Committee on Postwar Planning)
on Hospitals — Dr. Nathaniel W. Faxon, Suffolk, chairman. Dr. Faxon offered the following
as a report of progress:*

Postwar planning for doctors in hospitals divides itself into two parts: residencies lasting one or more years within the hospital and courses, which may or may not be held within the hospital, lasting from three to six months. The latter may be carried on in hospitals or medical schools. Certain points seem to be very definite: only veterans shall be considered in this and, so far as residents are concerned, hospitals must control the selection.

Residencies can be increased in present hospitals or can be established in hospitals which do not now have them. As an example, the Massachusetts General Hospital originally had 85 on the resident staff; it now has 64. They probably can be increased to about 100, with 60 recent medical-school graduates, as at present, and 40 returning veterans. There is no doubt that other teaching hospitals could provide a similar increase. Hospitals such as the Cambridge, Newton, Salem, St. Luke's in New Bedford, Worcester City and the Springfield, could undoubtedly develop real residencies, especially if some members of the staff could be induced to talk over the matter seriously. Other smaller hospitals might not be able to do this because of the staff's not really being competent to undertake such leadership. This will have to be explored.

Dr. Miller, of the American College of Surgeons, is examining the possibility of having teaching hospitals take returning veterans for from six months to one year as residents, with the understanding that they should be then moved to nonteaching hospitals where they would continue to serve as residents for another year.

Dr. A. J. Hockett, of the King County Hospital System, Seattle, Washington, has suggested a training program whereby a man after spending a certain time in the hospital would be apprenticed to members of the hospital staff to serve as an assistant during the remainder of his service. Graham Davis, of the Kellogg Foundation, is working on this in Michigan.

It was thought that hospitals would probably want to go back to approximately their prewar plans, with internships and residencies on a twelve months' basis and in hospitals such as the Massachusetts General four to five years in medicine and surgery; that the returned veteran residency should be additional to the present one; that perhaps certain veterans could be set up as instructors, either with a slight polishing course or even without it, as for instance, Richard Thompson in Salem, Pilcher in Newton, Carmody in Worcester and so forth.

It was pointed out that the United States Public Health Service expects to get money to finance stated services in their hospital situations.

Former Governor Saltonstall has passed on to Governor Tobin the appointment of the committee which would be expected to study the whole situation, especially the ability of nonteaching hospitals to set up residencies.

The American Hospital Association is also devising a questionnaire to be sent to hospitals for a survey, conducted under Dr. Bachmeyer, with Dr. Norby as assistant director.

It is possible that the Army and Navy will take over refresher courses, so-called, and carry them on in Army, Navy or Veteran hospitals. Additional Veteran hospitals might well be built close to medical centers instead of in the country, as in prewar times.

It was pointed out that it was necessary to sort out these war medical graduates and select those worth teaching and not waste time on the others.

Lastly, it was suggested that an extern service might serve to take care of a great many of these returning veterans.

Dr. Faxon moved the acceptance of the report. This motion was seconded by Dr. Ober, and it was so ordered by vote of the Council.

Committee on Medical Information Bureau — Dr. Walter G. Phippen, Essex South, chairman.

This report, which was offered by Dr. Phippen, is as follows:

Since the last meeting of the Council, the Bureau of Clinical Information of the Massachusetts Medical Society has become a going concern. Invitations were sent to twenty-two hospitals in Greater Boston to meet with this committee on October 25, 1944. Twenty hospitals accepted and sent a representative to the meeting. All not only were co-operative and offered the co-operation of their hospitals but were enthusiastic about the project.

The Bureau opened on November 13, 1944, with Miss Mary D. Gaston in charge as secretary. An announcement of this fact was sent out as follows: to the secretaries of every district medical society, with the request that it be read at the next meeting; to the secretaries of every state medical society in the United States; to the secretary of the American Medical Association; to the editors of every state medical journal, with the request that they print it; to the 240 hospitals in Massachusetts, with the request that they post it; to the editor of the *Journal of the American Medical Association*, with the request that he print it; to every Army (76) and Navy (20) hospital in Massachusetts, with the request that they post it; and to every member of the Massachusetts Medical Society with his bill for dues.

Seven hospitals sent us enough material concerning non-operative clinics, conferences, special rounds and so forth so that we could publish our first bulletin on November 20. This went to all the co-operating hospitals. By December 5, we had many requests for the bulletin and eleven hospitals had contributed material so that we issued a second bulletin, sending it to all the contributing hospitals and all who had requested it.

It was originally intended to issue the bulletins either every three or six months, but we found that most of the hospitals change their schedules every month. It was decided that we should issue the bulletin every month, and consequently the third number was sent out on January 2. It has proved to be very much desired, and we have had so many requests from physicians, hospitals, the Army, the Navy and many others, that the February mailing list will probably reach 180.

We have had many interesting letters from various parts of the Commonwealth. A particularly enthusiastic one came from Cape Cod, applauding the Bureau and asking for the bulletin. The Dispensary of the First Service Command also asked to be placed on the mailing list. Altogether we are much pleased with the reception accorded the bulletin.

In all, twenty-one hospitals and the Lahey Clinic now send us both operating lists and material for the bulletin. The demand for information concerning operations has not been so great as was expected, to date only about 75 such requests having been received. Contrary to expectations, most requests come between 11 a.m. and 5 p.m. Only one request came before 9 a.m., and only 2 after 5 p.m. It may be necessary to adjust our office hours.

The Bureau hopes to be of still greater usefulness in the future when it becomes better known. Particularly it anticipates a much broader usefulness when plans are perfected for postgraduate teaching for returning service men. It is anxious to co-operate with the national, state and local committees on postwar planning and stands ready to tabulate any information concerning internships, residencies and courses, and have it currently available for enquiring servicemen.

The committee begs your indulgence to continue on until the annual meeting.

Dr. Phippen moved the adoption of the report. This motion was seconded by Dr. Ober, and it was so ordered by vote of the Council.

Postwar Loan Fund Committee — Dr. George Leonard Schadt, Hampden, chairman.

This report (Appendix No. 10) was offered by Dr. Schadt who referred to the results of the questionnaire that had been sent to the members of the Society. Dr. Schadt made use of certain slides to illustrate the information gathered in this manner. He said that the questionnaire had been sent to 4600 fellows; 1916, or 41.6 per cent, had responded as of January 24, 1945. He added that this was an excellent return: 14 to 20 per cent being considered good. He said that 1484 members of the Society approved of the plan, that 380 disapproved and that there were 66 blanks. He said that the committee was inclined to look on this as a mandate to go through with the plan.

He said that there were three districts that showed disapproval — Bristol North, Franklin and Worcester North.

He pointed out that the report that was before the Council differed somewhat from that submitted in April, 1944; that this was principally by way of certain additions that had come about as the result of an analysis of the questionnaire by the committee.

At that point Dr. Schadt read the report in its entirety and the recommendations contained therein. He moved its acceptance. This motion was seconded by Dr. Richardson, and it was so ordered by vote of the Council.

Dr. Schadt moved the adoption of the first recommendation. This recommendation is as follows:

The Postwar Loan Fund Committee recommends that the Council of the Massachusetts Medical Society authorize the establishment of a postwar loan fund.

This motion was seconded by Dr. Chapin.

Dr. Parkins said that, while he was much in favor of helping people, he wondered if this was the way to go about it. He placed \$30,000 as the amount that would be raised under this plan. He thought this would be entirely inadequate. He expressed the thought that the money raised could be put

to better use if it were used as a credit pool against which a much larger sum could be made available through regular borrowing channels. He thought that the benefits under this plan should not be limited to those who were members of the Massachusetts Medical Society at the time of their enlistment, in other words, that the list should include those who were eligible for such membership.

Dr. Chapin took sharp issue with the previous speaker and urged the Council to try out the plan as outlined for one year.

Dr. Faxon said that he believed that the last recommendation in the list of recommendations read by Dr. Schadt would set up a permanent loan fund. He added there was some serious question in his mind whether this was a thing the Society should do. He said that this recommendation should contain some provision whereby the fund might be used for other than its original purpose when that particular purpose no longer existed.

Dr. Schadt could not agree with Dr. Parkins on the amount of money which the latter thought would be raised by the plan that the committee proposed. Dr. Schadt said that the amount would be at least \$45,000. He referred to the G. I. Bill of Rights and pointed out that it was possible under this legislation for the veteran to borrow up to \$4000 but that the Government guarantees but \$2000 of this amount and if the veteran wants the additional \$2000 he must have collateral. He added that the one objective of this fund was to make immediately available financial assistance to those of the members who, having served in the present war, are in need of such assistance at the time of their separation from the armed forces.

Dr. Schadt said he did not know and had no way of determining the number who would apply for a loan under this proposed plan.

He said that, although it was not planned to send the questionnaire to those in the service, certain replies had been received from servicemen. He said that certain of these indicated a need for such a fund.

Dr. Connor was critical of the way in which the questionnaire had been handled. He thought it should have been conducted as an Australian ballot is usually conducted. He expressed the view that the proposed fund was unnecessary because the serviceman's needs will be adequately cared for by the G. I. Bill of Rights. He said that, after the last war, he was able to negotiate a thousand-dollar loan without collateral. He added, "If the Massachusetts Medical Society feels so charitable about this matter, let us take the money we already have and place it behind the credit of any member who feels he may need a loan."

Dr. Parkins expressed the thought that the boys who will need help most are those who are not members of the Society.

Dr. Schadt said he was in agreement with Dr.

Parkins in this respect and that he personally thought that the proposed fund should be made available to every doctor in Massachusetts. He added that the committee was opposed to this all-inclusive feature. He said that the questionnaire indicated that only 52 of those who disapproved thought that the G. I. Bill of Rights would take care of the situation.

In answer to the criticism that the questionnaire was not conducted along the lines of an Australian ballot, he said that he questioned that anybody connected with the questionnaire remembered the names of those who recorded themselves in opposition. He added that 34 of those who approved and 3 of those who opposed made inquiries about the final disposition of the fund.

Dr. Carl Bearse, Norfolk, asked for how long a period of time, after being separated from the service, the veteran would be eligible to borrow from this fund.

Dr. Schadt answered this by saying that he thought that, inasmuch as this was for the immediate need of the returned doctor, it would probably end five years after the close of the war. He added that this was a detail that might be left to the board appointed to administer the fund and that once such details were established, the Executive Committee and the Council could pass on them at a later time.

Dr. Connor asked Dr. Schadt the following question: "Did you say that the G. I. Bill of Rights will not take care of the returning soldier doctor?"

Dr. Schadt replied that he had not said that. He added, however, that obtaining a loan under the G. I. Bill was a slow process, taking for consummation as much as seven weeks after the application was made.

Dr. Cheever said that he wanted to do everything possible for the returning veteran. He expressed the view that, although it seems that the Government is going to be very liberal with the veteran, no one actually knows just how liberal that aid is going to be. He said that the Society had the equivalent of something like \$200,000 in negotiable securities that it was at perfect liberty to use as loans. Why not, he asked, put this money out as loans to our members at 2 per cent interest? After the veterans have returned, he continued, the Society can evaluate the situation again and determine whether it wishes to go farther and to establish a separate loan fund. He thought that it was a mistake to designate definitely the final disposition of a fund. He concluded that this thing could be left in abeyance for the present without expressed approval of the report as a whole. He thought that the affirmation of a simple statement of the intention to help the veteran when, as and if such help was necessary was as far as the Society should go at present.

Dr. Schadt at that point was asked to read the recommendation before the Council. This he did as follows:

The Committee on Postwar Loan Fund recommends that the Council of the Massachusetts Medical Society authorize the establishment of a Postwar Loan Fund.

Dr. Cheever moved to amend the recommendation by adding to it the words "when, as and if necessary." This amendment was seconded by Dr. Richardson, who said that the adoption of this amendment would obviate the necessity of doubling the dues of members.

Dr. Fallon pointed out that it was obvious that everyone was in favor of some form of help for the returning serviceman whether it be by the G. I. Bill or by action of the Society. The Society had, however, he continued, a matured plan that had been considered by the committee for a long time. He expressed the thought that the Society could start out with this matured plan, collect the \$10.00 which could be spared this year, consider the suggestions that had been offered and possibly change the plan later so as to incorporate them.

Dr. Schadt took issue with Dr. Richardson's remarks to the effect that the plan proposed by the committee would double the dues of members. He said that the plan called for a specific assessment of \$10.00 for one year only. He added that whether or not there would be additional assessments depended entirely on separate action by the Council. He said that it was his frank opinion that if the Society did nothing about this it would find that it had "missed the boat."

Dr. Cheever asked what was Dr. Schadt's objection to using idle funds. Dr. Schadt replied that he was 100 per cent for the use of such funds as a means of financing the committee's proposal.

Dr. Allen G. Rice, Hampden, offered as an amendment to the amended motion the words "by drawing on the funds of the Society." This amendment was seconded by Dr. Parkins, and since it was accepted by Dr. Cheever, the maker of the original motion, and by Dr. Richardson, the seconder, it was declared by the President to be part of the original amendment.

Dr. Bagnall called on the Treasurer. Dr. Eliot Hubbard, Jr., Middlesex South. Dr. Hubbard said that the general fund stood at \$167,000, that the building fund stood at \$68,000 and that the latter fund could not be touched for the purpose under discussion.

Dr. Schadt pointed out that all the discussion about how the fund would be financed was not germane to the subject of the committee's first recommendation, which, he repeated, was simply that the Council authorize the establishment of a postwar loan fund. He added that the method of financing the fund would more properly come when the second recommendation was under discussion.

Dr. Chapin asked whether, if the amended motion prevailed, it would prevent the Council from immediately setting up this fund on the basis that necessity must be shown before the fund could be established. Dr. Bagnall said that he so understood the situation. He added that the establishment of such a fund in such a manner must also be contingent on the approval of the Finance Committee.

Dr. Richardson amended the amended motion so as to add the words "contingent on the approval by the Committee on Finance." This amendment was seconded by Dr. Cheever, who likewise accepted it as part of the original amendment.

Dr. Schadt again voiced his objection to the motion as amended.

The President called for a vote on the amendment, which was as follows:

That the Council of the Massachusetts Medical Society authorize the establishment of a postwar loan fund, when, as and if necessary and that this fund, contingent on the approval of the Committee on Finance, be established by drawing on the funds of the Society.

The amendment was carried by a show of hands — 35 for and 15 opposed. The motion as amended was put, and it was so ordered by vote of the Council.

At that point Dr. Schadt said that, in view of the action of the Council, no good purpose would be served by continuing the report.

Dr. Parkins moved,

That the Postwar Loan Fund Committee take this motion which we have passed to appropriate funds, evolve a program to use it, present it at the next Council meeting, with ways and means on how they would dispense it, and have the approval of the Committee on Finance and give us a working machine to handle it as they see fit.

This motion was seconded by Dr. Richardson.

In putting the motion, the President, with the apparent consent of Dr. Parkins, rephrased it so that the motion which was finally put was,

That this matter be referred back to the Postwar Loan Fund Committee to devise ways and means of carrying out the purpose of the motion just adopted.

It was so ordered by vote of the Council.

Military Postgraduate Committee — Dr. W. Richard Ohler, Norfolk, chairman.

This report, which was offered by the chairman, is as follows:

Since the meeting of the Council in October, seventy-two wartime postgraduate exercises have been given in twenty-two military installations by one hundred and ninety-five instructors. Since the formation of the New England Committee in June, 1943, a grand total of two hundred and eighty-one exercises have been conducted. Throughout this period, there has been maintained a fine spirit of co-operation between the various branches of the armed services and this committee, and there has always been a splendid response on the part of the instructors who have made this service possible. In this connection, I shall read from one of the many letters received by the committee: "I should like to convey to your committee sincere thanks and appreciation for the very fine lectures furnished us

during the time we have been here. I only trust that in our next assignments we can find a similar group of doctors who are interested in the continued education of the armed forces' physicians."

The question now arises, *How long is this work to continue?* In so far as your committee is concerned, we have taken the attitude that the work should continue as long as the armed services request it. Thus far, we have had no word to the contrary, and as a matter of fact, the usual allotment of funds has been made available recently by the American Medical Association, the American College of Physicians and the American College of Surgeons.

Nevertheless, during recent months, we have noted some falling off in enthusiasm on the part of certain Army and Navy installations, and this has naturally been reflected in the attitude of various groups of instructors. Unfortunately, owing to the change in the date of the Council meeting, it is necessary to render this report prior to a scheduled meeting of the New England Committee on February 2. We anticipate certain changes in the program and a curtailment of scheduled exercises. It is our hope that this work will not be allowed to die a lingering death, but that just as soon as it is apparent that this type of service is no longer needed it will be terminated by a directive from the armed services.

In the light of our present knowledge, it is recommended that the work of this committee be continued.

Dr. Ohler moved the acceptance of the report and the continuance of the committee. This motion was seconded by Dr. Cheever, and it was so ordered by vote of the committee.

Medical Advisory Committee to Regional OPA —

Dr. Joseph Garland, Suffolk, chairman.

The report, which was offered by the chairman, is as follows:

Since this committee last reported to the Council, drastic changes have taken place in food rationing. As of the first of the year, 85 per cent of all meat slaughtered went on the ration list, as compared with the 29 per cent that had been rationed since May, 1944, and the most popular canned vegetables, point-free since September, returned to rationing. At the same time, after a cancellation of outstanding points, the available red points per person were increased from $7\frac{1}{2}$ to 12 weekly.

Examples have been presented by the OPA to show what the new basic ration will provide per week — for instance $1\frac{1}{2}$ pounds of lamb chops and 1 pound of margarine, or 1 pound of liver and $\frac{1}{4}$ pound of butter, or 1 pound of the choicest steak, or 1 pound of rib roast and $\frac{1}{4}$ pound of butter, or 1 pound of bacon, 1 pound of lamb chops and $\frac{1}{2}$ pound of margarine. The basic processed food ration will buy 1 pint of asparagus, beans or spinach, or $\frac{1}{2}$ pint of applesauce, or $\frac{1}{2}$ pint of peaches or peas.

In other words, the demands made on our food supply, the production of which is suffering from labor and transportation shortages, are going to cut fancy eating to a minimum, and we are going to understand a little more clearly, in this fourth year of war, that the Nation, as well as its armed forces, is in the battle.

This committee has not found it necessary to change its allotments, however; less indulgence will be found advisable, and, as no well person need suffer who is subsisting on basic rations, so, also, no ill person need suffer who is entitled to extra rations, up to a weekly total of 4 pounds of meat and fat, and a similar amount of processed foods.

Local rationing boards have had returned to them the power of granting extra rations, up to these prescribed limits, for those conditions originally recognized by the National Research Council, namely, diabetes mellitus, active tuberculosis, chronic nephritis of the nephrotic type, cirrhosis of the liver, severe hepatitis, chronic suppurative disease, severe burns and certain gastrointestinal conditions, such as those resulting from operations on the stomach, intestine or colon for ulcer or cancer, high intestinal fistulas, ulcerative colitis and sprue.

All other cases must be reviewed by or with the guidance of medical committees, local or regional, which shall decide which ones, for any of a variety of reasons, are to be made exceptions to the list compiled by the National Research Council, in order that no undue hardship shall result. Thus, your committee recognizes that certain bona-fide cases of allergy, rheumatoid arthritis, of anemia, epilepsy or any other condition in reason may require extra rations, but each must be decided on its own merits, with full knowledge of the facts available, and only for a limited period of time.

Butter and sugar must be recognized as luxury foods. So much of our total milk supply is being processed for overseas shipment that the amount available for the more uneconomic manufacture of butter is considerably reduced, and butter is available only at the fantastic point value of 24 per pound — double an individual's weekly point allowance. Equally nutritious fortified oleomargarine is available at 3 points per pound, and most people are going to learn to like it or go without. Unless acceptable evidence is presented that an applicant for extra fats must have butter, any extra allowance made is on the basis of margarine. Your committee feels sure that no one, after the casualty lists from the Battle of Belgium are made public, will consider this too great a sacrifice. We continue to recommend extra sugar rations only under the most exceptional circumstances, and the allowance of heavy cream, under the jurisdiction of the War Food Administration, has been reduced to 36 particularly needy cases.

Local advisory committees, appointed with the cooperation of the War Participation Committee, are functioning in Lawrence, Pittsfield, Springfield, New Bedford, Worcester and Brockton, in addition to those that have been locally appointed in other places.

Dr. Garland moved the acceptance of the report as one of progress. This motion was seconded by Dr. Ohler, and it was so ordered by vote of the Council.

Committee on Maternal Welfare — Dr. Raymond S. Titus, Norfolk, chairman.

In the absence of any member of the committee, the Secretary offered the report (Appendix No. 11) as published in the circular of advanced information. He moved its acceptance. This motion was seconded by Dr. Parkins, and it was so ordered by vote of the Council.

Committee to Consider Expert Testimony — Dr. Frank R. Ober, Suffolk, chairman.

No report.

Committee on Physical Therapy — Dr. Arthur L. Watkins, Middlesex South, chairman.

No report.

Committee on Postgraduate Instruction — Dr. W. Richard Ohler, Norfolk, chairman.

Dr. Ohler moved the discontinuance of the committee saying that its personnel had been taken over as a subcommittee of the Committee on Post-war Planning. This motion was seconded by Dr. Ober, and it was so ordered by vote of the Council.

Committee on Council Rules — Dr. Charles E. Mongan, Middlesex South, chairman.

This report, which was offered by Dr. Mongan, is as follows:

Dr. Elmer S. Bagnall, president of the Massachusetts Medical Society, appointed an *ad interim* committee, consisting of Charles E. Mongan, chairman, Frank R. Ober and Michael A. Tighe, whose purpose it was to study ways and means of improving the activities of and, if possible, shortening the time consumed by the Council.

In its initial report this committee recommends that there be set up certain rules for the conduct of the business of the Council.

The first three rules are as follows:

Rule 1. All new business offered at Council meetings shall be referred automatically by the President to the appropriate committee before action is taken by the Council.

Rule 2. All committee reports must be referred to the Executive Committee in advance of any Council meeting. Such reports shall be submitted at least six weeks before the Council meets. (This will provide opportunity for consideration by the Executive Committee in advance of the Council.)

Rule 3. These rules may be suspended, changed or discontinued on a majority vote of the Council.

By the latter rule, the above rules are made flexible. (For example, if a councilor wishes to present new business in a manner not in accordance with the above rule, he may move that the matter in mind may be acted on immediately under a temporary suspension of this rule. A majority vote of the Council authorizes such a temporary suspension.)

The Committee on Council Rules recognizes that three types of reports are offered to the Council: one that is purely informational, another that contains a recommendation or recommendations and still another that may have the character of both.

The Committee offers certain recommendations with regard to such reports, which it believes, if adopted, will further facilitate the work of the Council.

Recommendation 1 (to be known as *Rule 4*). A report that is purely informational should contain a specific statement that it is being offered only for the information of the Council. At the completion of such a report, the person offering it should move its acceptance.

Recommendation 2 (to be known as *Rule 5*). Reports that contain a recommendation should specifically state the recommendation. Its adoption should then be moved by the person offering the report. In the case of reports that contain several recommendations which are closely related and dependent, one on the other, the recommendations should be stated specifically in one, two, three order and their adoption should be moved by the person offering them. At the end of all reports containing recommendations, the persons offering them should move their adoption as a whole, subject to whatever change the Council has made in the recommendations.

Recommendation 3 (to be known as *Rule 6*). In the case of reports that are informational as regards one subject and contain recommendations with regard to others, the principles outlined above should be followed in dealing with each part of the report.

Dr. Mongan moved the acceptance of the report. This motion was seconded, and it was so ordered by the Council.

Dr. Mongan moved the adoption of each rule and recommendation contained in the report. In each instance his motion was seconded, and it was so ordered by vote of the Council.

Dr. Mongan moved the adoption of the report as a whole. This motion was seconded by Dr. Ober, and it was so ordered by vote of the Council.

Dr. Mongan left the platform amid applause.

NOMINATION OF DELEGATES

The President presented the following list of nominees as delegates:

To the House of Delegates, American Medical Association, for two years, from June 1, 1945:

DELEGATES

Charles J. Kickham, Brookline
Leland S. McKittrick, Boston

ALTERNATES

John Fallon, Worcester
Patrick J. Sullivan, Dalton

To the House of Delegates, American Medical Association, for one year, from June 1, 1945:

Dr. Patrick E. Gear, Holyoke, alternate to Dr. Charles E. Mongan, Somerville.

To the annual meetings of the five New England state medical societies in 1945:

Maine: Merrill C. Sosman, Boston; Frank R. Ober, Boston.

New Hampshire: Dwight O'Hara, Waltham; Howard F. Root, Boston.

Vermont: Frederick S. Hopkins, Springfield; George Ballantyne, Worcester.

Rhode Island: W. Richard Ohler, Jamaica Plain; Leroy E. Parkins, Boston.

Connecticut: Eugene M. Landis, Chestnut Hill; Charles F. Branch, Boston.

To the Annual Congress on Medical Education and Licensure, American Medical Association, at the Palmer House, Chicago, February 12 and 13, 1945:

Reginald Fitz, Boston.

Dr. Bagnall said that the appointment of delegates to the annual meetings of the other state medical societies was from the personnel of the Committee on Postwar Planning so that this committee might know what was going on in this respect in other states.

The President asked if there were any nominations from the floor. There being none, Dr. Ober moved that the nominations as read by the President be confirmed. This motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

Ad Interim APPOINTMENTS

Dr. Bagnall offered the following *ad interim* appointments:

To the Council:

Dr. Alice M. Broadhurst, Middlesex South, replacing Dr. Stanton Garfield, resigned.

Dr. Ralph N. Brown, Middlesex South, replacing Dr. Brainard Conley, resigned.

Dr. Vlado A. Getting, Middlesex South, replacing Dr. Elliott Robinson, resigned.

Dr. William H. Blanchard, Suffolk, replacing Dr. William B. Breed, deceased.

Dr. William J. Elliott, Worcester, replacing Dr. Charles A. Sparrow, deceased.

Dr. William F. Regan, Middlesex East, replacing Dr. J. Harper Blaisdell, deceased.

To the Committee on Publications:

Dr. John Fallon, replacing Dr. William B. Breed, deceased.

To the Committee on Society Headquarters:

Dr. Frank R. Ober, chairman, replacing Dr. J. Harper Blaisdell, deceased.

Dr. Albert A. Hornor, a member, replacing Dr. Ober who has become chairman.

To the Committee on Legislation:

Dr. Edward J. O'Brien, representing Middlesex South, to replace Dr. Brainard F. Conley, resigned.

To the Committee on Membership:

Dr. Roy V. Bakctel, replacing Dr. Sumner H. Remick, resigned.

To the Committee on Postwar Planning:

Dr. Howard F. Root, *chairman*; Dr. Leroy E. Parkins, *secretary*; Drs. Arthur W. Allen, Edward P. Bagg, George Ballantyne, Charles F. Branch, C. Sidney Burwell, Allan M. Butler, Nathaniel W. Faxon, Vlado A. Getting, G. Philip Grabfield, Frederick S. Hopkins, Chester M. Jones, Eugene M. Landis, Leland S. McKittrick, J. Howard Means, Robert N. Nye, Frank R. Ober, Dwight O'Hara, W. Richard Ohler, Walter G. Phippen, Merrill C. Sosman, Michael A. Tighe and Charles F. Wilinsky.

To the Various Subcommittees of the Committee on Postwar Planning:

Co-ordinating Committee on Education:

Drs. Charles F. Branch, Nathaniel W. Faxon and W. Richard Ohler.

Subcommittee on Hospitals:

Dr. Nathaniel W. Faxon, *chairman*; Drs. Arthur W. Allen, James W. Manary and Charles F. Wilinsky.

Subcommittee on Medical Economics:

Dr. Leland S. McKittrick, *chairman*; Drs. Allan M. Butler, Vlado A. Getting and Merrill C. Sosman.

Subcommittee on Medical Schools:

Dr. Charles F. Branch, *chairman*; Drs. C. Sidney Burwell, Dwight O'Hara and Walter G. Phippen.

Subcommittee on Organization:

Dr. Chester M. Jones, *chairman*; Drs. Edward P. Bagg, George Ballantyne, Frederick S. Hopkins, J. Howard Means, Frank R. Ober, Joseph W. O'Connor, Francis J. Steele and Michael A. Tighe.

Subcommittee on Postgraduate Education:

Dr. W. Richard Ohler, *chairman*; Drs. Vlado A. Getting, G. Philip Grabfield, Edward G. Huber, Lewis M. Hurxthal, Charles J. Kickham, Eugene M. Landis, Robert N. Nye, Frank R. Ober, Joseph W. O'Connor and Samuel H. Proger.

To the Committee on Rehabilitation:

Dr. Joseph H. Shortell, *chairman*, replacing Dr. William E. Browne, resigned.

To the Committee on Council Rules:

Dr. Charles E. Mongan, *chairman*; Drs. Frank R. Ober and Michael A. Tighe.

Dr. Bagnall spoke of the resignation of Dr. Conley as chairman of the Committee on Legislation as having come about because of his change of residence.

Dr. Cheever moved the Council's approval of these appointments. This motion was seconded by Dr. Ober, and it was so ordered by vote of the Council.

Dr. Charles J. E. Kickham, Norfolk, expressed the belief that the Subcommittee on Hospitals of the Committee on Postwar Planning should be more representative of all the hospitals of Massachusetts. He pointed out that, as it was constituted, only the three main hospitals in Boston were represented. He expressed the belief that this condition should be remedied by making certain additions to this subcommittee.

Dr. Root said that it was planned to do just that. He added that, if the previous speaker would send in to the committee the name of a hospital representative who would be willing to attend meetings and participate in the job ahead, that name would be added. Dr. Kickham said that he had no particular person in mind.

OBITUARIES

Obituaries of former councilors were read by the President as follows:

DR. JOHN HARPER BLAISDELL, a member of the Council from Middlesex East District since 1931, died suddenly on October 25, 1944, in Boston. He was in his fifty-ninth year.

Dr. Blaisdell was graduated in 1907 from Dartmouth College and received his degree in medicine from the Harvard Medical School in 1911. After his internship at the Massachusetts General Hospital he began practice in Boston, specializing in dermatology. He taught for many years at the Harvard Medical School and was a member of the staffs of the Massachusetts General Hospital and the Boston Dispensary.

He had long been prominent in the affairs of the Massachusetts Medical Society having held the following positions: vice-president and president of the Middlesex East District Medical Society; a member of the Committee on Public Relations since its organization in 1931 and chairman of its Subcommittee on Hospital Relations; nominating councilor from Middlesex East District in 1932 and alternate nominating councilor for several years; secretary and chairman of the Section of Dermatology and Syphilology; chairman of the Committee to Revise the By-laws, which was established in 1942; chairman of the Committee on Society Headquarters; a member of the Committee Concerned with Prepayment Medical-Care Costs Insurance; and, finally, just before his death, chairman of the newly formed Committee on Council Rules.

Dr. Blaisdell was one of the prime movers in the organization and administration of the Massachusetts Hospital Service Corporation (Blue Cross) and the Massachusetts Medical Service Corporation (Blue Shield). He was one of the original signers of the charter granted the Massachusetts Hospital Service Corporation on March 11, 1937. He served as a member of the Board of Directors of the Blue Cross from 1937 until his death. He also served as a member of the Board of Directors of the Blue Shield from the time of its organization in 1942 until his death. He was chairman and joint representative for the Massachusetts Medical Service and the Massachusetts Hospital Service on the Interlocking Services Committee.

His memberships included the American Medical Association, American Dermatological Association, New England Dermatological Society, of which he was at one time president, and the Atlantic Dermatological Conference. He was formerly chairman of the Section of Dermatology and Syphilis of the American Medical Association.

Dr. Blaisdell is survived by his widow and two sons.

DR. ALFRED J. BONNEVILLE, of Hatfield, died January 11. He was in his seventy-fourth year.

Dr. Bonneville received his degree from the Medico-Chirurgical College of Philadelphia in 1911. He was vice-president of the Hampshire District Medical Society in 1920 and president of this district in 1921. He was district supervising censor and councilor of the Society from 1922 to 1945, and a member of the Committee on Public Relations from 1942 to 1945.

In 1944, Dr. Bonneville was cited by Governor Saltonstall for his work in civilian defense. He was on the staff of the Cooley Dickinson Hospital, Northampton, and was a fellow of the American Medical Association.

His widow and three sisters survive.

DR. GEORGE B. FENWICK, of Chelsea, died October 27. He was in his sixty-eighth year.

Dr. Fenwick graduated from Harvard University in 1900 and from Harvard Medical School in 1904. He was

a member of the local Selective Service board and organized the Civilian Defense Medical Unit in Chelsea. He served several terms on the Chelsea Board of Health. He had been a member of the Council from Suffolk District since 1936.

His widow, a daughter and a son survive.

At the request of the President, the Council stood for one minute in silent tribute to the memory of these former councilors.

NEW BUSINESS

Dr. Reginald Fitz, Suffolk, directed a question to Dr. Mongan, chairman of the Committee on Council Rules, as to what was meant by the words "majority vote of the Council" as these words appear in the rules that had been adopted. Dr. Mongan replied that this meant a majority of those present.

There being no further business before the Council, the President announced the meeting adjourned at 5:20 p.m.

MICHAEL A. TIGHE, *Secretary*

APPENDIX NO. 2

PROPOSED AMENDMENT TO THE BY-LAWS

The following amendment to the by-laws of the Massachusetts Medical Society is submitted by Dr. Jacob Fine:

Chapter V, Section 2b, is hereby amended to read as follows: The secretary of a district society shall receive an application from a graduate of a discontinued medical

school, a foreign medical school after the year 1933 or any medical school not approved by the Council only, when the applicant has possessed a license to practice medicine in the United States or its territories for at least five years. A graduate of a foreign medical school on the approved list of the National Board of Medical Examiners prior to 1934 may apply for membership to the secretary of a district society if he has possessed a license to practice medicine for a minimum of five years.

Dr. Fine offers in support of this amendment the following:

If the administration of this modification of the 1942 amendment would be difficult, I would ask the Executive Committee to consider reverting to the wording of this section of the by-laws prior to May, 1942. At the annual meeting of the Massachusetts Medical Society in May, 1942, an amendment to the by-laws was adopted under Chapter V, Section 2b, which reads as follows:

The secretary of a district society shall receive an application from a graduate of a discontinued medical school, a foreign medical school or any medical school not approved by the Council only when: The applicant has possessed a license to practice medicine in the United States or its territories for at least five years.

This amendment to the by-laws is a modification of a previous amendment adopted in 1939, which specified that eligibility for membership of applicants from such medical schools required practice for a minimum of five years. The 1939 amendment did not specify that the practice must have been within the confines of the United States or its territories. The reason for the adoption of the 1939 amendment, according to the Committee on Membership in its report of May 22, 1944, was that "an increasing number of physicians were beginning to infiltrate Massachusetts." When the more restrictive amendment of 1942 was presented to the Society the spokesman for those in favor stated that there was "nothing revolutionary as it appears in the text." He read the 1939 amendment for comparison with the 1942 amendment showing the distinction mentioned above. He added as the reason for the change that applicants for membership should have lived in their community sufficiently long to afford their conferees opportunity to pass on their standards of practice. Many of those who opposed the 1942 amendment felt that such a reason for adopting the change was discriminative, since if it requires five years to evaluate a physician's standards of practice, why should we customarily admit those trained in the United States shortly after their entry into practice? The implication from the spokesman's statement is that the ethics and the training of the European physicians are necessarily subject to greater scrutiny than those of native physicians.

It is therefore pertinent to inquire into the ethics and training of the foreign physician. As for the training of European physicians, some doubt that European schools during the last decade have been able to provide adequate training. The Committee on Membership stated in its May, 1944, report to the Council that no one knows how good an education foreign physicians had received and that the Committee on Medical Education found it "impossible to evaluate the medical education in foreign schools, particularly that gained on the Continent." According to the Committee on Membership, the Council on Medical Education and Medical Diplomas until 1939 had been determining what foreign medical schools were acceptable as offering an education equivalent to that of our recognized domestic schools. In actual practice, however, the Committee on Medical Education and Medical Diplomas did not undertake to evaluate foreign medical schools, but considered each applicant's qualifications on an individual basis. Data on foreign medical schools, however, was available to this committee, if such was needed, from the list of foreign medical schools published by the National Board of Medical Examiners as having acceptable standards. Since the Massachusetts Board of Registration in Medicine accepts diplomates of the National Board without further examination, it is fair to assume that the latter's standards for admission to examination are acceptable in Massachusetts. If this list became of doubtful value after 1933, the year when the European turmoil suddenly became aggravated due to the rise of Hitler, it was still valid for physicians who had graduated from medical schools before that time. Why should

such physicians, whose type of education was known and approved by the National Board of Medical Examiners be classed with those whose education obtained at a later time might be considered of dubious quality? Why is it not fair and proper to distinguish between graduates from foreign schools before and after 1933?

The Committee on Membership cites as evidence of the poor education of foreign-trained physicians their poor showing in the State Board examinations compared with that of native physicians. Any open-minded person will admit that any physician over forty (the minimum average age of medical emigres) not facile in the English language and psychologically traumatized could hardly be expected to do better. What is more appropriate for consideration by the Society is not the doctors who failed but those who passed. Shall those who passed be penalized because others failed?

One may speculate as to other motives than those alleged, which may have been responsible for the 1942 amendment. The Committee on Membership states that in 1939 foreign physicians "began to infiltrate Massachusetts" and the number who came in per year was mounting rapidly, totaling over three hundred according to the Committee on Membership, although the *American Medical Directory* and the files of the Boston Committee on Medical Emigres did not show much more than about half this number in actual practice in this state up to 1942. Is it not reasonable to assume that numbers, not qualifications, comprised the stimulus for this amendment? Even the larger figure indicates how trifling those numbers have been in proportion to the total number of physicians in this state. The Committee on Membership agrees that there will be an occasional foreign-educated physician on whom the five-year rule will work a hardship. Obviously, if no hardship were involved, this discussion would serve little more than an academic purpose. The fact, however, is that most of the foreign physicians who practice in small and many of those in large communities do not have hospital privileges because they are told they are not members of the Massachusetts Medical Society. This is a hardship which the 1942 amendment is working, and it is a real hardship, ample testimony for which is available to the Boston Committee on Medical Emigres and anyone else interested.

As for the ethics of foreign physicians, if some will say that it was not numbers but dubious ethics which brought about the 1942 amendment, I would ask them to state the evidence, not in general terms, innuendo or hearsay, but by specific case histories and the number of such instances before and since the adoption of the 1942 amendment, which could justify continuation of the amendment in its present form. I am sure it can be shown that the foreign-trained physician has behaved neither better nor worse than native physicians and that he should be so regarded from the point of view of the time when he should be eligible for membership in this society.

APPENDIX NO. 3

REPORT OF THE COMMITTEE ON PUBLICATIONS

The Committee on Publications wishes to record its sense of great loss in the death of Dr. William B. Breed. Dr. Breed contributed to the deliberations of the committee a broad vision, mature judgment and unflinching good will.

The committee has invited Colonel Walter Bauer, medical consultant to the Eighth Service Command to deliver the Shattuck Lecture. The invitation has been accepted subject to the exigencies of military duty.

The committee recommends the publication of the *Directory* for the year 1945. No directory has been published since 1942, and because many changes have occurred in the fellowship list since that time, the officers believe that there is a distinct need for a new directory. It recommends, however, that the printing be limited to 500 copies and that they be distributed to the members of the Council and to other members in good standing on request. It is recommended that \$1500 be appropriated for this purpose.

The committee has continued to supervise the publication of the *New England Journal of Medicine*. Again we wish to record our deep appreciation to the managing editor, Dr. Robert N. Nye, for his efficient management of the *Journal*. We should also like to commend the work of Miss

Davies and her assistants, who have accomplished a phenomenal task under most trying circumstances.

During 1944, the *Journal* received 6109 new "outside" subscriptions, a figure 42 per cent greater than that for 1943. Of these, 4221 were from regular subscribers, and 1888 from students. There were many cancellations, and the net increases were 2394 and 357, respectively. Of the 1531 student subscriptions that expired, it is interesting that 674 were renewed at the full rate. As of December 31, journals were being sent to 4317 members of the Society (including 288 in military service), 7512 regular subscribers, 2371 medical students and 348 miscellaneous readers, a grand total of 14,885, not including 337 copies sent once a month to members of the New Hampshire Medical Society. This is an increase of 2632 over the corresponding figures for 1943, in spite of a decrease of 240 in copies going to members of the Massachusetts and New Hampshire medical societies.

Operations for the year resulted in a net loss of \$7937, which is accounted for by cash payments totaling \$7900 from the Society and a loss of \$37 in total assets or surplus. This compares with a loss of \$5852 in 1943. The increase in expense, which is greater than would be expected because of increase in circulation, was occasioned by larger costs for printing and binding. The net cost for each active member of the Society was \$1.81, compared with \$1.30 in 1943.

The editorial board considered 194 manuscripts during 1944, of which 151 were accepted, a slight reduction over the figures for 1943, which were 211 and 162, respectively. This has, of course, cut down the pagination devoted to original articles, but such a policy has seemed to be more desirable than the acceptance of papers that do not meet the standards set by the editorial board.

The *Journal* is still troubled by the paper shortage. We were able this year to continue publication because of an extra allowance of paper from the War Production Board, owing to the fact that so many journals were sent to military organizations and men in military service, and by reducing the weight of paper stock. The year 1945 presents unusual difficulties in relation to paper supply. It will be necessary to receive another ex-quota allotment from the War Production Board and possibly to use a lighter weight of paper.

The Council will remember that a year ago the Committee on Publications reported that a change had been made in the firms responsible for the printing, binding and mailing of the *Journal*. It was hoped that this change would overcome some of the difficulties that had been present in previous years because the former printer was unable to do satisfactory work. The change in printers obviously presented many annoying and time-consuming incidents because of the new printer's unfamiliarity with many of the details. It was hoped that these difficulties would decrease as the year advanced. They are, however, still present. The reprints have been delayed, much as before. There has been continued difficulty with the mailing stencils, and this has necessitated increased work by the clerical staff. These difficulties we hope will be ironed out in the course of time. If the *Journal* continues to increase its circulation and the office work continues to expand, additional space will soon be needed.

Because of the increasing circulation outside of Massachusetts, about the first of the year a form letter with a return post card was sent to subscribers in four widely separated sections of the United States—Connecticut, Ohio, Texas and two West-Coast states, Oregon and Washington. The letter requested that the subscriber indicate on the post card his choice of various features of the *Journal* and whether or not he would probably subscribe if the progress reports were reprinted as a quarterly publication. The preliminary tabulation of replies indicates that by far the majority of these readers subscribe to the *Journal* because of its total content and that the case reports are the most popular of the individual features. The response to the question concerning the quarterly reprinting of the progress reports appears to indicate that such an undertaking would be successful.

The outlook for 1945 is difficult to visualize. The shortage of book paper may necessitate a further cut in the size of the *Journal*. Our difficulties with printing, binding and mailing may become less troublesome. Advertising contracts promise to bring in a larger net return than ever before; the rates were again increased on January 1, and those of

January 1, 1944, become effective for the advertisers whose contracts were extended a year ago at the 1943 rate. There is no appreciable letup in the increase of circulation, although the net increase will probably be less than in 1944. Operating costs should increase only proportionally with the circulation, and because of the increase in revenue, the net cost to the Society should be lower. On account of unpredictable factors, however, an appropriation of \$8000 has been requested.

The accounts of the *Journal* have been audited and found to be in order.

RICHARD M. SMITH, *Chairman*

APPENDIX NO. 4

REPORT OF THE COMMITTEE ON PUBLIC HEALTH

BASIC GENERAL PLAN FOR A MASSACHUSETTS PROGRAM FOR THE CARE OF CHILDREN WITH ACUTE RHEUMATIC FEVER

It is intended that the proposed acute rheumatic fever program as described in the following pages shall be conducted as a part of Services for Crippled Children. There are several good reasons for including such dissimilar conditions as orthopedic and plastic cases with acute rheumatic fever in one administrative unit other than that the funds for all those conditions emanate from the Children's Bureau of the Department of Labor. The most important reason is that the members of the Department of Public Health who are conducting Services for Crippled Children have, during the eight years that the Service has been in operation, maintained excellent relations with the members of the Massachusetts Medical Society, both individually and collectively.

The acute rheumatic fever program will be administered as nearly in accordance with the principles that have guided the conduct of Services for Crippled Children as is possible, taking into consideration the clinical differences between the two types of patients. The same high ethical standards will be maintained and professional standards will be equally high.

No children will be accepted for care under the acute rheumatic fever program unless a request for such care signed by a licensed physician has been received and unless a social service worker has investigated the home and has determined the fact that the family is medically indigent. A patient having been accepted for care will be given medical and hospital care, and care in a convalescent home, if necessary. The program will be limited to children of school age, and no custodial care for children with far-developed heart disease will be provided. The same relations will be maintained with the family physician as has been done in Services for Crippled Children, that is, the patient is always regarded as having been merely referred to the department for special services. The family physician will be kept informed of the progress of his patient and the patient will be referred back to him on discharge.

It will be recalled that the Department of Public Health in 1936, after state-wide conferences with members of the respective district medical societies, obtained the approval of the Council of the Massachusetts Medical Society for the conduct of the Crippled Children's program. The Department of Public Health intends to conduct the rheumatic fever program under the same basic policy as has always been in effect, namely, that there will be no infringement upon the rights of practicing physicians. All children accepted for care under the Crippled Children's program have invariably presented an application signed by a physician.

It is desired to secure the authority of the General Court so that hospitalization and convalescent care for the majority of the children cared for under the program can be provided at the North Reading State Sanatorium. It is also planned to purchase hospital care in other hospitals in the state for children whom it would be preferable to hospitalize locally because of transportation difficulties, or for social or other reasons. Similarly, convalescent care would be provided elsewhere whenever necessary.

About fifteen states now have programs in operation for the care of children with acute rheumatic fever or heart disease, but in only one of these states is the program state-wide. The Children's Bureau has, however, indicated that a state-wide program for Massachusetts would be acceptable. Such a program in order to receive the approval of the chief

of the Children's Bureau and at the same time to meet the needs of the Commonwealth must be organized and administered along the following lines.

1. *Administration of the program.* — The administration of a Massachusetts rheumatic fever program should be the responsibility of the Orthopedic Bureau of the Division of Child Hygiene of the Department of Public Health. A pediatrician with special knowledge of this field should assume direct responsibility for planning and developing these services. An advisory committee should be appointed by the Commissioner of Public Health, which should be composed of representatives of the various professional fields involved in a program of this type — medical, social, nursing, education and so forth.

2. *Eligibility for care.* — Children under the age of twenty-one with heart disease or conditions leading to heart disease, who are medically indigent, are eligible for care. Emphasis would be given to the care of children with rheumatic fever or rheumatic heart disease; particularly early in the disease, but children with other types of heart disease which offer a reasonable expectation of improvement through treatment should also be eligible for care. Mere custodial care would not be authorized. As in the case of children with orthopedic or plastic defects, diagnostic services would be available, on the signed request of a registered physician, to all children of the Commonwealth, but a child would be accepted for further care only when it has been determined (as is done at present) that the child's family is unable to meet, in whole or in part, the expenses of prescribed treatment.

3. *Basic professional services.* — a. *Medical services.* — A pediatrician employed by the Department of Public Health on a full-time basis would be administratively responsible for medical care of these children in all stages of treatment, whether in clinic, hospital, convalescent home, foster home or the child's own home. This would ensure continuity of medical care. This pediatrician should either have already had special training or experience in the field of rheumatic fever and heart disease in children or should be given special training in this field. Consultation services by cardiologists, surgeons and specialists in other branches of medicine and surgery would be provided when necessary by qualified consultants who are certified by, or eligible for certification by, the boards of their respective specialties. Fees for such services would be paid by the Department of Public Health.

b. *Medical-social services.* — Medical-social consultants on the staff of the Department of Public Health would be responsible for meeting the medical-social needs of these children. These workers would not merely give direct service in connection with all phases of the care of the children but their function would be largely that of developing and helping to improve the social services available in the community to those children.

c. *Public-health nursing services.* — A public-health nursing consultant on the staff of the Department of Public Health would supervise the public health nursing services for children under this program. Generalized public-health nursing services are more widely available in Massachusetts than in almost all other states, so that a state-wide program could be easily administered.

4. *Diagnostic services.* — Diagnostic services would be provided in clinic centers, as is done in the orthopedic consultation clinics. If, for diagnosis, observation or any procedure too elaborate for the clinic is necessary, the children would be hospitalized for diagnosis. Diagnostic service would be arranged for by the Department of Public Health pediatrician. If a child who needs diagnostic service is too sick to come to the clinic, the pediatrician would make a home visit, in consultation with the family physician.

5. *Treatment services.* — a. *Clinic services.* — Regular clinics would be held for diagnostic services and follow-up care. These clinics would be conducted by a pediatrician, assisted by a medical-social worker and a public-health nurse. Not more than six or eight children would be seen in a half-day clinic session.

b. *Hospital care.* — The Department of Public Health will seek legislation authorizing the admission of children suffering from rheumatic fever and heart disease to the North Reading State Sanatorium. It is also planned to purchase hospital care in other hospitals in the state for children whom it would

be preferable to hospitalize locally because of transportation difficulties, or for social, or other reasons.

c. *Convalescent care.* — Children would be kept in hospital only during the acute stage of the disease and would then be transferred elsewhere for a period of prolonged bed rest during the chronic stage. This type of care is usually provided in a convalescent home, a foster home, or the child's own home.

(1) *Convalescent home care.* — At these homes medical, nursing and social supervision adequate for the care of the sick child in bed would be given. Such homes would also be used for children who have entirely recovered from rheumatic fever but who are not physically up to par because of the recent acute attack. It is probable that a portion of the North Reading State Sanatorium could be set aside for this type of care.

(2) *Foster-home care.* — Occasionally, foster homes are the only resource available, although experience in Services for Crippled Children indicates that this service is not often needed. This type of care seems preferable to institutional care for some individual children.

(3) *Care in the child's home.* — Services in the child's own home include diagnostic services for the child who is physically unable to attend a clinic and treatment for the child with rheumatic fever or a complicating illness if he can be cared for in his own home. Joint planning by the pediatrician, the medical-social consultant and the public-health nursing consultant would be necessary to meet any personal and environmental difficulties which might obstruct the treatment and care of the child in the home situation.

6. *Transportation of children.* — This can usually be arranged in co-operation with local community agencies. Ambulance service would need to be provided by the Department of Public Health when necessary.

7. *Educational needs of the rheumatic child.* — Social Security funds are not provided for education of the physically handicapped child, but medical-social workers would be expected to arrange for such services through official educational agencies.

8. *Vocational guidance.* — There is already a close relation between the Department of Public Health and the Division of Vocational Rehabilitation of the Department of Education for vocational guidance for crippled children. This co-operation would be extended to the children cared for in an acute rheumatic fever program.

ROY J. WARD, *Chairman*
ERNEST M. MORRIS, *Secretary*

APPENDIX NO. 5

REPORT OF THE COMMITTEE ON SOCIETY HEADQUARTERS

A meeting of this committee was held on June 7, 1944, the chairman, Dr. J. H. Blaisdell, presiding. There were present Drs. D. B. Reardon, F. R. Ober, M. A. Tighe, R. Fitz and E. S. Bagnall. The space occupied by the Society and the *New England Journal of Medicine* was inspected. Following this, there was a discussion of the duties of the committee and what funds were available for carrying out those duties. It was voted that the chairman, together with the Treasurer and the chairman of the Committee on Finance, should look into the question of what money is available to this committee and what charges should be made against it, and also to report on how and what rent is paid to the Boston Medical Library, reporting their findings back to the Committee on Society Headquarters.

A second meeting of this committee was held on October 25, at 1:15 p.m. There were present Drs. Tighe, Ober and Reardon of the committee and also Drs. R. N. Nye, R. M. Smith, F. C. Hall and Eliot Hubbard and Mr. R. St. B. Boyd. In the absence of the chairman, Dr. Blaisdell, Dr. Ober called the meeting to order. Dr. Nye explained that the purpose of the meeting was to consider the item in the budget labeled "Headquarters." The money in this item although spent was never approved by any committee, which is required by the by-laws. It was explained that the chairman of the committee, Dr. Blaisdell, thought this ought to be a function of the Committee on Society Headquarters. Under this budget would be included miscellaneous items, clerical assistance for various committees and so forth. It was ex-

plained that this sum should be split up and allocated to its proper authorities. Such items as rental, cleaning and lighting should be charged to the Committee on Society Headquarters, and the remainder of the charges should be under a separate heading and charged to the Secretary's expenses, allowing an additional budget of about \$6000 a year to cover such expenses. This would be a more businesslike procedure and would also be according to the by-laws of the Society. It was suggested that the heading for this item be called "Administration Expenses."

It was voted to set up a budget for general administrative expenses for the Massachusetts Medical Society and that this fund should be in the hands of the officers of the society.

At that point in the meeting word was received that Dr. Blaisdell, chairman of the committee, had just been killed in an automobile accident. The meeting was then adjourned.

On November 1, Dr. Ober was appointed chairman of the committee, and later on Dr. A. A. Hornor was appointed to fill the vacancy that had occurred as a result of the death of Dr. Blaisdell. The office space occupied by the Massachusetts Medical Society was inspected and measured. It was found to be in need of furniture and other accessories to make it useful to the Society. A budget was made out covering the estimated cost of these necessary items and was submitted to the Committee on Finance. This sum will appear in the report of the Committee on Finance.

FRANK R. OBER, *Chairman*

APPENDIX NO. 6

REPORT OF THE COMMITTEE ON FINANCE

The Committee on Finance met on December 13, 1944, at the Headquarters of the Massachusetts Medical Society, 8 Fenway. Present were Drs. Peer P. Johnson, Ernest L. Hunt and Francis C. Hall as members of this committee. Also present were President Elmer S. Bagnall, Secretary Michael A. Tighe and Treasurer Eliot Hubbard, Jr.

At this meeting the committee noted the amount and nature of our income for 1944 — \$59,629.26. A list of the items from which we derived this income is set forth below. The committee set up a budget for the fiscal year of 1945 — a figure of \$52,960.00. This budget is set forth below. We noted the sales and purchases of investments by the Treasurer carried out on the advice of Loomis and Sayles, investment counselors. We noted also the expenses submitted by the different committee chairmen.

It will be noted that our income is slightly larger than last year despite the further falling off in the item of dues of \$3110. This falling off in the amount from dues, owing to remissions given to doctors going into the service, is less than before, and should not decrease very much from now on. The increased income is largely due to an increase in the amount coming to us from investments and seems to justify our employment of expert investment counselors. Our budget for 1945 is well within our estimated income. It is \$6000 larger than that for 1944, owing to increases in three items of expense. The first is the setting up of a Bureau of Clinical Information at Society Headquarters estimated at \$2800 for maintenance. The second is the setting up of the Committee on Postwar Planning, which plans to be very active, with a cost estimated at \$3000. The third is the increased habit of committees to have dinner meetings. Unquestionably dinner meetings result in better attendance of members and are fair to the men coming to Boston from a distance. This custom should result in benefit to the Society if used with discretion.

Again, the Committee on Arrangements brought in a surplus instead of a deficit, due in large part to the efficiency of our executive secretary, Mr. Boyd, in selling booths to advertisers wishing to exhibit at the annual meeting and due to increased charges for these booths. The profit last year was \$3542. For three successive years the chairmen of the Committee on Arrangements have recommended that Mr. Boyd's salary be increased because of the fact that over a period of some years now his efforts have resulted in a change from a marked deficit to a real profit. They also pointed out that Mr. Boyd has taken on more and more work in relation to the activities of the various committees. He is giving all his time to the work of the Massachusetts Medical Society. The Committee on Finance recommends that his salary be

increased to \$4000, and that more opportunities be given Mr. Boyd to serve the Society by having him sit in on committee meetings and carry out the wishes of the committees, and by studying the methods of running other state medical societies.

Dr. Robert N. Nye continues to run the *New England Journal of Medicine* with such efficiency that subscriptions are continuing to increase, advertising rates have been raised, and the cost of the *Journal* to the Society is less each year. In 1944 instead of requiring the \$13,000 allotted to the *Journal* in the budget, Dr. Nye required only \$7000. He is asking for only \$8000 next year, and probably will not need to use this amount.

We recommend the setting up of a special item under General Administrative Expense with a budget of \$2000, this fund to include expenses for stenography, telephone and innumerable items plus extraordinary expenses which have previously been assigned to Society Headquarters as separate from the Committee on Society Headquarters. This does not constitute extra expense but assigns these items to the care of the President and Secretary, leaving to the Committee on Society Headquarters merely the definite items of rent, light, heat and cleaning of the Headquarters rooms. The type of items included under Administrative Expense will be assigned to committee so far as possible, and we hope that a large part of this budget will be unexpended, but in the past no one has been responsible for them.

It seems to the committee that the Society is being run with increasing efficiency and conservatively so far as expenditures are concerned. The investment portfolio seems to be in sound hands.

FRANCIS C. HALL, *Chairman*

of the Children's Bureau and at the same time to meet the needs of the Commonwealth must be organized and administered along the following lines.

1. *Administration of the program.* — The administration of a Massachusetts rheumatic fever program should be the responsibility of the Orthopedic Bureau of the Division of Child Hygiene of the Department of Public Health. A pediatrician with special knowledge of this field should assume direct responsibility for planning and developing these services. An advisory committee should be appointed by the Commissioner of Public Health, which should be composed of representatives of the various professional fields involved in a program of this type — medical, social, nursing, education and so forth.

2. *Eligibility for care.* — Children under the age of twenty-one with heart disease or conditions leading to heart disease, who are medically indigent, are eligible for care. Emphasis would be given to the care of children with rheumatic fever or rheumatic heart disease; particularly early in the disease, but children with other types of heart disease which offer a reasonable expectation of improvement through treatment should also be eligible for care. Mere custodial care would not be authorized. As in the case of children with orthopedic or plastic defects, diagnostic services would be available, on the signed request of a registered physician, to all children of the Commonwealth, but a child would be accepted for further care only when it has been determined (as is done at present) that the child's family is unable to meet, in whole or in part, the expenses of prescribed treatment.

3. *Basic professional services.* — a. *Medical services.* — A pediatrician employed by the Department of Public Health on a full-time basis would be administratively responsible for medical care of these children in all stages of treatment, whether in clinic, hospital, convalescent home, foster home or the child's own home. This would ensure continuity of medical care. This pediatrician should either have already had special training or experience in the field of rheumatic fever and heart disease in children or should be given special training in this field. Consultation services by cardiologists, surgeons and specialists in other branches of medicine and surgery would be provided when necessary by qualified consultants who are certified by, or eligible for certification by, the boards of their respective specialties. Fees for such services would be paid by the Department of Public Health.

b. *Medical-social services.* — Medical-social consultants on the staff of the Department of Public Health would be responsible for meeting the medical-social needs of these children. These workers would not merely give direct service in connection with all phases of the care of the children but their function would be largely that of developing and helping to improve the social services available in the community to those children.

c. *Public-health nursing services.* — A public-health nursing consultant on the staff of the Department of Public Health would supervise the public health nursing services for children under this program. Generalized public-health nursing services are more widely available in Massachusetts than in almost all other states, so that a state-wide program could be easily administered.

4. *Diagnostic services.* — Diagnostic services would be provided in clinic centers, as is done in the orthopedic consultation clinics. If, for diagnosis, observation or any procedure too elaborate for the clinic is necessary, the children would be hospitalized for diagnosis. Diagnostic service would be arranged for by the Department of Public Health pediatrician. If a child who needs diagnostic service is too sick to come to the clinic, the pediatrician would make a home visit, in consultation with the family physician.

5. *Treatment services.* — a. *Clinic services.* — Regular clinics would be held for diagnostic services and follow-up care. These clinics would be conducted by a pediatrician, assisted by a medical-social worker and a public-health nurse. Not more than six or eight children would be seen in a half-day clinic session.

b. *Hospital care.* — The Department of Public Health will seek legislation authorizing the admission of children suffering from rheumatic fever and heart disease to the North Reading State Sanatorium. It is also planned to purchase hospital care in other hospitals in the state for children whom it would

be preferable to hospitalize locally because of transportation difficulties, or for social, or other reasons.

c. *Convalescent care.* — Children would be kept in hospital only during the acute stage of the disease and would then be transferred elsewhere for a period of prolonged bed rest during the chronic stage. This type of care is usually provided in a convalescent home, a foster home, or the child's own home.

(1) *Convalescent home care.* — At these homes medical, nursing and social supervision adequate for the care of the sick child in bed would be given. Such homes would also be used for children who have entirely recovered from rheumatic fever but who are not physically up to par because of the recent acute attack. It is probable that a portion of the North Reading State Sanatorium could be set aside for this type of care.

(2) *Foster-home care.* — Occasionally, foster homes are the only resource available, although experience in Services for Crippled Children indicates that this service is not often needed. This type of care seems preferable to institutional care for some individual children.

(3) *Care in the child's home.* — Services in the child's own home include diagnostic services for the child who is physically unable to attend a clinic and treatment for the child with rheumatic fever or a complicating illness if he can be cared for in his own home. Joint planning by the pediatrician, the medical-social consultant and the public-health nursing consultant would be necessary to meet any personal and environmental difficulties which might obstruct the treatment and care of the child in the home situation.

6. *Transportation of children.* — This can usually be arranged in co-operation with local community agencies. Ambulance service would need to be provided by the Department of Public Health when necessary.

7. *Educational needs of the rheumatic child.* — Social Security funds are not provided for education of the physically handicapped child, but medical-social workers would be expected to arrange for such services through official educational agencies.

8. *Vocational guidance.* — There is already a close relation between the Department of Public Health and the Division of Vocational Rehabilitation of the Department of Education for vocational guidance for crippled children. This co-operation would be extended to the children cared for in an acute rheumatic fever program.

ROY J. WARD, *Chairman*
ERNEST M. MORRIS, *Secretary*

APPENDIX NO. 5

REPORT OF THE COMMITTEE ON SOCIETY HEADQUARTERS

A meeting of this committee was held on June 7, 1944, the chairman, Dr. J. H. Blaisdell, presiding. There were present Drs. D. B. Reardon, F. R. Ober, M. A. Tighe, R. Fitz and E. S. Bagnall. The space occupied by the Society and the *New England Journal of Medicine* was inspected. Following this, there was a discussion of the duties of the committee and what funds were available for carrying out those duties. It was voted that the chairman, together with the Treasurer and the chairman of the Committee on Finance, should look into the question of what money is available to this committee and what charges should be made against it, and also to report on how and what rent is paid to the Boston Medical Library, reporting their findings back to the Committee on Society Headquarters.

A second meeting of this committee was held on October 25, at 1:15 p.m. There were present Drs. Tighe, Ober and Reardon of the committee and also Drs. R. N. Nye, R. M. Smith, F. C. Hall and Eliot Hubbard and Mr. R. St. B. Boyd. In the absence of the chairman, Dr. Blaisdell, Dr. Ober called the meeting to order. Dr. Nye explained that the purpose of the meeting was to consider the item in the budget labeled "Headquarters." The money in this item although spent was never approved by any committee, which is required by the by-laws. It was explained that the chairman of the committee, Dr. Blaisdell, thought this ought to be a function of the Committee on Society Headquarters. Under this budget would be included miscellaneous items, clerical assistance for various committees and so forth. It was ex-

Medical Society shall report to the Council of the Massachusetts Medical Society that this committee is in favor of finding and expanding common grounds of agreement with representative groups of the public and that a committee be appointed by the President with the end in mind of creating a general understanding of the problems involved in good medical care.

After general discussion in the committee the following motion was unanimously passed, namely, that, recognizing our obligation to further the education of the public in regard to medicine, it be recommended to the Council that the President appoint a special committee, containing representatives of the Committee on Public Relations, Committee on Ethics and Discipline, Committee on Publications, Committee on Public Health and any others that he desires to further the education of the public in regard to medical questions, particularly through popular magazines.

Three questions about industrial-accident cases were referred to the subcommittee on Industrial Accidents, headed by Dr. Ellison. These questions were: the abuse of the rules that an injured employee may have the services of a physician of his own choice; a question of the correct charge by a doctor to a patient whom he treated, the case having previously been declined by the Committee on Ethics and Discipline; and the question of simplified insurance forms, which was brought to the attention of the committee by the Norfolk District Medical Society.

The report of the meeting attended by representatives of the New England Roentgen Ray Society, the chairman of the Section of Radiology of the Massachusetts Medical Society and the Committee Appointed to Confer with the Massachusetts Hospital Association was read and discussed by the Committee on Public Relations. The committee approves the principles laid down by the above-mentioned groups. These principles will be outlined in the report furnished by Dr. Phippen, chairman of the Committee Appointed to Confer with the Massachusetts Hospital Association.

ALBERT A. HORNOR, *Secretary*

APPENDIX NO. 8

REPORT OF THE SUBCOMMITTEE TO MEET WITH THE MEDICAL ADVISORY COMMITTEE OF THE STATE INDUSTRIAL ACCIDENT BOARD

This subcommittee was originally appointed to meet with the Advisory Committee of the State Industrial Accident Board but at the last meeting of the Committee on Public Relations, the subcommittee was asked to take up three problems directly with the Board itself.

The first concerns a complaint in writing against an alleged practice of insurers and employers of compelling an injured employee to submit to treatment by the surgeon and at the hospital designated by them. Many surgeons say that when employees request their services rather than those of the company-appointed man that the employee faces discharge or at best unpleasant treatment thereafter by the employer. The chairman of the State Industrial Accident Board authorizes the subcommittee to say that if any doctor who has had such an experience or who knows of such a case will present all the facts in writing to her, including the date of the accident, the name of the employee and of the foreman, nurse or other that in any way shows this illegal action toward an injured employee, she will take prompt action to stop such practices.

The second problem was concerned with a matter of ethics and procedure that is becoming increasingly serious to the Industrial Accident Board. An employee developed an inguinal hernia, responsibility for which was denied by the insurance company. He then contracted to have the hernia operated by a private physician to whom he agreed to pay \$250, this amount to include hospital and operation fees. Subsequently the Industrial Accident Board found for the employee, and he felt that the insurer should pay the entire \$250. Your subcommittee thought, and this opinion was endorsed by the chairman of the Industrial Accident Board, that the insurer should pay only the amount usually allowed by the Board for the surgeon and hospital in an uncomplicated case of this type.

This matter of industrial accidents is not a one-way street. One of the great problems now facing the State Board is a practice that is becoming widespread, especially in Boston. An employee has an abdominal pain and calls a physician, who examines him, makes a diagnosis of hernia, says the operation must be done at once, sends the sick man into some private nonapproved hospital and operates. These hospitals keep very sketchy records. There is no proof available whether the patient had a hernia or, believe it or not, whether a herniotomy was done. The Board does not want to penalize an honest workman who has a real hernia; on the other hand it does not intend to encourage this practice. Your subcommittee recommends that a committee from the Society be appointed to study this problem and report at some future time to this Council.

The third problem was in the form of a suggestion from the Norfolk District Medical Society that industrial accident forms be shortened. We should appreciate this district society's presenting us with a form that it considers adequate. It would seem rather difficult to do this, as most certainly there must be a name, an address, a date, a history, a physical examination, a relation of the cause and effect, a report of laboratory findings, including x-ray, a report of the number of visits, a statement of complications and a prognosis. On submission of a short form, however, your subcommittee will be happy to go back to the Board with it.

As chairman of this subcommittee for the past two years, I want to pay tribute again to Mrs. Emma Tousant, chairman of the State Industrial Accident Board. This woman has the interest of all parties at heart—the insurer, the employee and the doctor. She is as nearly impartial and just in her decisions as any human being can be. I consider her one of the outstanding women in public life in this state.

DANIEL J. ELLISON, *Chairman*

APPENDIX NO. 9

REPORT OF COMMITTEE ON POSTWAR PLANNING

The Committee on Postwar Planning held its first meeting on November 8, 1944. It was voted that subcommittees be appointed to deal with certain subjects and that a secretary of the committee be appointed by the chairman. Dr. L. E. Parkins agreed to serve as secretary.

The Subcommittee on Hospitals, under the chairmanship of Dr. Nathaniel Faxon, will consider the changing place of hospitals in medicine and in the community, the need for providing additional internships and residencies and the opportunity for responding to the greatly increased public interest in hospitals.

The Subcommittee on Postgraduate Education, under the chairmanship of Dr. W. R. Ohler, will study the field of postgraduate education, not merely in hospital centers but in regions at a distance from medical schools.

The Subcommittee on Medical Schools, under the chairmanship of Dr. Charles F. Branch, will report the influence of the changing curriculums in medical schools, particularly the part played by medical schools in the postgraduate education of the future.

The Subcommittee on Organization, under the chairmanship of Dr. Chester M. Jones, will consider means of increasing the services that the Society renders to its members and also the relation of the Society to other organizations within the community, both lay and professional.

The Subcommittee on Economics, under the chairmanship of Dr. L. S. McKittrick, will study the changing economic relations of medicine, particularly in the fields of prepayment insurance and of contract medicine and the probable place of private practice in the changing economic order.

A second meeting of the committee was held on January 24. The committee believes that the interest of each community in Massachusetts in the general problem of public health is now greater than ever before. Many women as well as men have given volunteer service to hospitals and medical and public-health institutions, and coming for the first time in direct contact with modern medicine, they appreciate its promise. It is common knowledge that during the war years medical students have been hurried through an accelerated medical course, have experienced short internships and have often been placed on active duty as medical officers in positions where they have had little opportunity to acquire ex-

APPENDIX NO. 7

REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

The committee has studied the question of policy in supplying advice to lay inquirers coming into a community about the selection of a family physician. The committee recommends that all requests for information by the laity, as to whom they should consult, should be referred to the secretary of the respective district society.

The Subcommittee on Publicity reported to the Committee on Public Relations, and their report was unanimously adopted. Important features of this report were as follows: it was the unanimous vote of the subcommittee that in view of the probability of not getting an ideal man now we should not try to hire a publicity agent at the present time; meantime, the secretary of the Society should instruct and encourage the executive secretary of the Society to familiarize himself with medical publicity; it was the unanimous opinion of the subcommittee that the expense of the work suggested in the above recommendation should be charged to administration; and it was the unanimous opinion of the subcommittee that the publicity of the annual meeting is the responsibility of the Committee on Arrangements. The Committee on Public Relations recommends the adoption of these principles.

After prolonged discussion it was duly moved and seconded and the following motion carried unanimously, namely, that the Committee on Public Relations of the Massachusetts

that such a fund will enable the Society to assist certain members or the families of members who have served the Nation during these trying days and members in the future who may be faced at any time with unexpected financial vicissitudes. (Its establishment at the present moment will make of it an expression of appreciation by the Society to those of our members who served with the armed forces during the present war.)

GEORGE LEONARD SCHADT, *Chairman*

APPENDIX NO. 11

REPORT OF THE COMMITTEE ON MATERNAL WELFARE

Dr. R. S. Titus presided at a meeting held October 26, 1944, at which the following members were present: Drs. R. M. Smith, T. Almy, R. L. DeNormandie, W. R. Sisson, J. M. Baty, Florence L. McKay, R. P. Moulton and E. S. Bagnall.

Dr. Smith asked if the Society should aid in distributing information concerning the EMIC Program. Dr. Bagnall discussed this and stated that he felt it was unfortunate that the Society and doctors in certain communities were so antagonistic to the program.

The question was brought up concerning how many members of the Society were participating in the EMIC program. It was thought that the Massachusetts Medical Society should do more to publicize the service which the EMIC program offered. Attention was called to the fact that physicians have not read the available literature released by the Department of Public Health.

It was brought to the committee's attention that supplemental fees are said to be demanded by physicians in some cases before they would agree to take cases under the EMIC Program. Before further discussion on this subject, a motion was made by Dr. Smith, that the secretary send a letter to Dr. Florence L. McKay, director of the Division of Child Hygiene of the Massachusetts Department of Public Health, calling her attention to the fact that physicians were said to be collecting a fee for obstetric service under the EMIC Program after mothers had requested such service but before the applications were signed by the phy-

sician and requesting that Dr. McKay furnish any facts that she may have concerning this report.

It was the sentiment of the committee that further investigation of maternal deaths be held in abeyance at this time.

A motion was made that a subcommittee be appointed for the purpose of keeping themselves informed about the activities of the EMIC Program and making necessary recommendations with the co-operation of the Massachusetts Department of Public Health.

A survey of the prenatal program was discussed.

The direction given to the secretary of the committee in the fourth paragraph of this report brought forth the following answer:

November 21, 1944

Dear Dr. Sisson:

In reply to your letter of November 10, 1944, I would say that we have received verbal information that some physicians are charging mothers a fee before they sign the application for Emergency Maternity and Infant Care. This has been reported to me by two different physicians who came to the office to discuss the matter, by agencies, and by the mothers themselves. We have nothing whatever in writing. In some cases names have been given, and in one, a physician informed Dr. Saunders, during a telephone conversation, that it was his custom to do this.

We would appreciate any action which the Massachusetts Medical Society might wish to take to improve the situation and to bring about a better understanding with the attending physician as to the purpose of the Emergency Maternity and Infant Care Program.

Sincerely yours,

(Signed)

FLORENCE L. MCKAY, M.D.
Director, Division of Child Hygiene

Following the meeting, Dr. Bagnall and Dr. Titus appointed the following subcommittee: Dr. Ralph E. Cole, chairman, Dr. Benjamin Lambert and Dr. Daniel J. Ellison. Letters have been sent to these men, notifying them of their appointment to the committee.

WARREN R. SISSON, *Secretary*

perience useful to a civilian medical practice. By necessity they will need opportunities for further preparation before commencing their professional civilian careers. On the whole, a unique opportunity is close at hand for medicine in Massachusetts to increase its service in a variety of ways.

At the meeting of the Council on June 9, 1936, certain recommendations by the Subcommittee on the Adequacy of Medical Care of the Committee on Public Relations were duly adopted by vote. These recommendations were as follows:

I. That each district society be urged to form, within its area, medical service councils composed of carefully chosen representatives of its own membership, representatives of welfare agencies, hospital boards, health and welfare departments, nursing and dental societies and the general public. The functions of these councils to be:

1. Education of the public in the needs and possibilities of medical service, preventive as well as curative, and in the ways available for securing it.

2. Making provision for suitable clinics or district visiting services where need is found (rural and factory village areas).

3. Securing co-operation in its program from industrial, fraternal, social and health organizations.

4. Establishing welfare department responsibility for and intelligent administration of medical care for the indigent and near-indigent in each town and city by:

a. Employing the licensed physicians of the community at reasonable pro rata fees.

b. Subsidizing licensed practitioners to locate where there are no resident physicians.

5. Influencing established hospitals to broaden their function so as to serve as health centers in co-operation with local health departments and as welfare centers in co-operation with local welfare departments.

6. Promulgating, locally organizing, and thereafter serving as an advisory body in the administration of any programs of voluntary insurance for hospitalization and medical care which may receive the approval of the State Society.

II. That a state medical service council of similar constitution be developed whose functions shall be to co-ordinate the work of the local councils, advise as to methods, study legal relations and devise enabling statutes when necessary to simplify procedures and increase efficiency in carrying out the primary purpose of promoting better health by bringing adequate medical care to the people and relieving economic distresses which are detrimental thereto.

At present twenty-three local health councils are in existence, co-operating with the Central Health Council. Although physicians have been members of such councils, the fellows of this Society have not taken such an active interest in their proceedings as is desirable. This committee believes that they should be activated and that additional councils should be organized.

The chairman suggests that the Council authorize the President to inform the president and secretary of each district society, the chairman of each health council, the superintendent or chairman of the staff and the chairman of the board of trustees of each hospital in the Commonwealth whose staff members are in community practice concerning the following resolution:

RESOLVED, That the Council of the Massachusetts Medical Society, having in mind the unusual problems of medical care to be presented now and in the postwar period, recommends (1) the formation of health councils where none exist, or where the present council is inactive, to be composed of physicians and dentists, hospital trustees, public-health specialists, educators, editors, employers and representatives of labor and groups concerned with the distribution of medical care, to consider and adopt further measures for extending medical services in the community and increasing preventive-health education both by local effort and through co-operation with state and federal bodies, (2) more active participation by physicians

in the work of health councils already in active existence, and (3) that the Committee on Public Relations implement these recommendations in such manner as the committee deems most profitable.

HOWARD F. ROOT, M.D., Chairman

APPENDIX NO 10

REPORT OF THE POSTWAR LOAN FUND COMMITTEE

The Postwar Loan Fund Committee approves in principle the desirability of raising funds from which loans can be made to members of the Massachusetts Medical Society who, having served in the Armed Forces, may be in need of immediate financial assistance on discharge from active duty.

The committee makes the following recommendations:

1. That the Council of the Massachusetts Medical Society authorize the establishment of a postwar loan fund.

2. That the Postwar Loan Fund be established by an assessment of \$10.00 for the current year, the amount of any subsequent assessment, if any, to be determined by the Council at its annual meeting.

3. That payment of the Postwar Loan Fund assessment by members of the Massachusetts Medical Society while in the armed forces be entirely optional.

4. That those members who have been in the armed services, together with nonresident members, be exempt from the assessment if they request it, and that those members who are ill, aged or in difficult financial circumstances be exempt if they have the approval of the Committee on Membership for such exemption.

5. That the amount of loan granted be left to the discretion of the board or committee appointed by the President, that just enough interest be charged — not to exceed 2% — to cover carrying charges and remind the member obtaining a loan of his obligation, and that no endorsers be required.

6. That loans shall be limited to a period of twelve months, subject to renewal at the discretion of the board or committee appointed.

7. That only those who were members, in good standing, of the Massachusetts Medical Society on the date they entered the armed forces shall be permitted to borrow from this fund.

8. That to inform members of the Society in the armed forces of the availability of this fund, information be printed in the *New England Journal of Medicine*. There shall also appear in a box on the cover of the *Journal* an announcement calling attention of the members to the article on the inside page, that form letters shall be sent to the members in the armed forces, notifying them of the existence of this fund, and that form letters shall be sent out to the other members of the Society with the annual bills for dues bringing to their attention the existence of this fund and its purpose.

9. That the Postwar Loan Fund be supervised by the Massachusetts Medical Society and not by the district medical societies.

10. That the president of the Massachusetts Medical Society appoint a committee or board of five members, to include the treasurer and the secretary of the Society, and the present chairman of the Postwar Loan Fund Committee, to administer this fund.

11. That the immediate purpose of the proposed Postwar Loan Fund of the Massachusetts Medical Society is to establish a fund which shall make available financial assistance to such members of the Society who, on discharge from active service as medical officers in the present war, may need temporary financial aid, that the fund will become a permanent fund of the Society, the income or principal to be used from time to time for the purpose of assisting members or families of members of the Society who may be in need of temporary financial aid (the fund will be administered by a committee elected each year by the Council on nomination by the President),

that such a fund will enable the Society to assist certain members or the families of members who have served the Nation during these trying days and members in the future who may be faced at any time with unexpected financial vicissitudes. (Its establishment at the present moment will make of it an expression of appreciation by the Society to those of our members who served with the armed forces during the present war.)

GEORGE LEONARD SCHATZ, *Chairman*

APPENDIX NO. 11

REPORT OF THE COMMITTEE ON MATERNAL WELFARE

Dr. R. S. Titus presided at a meeting held October 26, 1944, at which the following members were present: Drs. R. M. Smith, T. Almy, R. L. DeNormandie, W. R. Sisson, J. M. Baty, Florence L. McKay, R. P. Moulton and E. S. Bagnall.

Dr. Smith asked if the Society should aid in distributing information concerning the EMIC Program. Dr. Bagnall discussed this and stated that he felt it was unfortunate that the Society and doctors in certain communities were so antagonistic to the program.

The question was brought up concerning how many members of the Society were participating in the EMIC program. It was thought that the Massachusetts Medical Society should do more to publicize the service which the EMIC program offered. Attention was called to the fact that physicians have not read the available literature released by the Department of Public Health.

It was brought to the committee's attention that supplemental fees are said to be demanded by physicians in some cases before they would agree to take cases under the EMIC Program. Before further discussion on this subject, a motion was made by Dr. Smith, that the secretary send a letter to Dr. Florence L. McKay, director of the Division of Child Hygiene of the Massachusetts Department of Public Health, calling her attention to the fact that physicians were said to be collecting a fee for obstetric service under the EMIC Program after mothers had requested such service but before the applications were signed by the phy-

sician and requesting that Dr. McKay furnish any facts that she may have concerning this report.

It was the sentiment of the committee that further investigation of maternal deaths be held in abeyance at this time.

A motion was made that a subcommittee be appointed for the purpose of keeping themselves informed about the activities of the EMIC Program and making necessary recommendations with the co-operation of the Massachusetts Department of Public Health.

A survey of the prenatal program was discussed.

The direction given to the secretary of the committee in the fourth paragraph of this report brought forth the following answer:

November 21, 1944

Dear Dr. Sisson:

In reply to your letter of November 10, 1944, I would say that we have received verbal information that some physicians are charging mothers a fee before they sign the application for Emergency Maternity and Infant Care. CASE 31201

PRESENTATION OF CASE

A thirty-eight-year-old janitor was admitted to the hospital because of progressive dyspnea.

About four weeks before entry he developed a sore throat, hoarseness, a cough productive of thick phlegm, definite swelling of the legs, dyspnea and orthopnea. The dyspnea was most marked on exercise and when lying in bed. During the three to four weeks before entry he had slept fitfully and used three pillows. He thought that he had lost about 30 pounds in the six to eight preceding weeks.

He had had no chest pain, palpitation, nausea or vomiting. He had had nocturia (two times) during the two nights before entry. Sometimes, especially recently, the urine had been quite cloudy.

He had had measles and mumps but had not had scarlet fever. At the age of nine he had had chorea and swelling of the legs for over a month. Repeated epistaxis but no fever, rash, pains or sore joints accompanied this illness. He recovered completely and had not been susceptible to upper respiratory infections until the present illness except that on two occasions in the past few years he had had an episode of "grippe," accompanied by back and leg pains, which lasted about a week. He had worked at many jobs, having been in the Army at approximately the age of eighteen. He had had frequent physical examinations, the last one having been made four months before admission, and at none of these was he told that he had a heart murmur. Thirteen months before admission his blood pressure was 140 systolic, 92 diastolic. He had never before been hospitalized. About one and a half years before entry he traumatized his left testis, which had since become large. He smoked one package of cigarettes a day and drank an occasional glass of beer and little coffee.

Physical examination revealed a moderately well nourished, well developed, pale, ill appearing, orthopneic man. The teeth were decayed. There was marked pitting edema of the entire lower half of the body, extending up to the scapula. The right chest was clear, and over the left posteriorly were heard numerous musical and crackling rales. The

heart sounds were regular, and there was a Grade I apical systolic murmur. In the left scrotum was a large, firm, nontender mass measuring 25 by 10 by 10 cm. The prostate was slightly tender and somewhat enlarged.

The temperature was 100°F., the pulse 112, and the respirations 20. The blood pressure was 180 systolic, 115 diastolic.

The urine was cloudy, amber and acid in reaction, with a specific gravity of 1.024, and gave a +++ test for albumin; the sediment contained innumerable white cells and many red cells and hyaline, granular and cellular casts. Examination of the blood showed a white-cell count of 10,400, with 59 per cent neutrophils, 23 per cent large lymphocytes and 12 per cent small lymphocytes. The red-cell count was 3,300,000, with 10.8 gm. of hemoglobin. The stool was formed and brown and showed a +++ guaiac test. The corrected sedimentation rate was 1.4 mm. per minute. A blood Hinton test was negative, and tuberculin tests in dilutions of 1:10,000 and 1:100,000 were negative in forty-eight hours. The serum nonprotein nitrogen was 61.0 mg. per 100 cc., and the protein 5.08 gm., with an albumin-globulin ratio of 0.97. The cholesterol was 185 mg. per 100 cc. A cephalin flocculation test was negative in forty-eight hours. Urine cultures showed a few colon-bacillus colonies and a rare colony of a nonhemolytic streptococcus. A phenol-sulfonephthalein test showed 15 per cent excretion in the first fifteen minutes and a total of 67 per cent at the end of two hours. An electrocardiogram showed normal rhythm at a rate of 90, a PR interval of 0.16 second and sagging ST segments in Leads 1, 2 and CF₁. The T waves in Leads 1, 2, CF₁ and CF₂ were inverted; those in Leads 3 and CF₃ were low and upright. The ST segment in Lead 3 was slightly elevated. The patient was digitalized with Cedilanid shortly after admission.

X-ray examination of the chest showed no distinct outline of the heart, owing to density in the adjoining lung fields. The vascular markings appeared to indicate diffuse engorgement, and there were widespread areas of increased density in both lungs, particularly in the lower portions. There was a small amount of fluid in both pleural cavities. Following an intravenous pyelogram, there was poor concentration of dye, and definite evidence of impairment of kidney function bilaterally; there appeared to be some fluid in the abdomen.

The temperature was approximately normal until the seventh day, when, immediately after the intravenous pyelogram, there were chills and fever; the temperature was 105°F. for thirty-six hours and then returned abruptly to normal. The white-cell count during the fever was 22,000. The pulse was paradoxical at a rate of 150 for a brief period, and the respirations 40. The urine contained enormous numbers of red cells, along with the white cells and casts, and still gave a +++ test for albumin. There

*On leave of absence.

was slight tenderness in the costovertebral angles, which was more pronounced on the left than on the right. With digitalis and ammonium chloride the edema disappeared and the patient lost about 15 pounds. An x-ray examination of the chest on the eighth day showed most of the increased density of the right lung to have cleared, a small amount persisting in the right costophrenic angle. The left lower lobe had decreased markedly in size, but there was still considerable density within it. The total twenty-four-hour protein loss in the urine was 13.6 gm.

On the tenth day, although the patient was not dyspneic or uncomfortable, the serum nonprotein nitrogen was 110 mg. per 100 cc., the carbon dioxide 5.4 millimols per liter, and the chloride 107 milliequiv. The acid phosphatase was 1.7 Bodansky units per 100 cc., the alkaline phosphatase 5.4 units, the phosphorus 3.8 mg. and the calcium 7.6 mg. Ammonium chloride was stopped, and the carbon dioxide promptly began to rise.

The temperature, pulse and respirations after the ninth day remained approximately normal.

After two weeks in the hospital, the urinary output fell from 1500 to about 1000 cc. and the non-protein nitrogen and albumin-globulin ratio improved somewhat. A repeat chest film three weeks after admission showed almost no change. Dental x-ray films revealed multiple carious teeth, apical abscesses and retained root fragments. During the third and fourth weeks, the chemical determinations and the patient's appearance and well-being showed definite improvement, the carbon dioxide reaching 15.3 millimols per liter; the urine remained unchanged.

Shortly after receiving a whole blood transfusion the patient went to the bathroom, where, apparently without straining, he turned ashen gray and became dyspneic. Loud gurgling rales were heard, and within five minutes he expired.

DIFFERENTIAL DIAGNOSIS

DR. JACOB LERMAN: In summary, we have a thirty-eight-year-old man who came in with an acute respiratory infection associated with congestive failure. The weight loss of 30 pounds is puzzling, for in congestive failure there should be a gain in weight. One must assume some underlying process in addition to congestive failure.

The past history suggests a rheumatic type of infection without any residual. He is known to have had good health except for one blood pressure reading of 140 systolic, 92 diastolic, which has to be considered as borderline. He had had trauma to the left testicle, which resulted in a mass about 10 cm. long. Examination showed an orthopneic, dyspneic man with extensive edema, obvious congestion of both lungs and some underlying disease in the lungs. I should like to hear from the roentgenologist whether or not there was evidence of underlying

infection. The urine was consistent with acute nephritis. He had a moderate anemia, a rapid sedimentation rate and negative Hinton and tuberculin tests. He had some evidence of impairment of renal function, a low serum protein and reversal of the albumin-globulin ratio, probably owing to albumin loss. I should interpret the electrocardiographic changes as being due to left ventricular strain and digitalis effect rather than to coronary disease.

He had a rather uneventful course in the hospital for the first three or four weeks except for the episodes of fever following the injection of diodrast and the residual changes in the lungs as indicated by x-ray examination. Perhaps we should look at the films now.

DR. MILFORD D. SCHULZ: The heart is enlarged but without characteristic configuration. Some fluid is present in both pleural sinuses, and there are some patches of airless lung in both bases that obscure the heart shadow. In a week this process is seen to have subsided, but there is still fluid in the right pleural sinus. Then a week later another patch of airless lung has appeared at the left base, with the evidence of fluid no longer present.

DR. LERMAN: The record states that the left lung was diminished in size.

DR. SCHULZ: Yes; the left hilum is depressed, and the left lower lobe is reduced in size.

At the time the excretory urograms were made the dye was eliminated by the kidneys in such poor concentration that nothing can be said about the morphology of the calyces and pelves. The outlines of the kidneys can be made out; they seem to be normal.

DR. ALLAN M. BUTLER: Are not the shadows of the kidneys large?

DR. SCHULZ: Perhaps they are slightly enlarged. I still think that they are probably within normal limits.

DR. LERMAN: Do you still see evidence of collapse in this last film or does the lung appear normal?

DR. SCHULZ: I cannot tell.

DR. LERMAN: Apparently there are three groups of signs and symptoms to be considered: cardiorenal, pulmonary and those of the mass in the testicle. Everything in the story seems to be consistent with a diagnosis of acute glomerulonephritis following a respiratory infection. There is nothing in the history or physical examination to suggest that the patient had a previous underlying chronic glomerulonephritis. Acute glomerulonephritis explains the hypertension, the acute cardiac failure, the extensive edema and the urinary changes.

The nephrotic stage of chronic glomerulonephritis has to be considered. As I have already said, there is no evidence of chronic glomerulonephritis. In any case, it explains only part of the picture, and one would have to assume an acute process on top of the chronic. The same is true for acute pyelonephritis. Here one finds that white cells predominate

jerks were less active on the right than on the left; both ankle jerks were absent; the plantar response was extensor on the right, and flexor on the left. Sensory examination was unsatisfactory; at times there seemed to be some impairment of the sense of passive movement, but there was always some doubt about this.

The temperature was 98°F., the pulse 80, and the respirations 20. The blood pressure was 110 systolic, 78 diastolic.

Examination of the blood showed 4,040,000 red cells, with 12.2 gm. of hemoglobin, and a white-cell count of 8100. The urine gave a + test for albumin; the sediment contained 25 white cells, a few epithelial cells and rare red blood cells per high-power field, as well as calcium oxalate crystals. The blood sugar was 96 mg. per 100 cc., and the nonprotein nitrogen 34 mg. A blood Hinton test was negative. Lumbar puncture revealed an initial pressure equivalent to 210 mm. of water; there were no cells, the protein was 44 mg. per 100 cc., the colloidal-gold reaction was normal, and the Wassermann reaction was negative.

X-ray examination revealed normal lung fields and a calcified tortuous aorta. In the skull there was an area of greatly increased density, measuring 7 by 7 by 2 cm., in the right anteroparietal region. This was sharply defined and appeared to lie against the inner table. No pineal shadow was visualized. The posterior clinoid processes were somewhat decalcified.

An electroencephalogram was reported as grossly abnormal, showing high-voltage, slow-wave activity throughout but most pronounced in the left postfrontal region. Examination by the cortical testing laboratory seemed to indicate that former intelligence had been normal and that defects had developed, particularly inability to think out a problem, choice of words, reading ability and memory.

After about two weeks there was some return of motion of the right leg, and following that, slight voluntary motion of the right arm and hand. The right foot remained paralyzed. There was never any spasticity. On the twenty-seventh hospital day the patient had a convulsive seizure. She first lost consciousness and then had convulsive movements of the left arm and leg lasting one minute. She was unconscious about five minutes and was incontinent of urine and feces. The findings following the seizure were essentially unchanged. After this there was no further improvement, the right arm and hand even becoming a little weaker. There was never any headache. Just before discharge, five weeks after entry, the senses of position, passive movement and two-point discrimination were found to be impaired.

Second admission (two months later). The patient had improved for a time and was eventually able to walk a few steps. Then the paralysis gradually

became worse, and beginning a few days before entry, she rapidly lost ability to talk. There had not been any headache.

Physical examination revealed a wide-awake and fairly alert patient. She obviously recognized her former doctors and understood at least a part of what was said to her. All that she could say was "yes" and "no," and these words were not always used appropriately. There was a right hemiplegia, with marked weakness of the face and complete paralysis of the arm and leg.

The temperature was 100°F., the pulse 90, and the respirations 20. The blood pressure was 95 systolic, 70 diastolic.

The urine showed a + test for albumin, and the sediment contained 15 white cells per high-power field. Examination of the blood showed a white-cell count of 9200, with a hemoglobin of 14.3 gm. The nonprotein nitrogen was 22 mg. per 100 cc.

On the ninth day after admission the patient became less responsive and in the late afternoon was found unconscious and covered with vomitus. Shortly after that she "stiffened out," with the head retracted and the respirations deep and noisy. The left arm was rigid and extended, and the right arm was partly flexed as before. The eyes were directed straight forward, and there were fine nystagmoid movements of the left eye. The pupils were 2 mm. in diameter, equal and fixed to light. After a short time the left arm relaxed. The arm and knee jerks were present and equal. There was no plantar response on either side. The patient remained in deep coma and died eight hours later, the temperature rising to 102.5°F. before death.

DIFFERENTIAL DIAGNOSIS

DR. MANDEL E. COHEN: The history of this illness covers six months from the first symptom to death. The first three months showed paralysis and weakness, first of the right leg and then the right arm, and finally definite hemiplegia, aphasia and confusion. The patient was studied in the hospital for over a month. During that time she showed slight confusion and had one convulsion. Apparently she improved somewhat and went home. In a couple of months she became progressively worse, particularly with regard to the right hemiplegia and aphasia. She was readmitted to the hospital and within a week went into coma and died. In other words, we have an illness of six months' duration, with a fairly steady progression of symptoms, except for a slight, short remission.

In considering a case of this kind, we should ask ourselves, What are the facts? Where is the lesion? What is the diagnosis? One has to emphasize the first question somewhat because, unfortunately, the instrument with which the patient gives the facts, namely, the brain, is diseased, so that sometimes the information may be misleading or even unobtainable.

"About a week before admission to the hospital she became confused and had difficulty in saying what she wanted to say, not being totally aphasic." At this point I should like to know just what "confused" meant. This word is used to describe a variety of symptoms. It may mean that a patient cannot find the right word to express himself but has nothing wrong with his understanding; it may also mean that a patient may not be able to enunciate clearly or understand the spoken language. These different disabilities may all be called "confusion." Some of these details are important in the localization of a lesion. This patient had had no headaches or at least complained of no headaches. In thinking about the possibility of brain tumor that has to be seriously considered.

At the time of the second admission the reflexes were less active on the right than on the left, and both ankle jerks were absent. Then there was some impairment of the sense of passive movement, but it does not say on which side.

DR. CHARLES S. KUBIK: It was on the weak side.

DR. COHEN: X-ray films of the skull showed something on the right side that was said to be sharply defined and to lie against the inner table of the skull, the posterior clinoids being somewhat decalcified. The location of the increased density immediately introduces a great difficulty, because the hemiplegia was on the right side. The patient was aphasic, and although we are not told, she was presumably right-handed, so that we should naturally look for a lesion on the left side. We are told, however, that there was a large calcified lesion, which was 7 by 7 by 2 cm., on the right side of the skull.

I think we must accept it as a fact that the patient had a right hemiplegia; that, in addition to the aphasia, was the main disability and should be the basis of our localization.

Do we know whether she was right-handed?

DR. KUBIK: I believe that she was.

DR. COHEN: Let us assume that she was right-handed. Occasionally one can be misled in lateralizing lesions from handedness since about 5 per cent of right-handed people have their speech centers on the right.

DR. KUBIK: The hemiplegia was on the right side too.

DR. COHEN: The most reasonable supposition is that she had a right hemiplegia and aphasia. The

not in-
hat she
hat in-
s to do
rea 44,

ie diffi-
mass or
In the

convulsion that was observed, most of the motor movements were on the left side. What does a convulsion tell us about localization? If the seizure is observed from the beginning and if there are unilateral movements, it is good betting that the lesion is on the opposite side. There are some other points, however, that should be mentioned. Sometimes a convulsion lasts an extremely short time. The crucial observation may be made by a student nurse or an untrained attendant who rushes in, and in the excitement, rights and lefts may be mixed up. A second possibility is that the fit may start on one side, but by the time it is observed, the only movements discernible are on the nonaffected side, the affected side having developed paresis. Another possibility is that in a patient who has a hemiplegia one sometimes observes that that paralyzed part does not enter into the convulsion. I had the opportunity once to observe a young man in another clinic who was diagnosed hysteria. He had a hemiplegia, and one physician thought a good cure for this would be to give an electric shock. This was given and his fit was observed only on one side of the body, that is, the paralyzed side did not convulse.

We have two bits of evidence to make us wonder about a lesion on the other side—the x-ray films and the fit on the wrong side. This brings up the possibility of two lesions or of one very extensive one.

Terminally the patient went into coma; the neck was retracted, and she developed the type of phenomenon which is evidence of what might be called decerebration. There are two possible explanations of that. One is that the patient had a mass with increased intracranial pressure and eventually suffered from herniation of the brain stem, with coma, pupillary abnormality and death. The other and less likely explanation is that the patient had intraventricular hemorrhage with blood in the third ventricle. We sometimes see this identical phenomenon in a patient with subarachnoid hemorrhage. Most of the evidence points to the fact that the lesion that gave the patient the most trouble was on the left side and was mainly frontal, although the function of the parietal area was also affected.

What was the nature of the lesion? One must consider various diagnoses here because certainly this is not an open-and-shut case, and even when a case seems to be clear cut it sometimes turns out not to be. The first consideration is a mass of some kind; the second, vascular disease, and then syphilis; and finally one should also include degenerative disease, such as Alzheimer's disease.

In favor of a mass of some kind, particularly a brain tumor, is the course of this illness. It was slowly progressive, with but slight remission. The march seemed rather steady and slow, which is in all likelihood the progress of a brain tumor. If this was a brain tumor, was it metastatic or primary?

There is no evidence of any primary source for a metastatic lesion. The patient apparently was in good health, had not lost weight and had no symptoms that pointed to any system of the body. So if she had a secondary neoplasm we are not able to diagnose it from the evidence. To be sure she had slight albumin and a few white cells in the urine, but she had no significant urinary symptoms to incriminate the kidney as a primary source for the tumor.

Could the mass have been of some nature other than neoplastic? Could she have had an intracranial hematoma, or two intracranial hematomas? She had had an injury fifteen years previously. As you know, everyone has injuries at some time or other, and in the evaluation of a case injury always comes in, sometimes as a red herring. If hematomas, they were quite chronic subdural hematomas; it is barely possible that the mass on the opposite side was an old calcified subdural hematoma. May we get an expression from the X-ray Department at this time?

DR. MILFORD D. SCHULZ: This is the area of increased density, which is continuous with the inner table of the right side of the skull; it apparently straddles the frontoparietal suture. It is homogeneous in density and thins out at the edges to meet the normal bone. It did not change during the three-month period of observation. The only thing that seems to have happened during this interval is that the posterior clinoid processes are not so well seen on the last examination as on the first. There are a lot of diploic channels in the parietal bones, particularly on the left side, but I think they are still within the bounds of what may be seen in normal people.

DR. COHEN: There are more channels on the left than on the right. They come to no special focus?

DR. SCHULZ: They are more prominent on the left, but they certainly can also be seen on the right side.

DR. COHEN: Can you tell by stereoscopic examination whether the mass is outside the dura, inside the dura or in the brain?

DR. SCHULZ: No, because you cannot see the dura. The dense mass is probably outside the dura, however, by reason of the fact that it seems to be continuous with the inner table; there is nothing in between it and the parietal bone.

DR. COHEN: The x-ray films do not help us a great deal in arriving at a diagnosis. It is possible that they may lead us away from the answer.

The second possibility is that this was vascular disease of the brain. In any patient sixty-two years old there is always the possibility of cerebral thromboses. The course, however, seems too gradual, and the method of death, probably by herniation of the brain stem, is not the proper one for cerebral thromboses. The spinal-fluid pressure was only slightly elevated, which could be consistent with this idea;

however, even a slight increase, if reliably measured, points to the tumor.

Syphilis would be unusual. It can cause the slow progression of hemiplegia and also convulsions. The patient had no serologic or other evidence of syphilis, and if she had syphilis we cannot diagnose it.

Against Alzheimer's disease or Pick's disease, both of which may give hemiplegia and fits, is the fact that the local manifestations were more pronounced than the general psychologic difficulties. Pick's disease has, however, been described as giving quite localized symptoms at the onset. These rare disorders are only remote possibilities.

The reason it is necessary to mention all the other possibilities is that this patient, a brain-tumor suspect, lacked headache, choked disks and obviously increased spinal-fluid pressure—the three characteristic signs of brain tumor. She apparently had no choked disks in the first examination. We are not told about the second time. The spinal-fluid pressure was not particularly elevated. She had no headaches. About 90 per cent of people with brain tumor have headache. Patients with aphasia may not be able to tell about headache or may forget to tell; nevertheless, lack of headache is a serious difficulty in diagnosis.

Another question that we must consider since we see a mass by x-ray on the opposite side from our suspected lesion is, What diseases give bilateral intracranial lesions?

Perhaps she had multiple lesions or one extensive lesion covering both sides of the brain. Of course, this mass may have been unrelated to her symptoms. But how could it have been related to the lesion? Subdural hematomas are frequently bilateral and sometimes do calcify. Brain tumors, particularly meningiomas, neurofibromas and angiomas, may be bilateral and also may calcify. Parasagittal meningiomas that grow to such an extent that they are visible on both sides of the head have been described, so one could include this possibility in the diagnosis. But we cannot say really what is on the other side of the head by x-ray.

We are left with the bare facts that this patient developed hemiplegia and aphasia over a six-month period and died. It is on these unequivocal facts that we must rest our case. Most of the findings indicate that the patient had a left-sided lesion. Putting all the evidence together the best bet is that the patient had a brain tumor of some kind. Glioma is the most frequent brain tumor, and it is proper to pick that on the basis of probability. A diagnosis of meningioma, however, would include the possibility of bilateral lesions, which is the most reasonable way to explain the left-sided lesion and the right-sided mass.

DR. W. JASON MIXTER: I think it is only fair to say that when I saw this patient I had the same feeling that Dr. Cohen had. It seemed to me that there was x-ray evidence of an extensive lesion on the

right side, with symptoms suggesting a tumor on the left side.

DR. KUBIK: The patient herself was opposed to having anything done at the time of the first entry, and because she had improved slightly, she wanted to go home for a while. At the time of the second entry, while we were wondering what to do, being reluctant, because of the aphasia and apparently conflicting findings, to do anything at all, the patient rapidly got worse and in the course of about twenty-four hours died. The clinical diagnosis on the death report was brain tumor, and that was also the diagnosis made at the time of the first entry.

CLINICAL DIAGNOSIS

Brain tumor.

DR. COHEN'S DIAGNOSES

Brain tumor, left frontal region: bilateral meningioma or glioma.
Herniation of brain stem and cerebellum.

ANATOMICAL DIAGNOSES

Meningioma: left parietal region.
Osteoma of skull, right.
Pressure cones, cerebral and cerebellar.
Cerebral infarction: left occipital lobe and cerebellum.

DR. KUBIK: At post-mortem examination the left hemisphere was considerably larger than the right. On the right side there was a depression, made by the bony mass that was seen in the x-ray films. That was solid bone, about 2.0 or 2.5 cm. thick, apparently an osteoma. There was every common variety of pressure cone, each one marked. A large part of the medial surface of the left cerebral hemisphere had herniated beneath the falx, and there was a large left temporal pressure cone, as well as a cerebellar pressure cone. Associated with the left temporal pressure cone there was hemorrhagic infarction of the medial portion of the left occipital lobe, including the calcarine cortex. This has been observed a number of times with temporal pressure cones. As the medial portion of the temporal lobe is forced into the notch of the tentorium the posterior cerebral artery is compressed against the inner free edge of the tentorium, and that presumably is responsible for the infarction. In this case there was also infarction of the superior surface of the cerebellum over the distribution of the left superior cerebellar artery. There was a firm, discrete tumor 3 cm. in diameter in the left upper parietal region, and an enormous amount of swelling of the white matter of almost the entire left cerebral hemisphere. Although such swelling of the brain occurs regularly with brain tumor, it was unusually marked for the size of the tumor in this case. It is quite possible that diminution in the size of the cranial cavity by the osteoma intensified the pressure effects. The tumor was a meningioma.

EPIDEMIOLOGY OF WOUND INFECTIONS

As in all infectious diseases the epidemiology of wound infections involves many factors that concern the host, that is, the patient and his wound, on the one hand and the invading organisms on the other. Some of the reservoirs from which these organisms arise and the importance of their recognition in the prevention of serious wound infections have recently been reviewed in a lecture by A. A. Miles,* professor of bacteriology at the University of London, who has made notable contributions in this field. What he has to say about these infections

is equally applicable to war wounds and to surgical wounds in civilian life.

Alexander Fleming, now widely known as the discoverer of penicillin, is given credit for the first complete bacteriologic history of an infected war wound. He distinguished three phases: the first, which is characterized by a dark, reddish-brown, foul-smelling, watery discharge, lasts about a week; the second, during which the discharge becomes less copious and more purulent, lasts another week or so; and the final stage, which is one of pyogenic infection, lasts for a varying length of time. In the first stage, spore-bearing and gram-negative bacilli predominate. These are replaced during the second stage by pyogenic cocci, which persist and flourish. Similar descriptions, with some variations, have been given by numerous other writers since that time.

In a study of wounds in men from Dunkirk and in air-raid victims, Miles found that indifferent cocci, spore-bearing bacilli and coliform organisms appeared early and were gradually replaced by pyogenic cocci, mostly *Staphylococcus aureus* and hemolytic streptococci, and other coliform bacilli. The original contaminants behaved like saprophytes, since the majority seemed to be killed by the tissues of the host. Because of the possibility of accurately identifying the late-appearing hemolytic streptococci by grouping and typing, these were selected as the best organisms to follow in tracing the origin of wound infections.

Such infections may arise from two sources, namely, the injury and its environment. Surgeons, on the whole, hold to the opinion that the organisms are implanted at the time the wound is sustained and that they become clinically and bacteriologically predominant later. They therefore place the chief emphasis on operative technics, débridement and cleansing procedures and the use of sulfonamides and penicillin locally and systemically to prevent their multiplication and spread. Bacteriologists, on the other hand, consider that most of the late-appearing organisms are usually added after the infliction of the wound. The distinction is important, for if the former is correct, then the entire attention must focus on the early treatment of the wound; whereas if the latter is true, then "the whole life of the wound must be our concern."

*Miles, A. A. Epidemiology of wound infections *Lancet* 1: 809-813, 1944

Miles considers two main reservoirs of hemolytic streptococci—one the open lesions of patients with streptococcal wound infection, pharyngitis, scarlet fever or puerperal fever and the other the throats and, to a lesser extent, the noses of healthy carriers. From these sources there arise contaminations of the dust, clothing and bedclothes, which in turn may cause infection both of the cases and of the carriers from which the organisms arise and of those around them.

Recent evidence indicates the chief reservoirs of virulent staphylococci to be not the skin, as previously thought by most workers, but rather the anterior part of the nasal cavity. From 30 to 70 per cent of persons can usually be found to carry *Staphylococcus aureus* in the nose, whereas only 5 to 20 per cent are skin carriers. Significantly enough, most of the skin carriers are also nasal carriers. In addition, the staphylococcus-carrier state is usually a permanent rather than a transient one. Throat carriers of pathogenic staphylococci are infrequent.

Another highly important feature of staphylococcal infections is their dependence on personal contact and not on environmental factors. Staphylococci are not usually found in large numbers in the air even in a ward in which there are many patients whose wounds are infected by them. Streptococci, on the other hand, are broadcast from the throat through droplets during talking, coughing and sneezing. Since staphylococci are rare in the throat, they are spread by droplets only during occasional sneezing. The real broadcasters of staphylococci are the hands, which have innumerable opportunities of becoming contaminated with them. As compared to streptococci, the potentially pathogenic staphylococci seem to be much more dependent on actual contact for access to wounds, but the latter organisms are also much more widely distributed among human carriers, all of whom carry them in large numbers.

Silent infections, that is, the presence of streptococci or staphylococci in clinically clean wounds, both large and small, constitute another significant reservoir of infection. This is true both in civilian and in military practice. Such silent infections may be as frequent or even more frequent than clinical

infections, and they are mostly staphylococcal. The infecting organisms are often added after infliction of the wound, and their presence has been shown definitely to prolong the healing time. Epidemiologically, these silent infections may be of even greater danger than the manifest ones because of the fact that they are unrecognized. A typical example is a small cut on the finger of the doctor or nurse, "which serves as an *entrepreneur* between the upper respiratory tract and the patient's wound and goes into production on its own."

The risks of infection from each of the reservoirs vary with the age of the wound. In this respect, Miles distinguishes three types of infection. The first, of course, is the infection of the wound that takes place at the time the injury is sustained. The second is self-infection from the upper respiratory tract and the skin, and its danger is continuous throughout the history of the wound. Miles has been able to show that the wounds of those who are staphylococcus carriers are likely to be contaminated with that organism at the time of injury. The third is infection in the hospital, which is considered to be the gravest, because of the concentration of the reservoirs of infection and of the susceptibles. It is there that wounds are exposed for dressings under conditions highly favorable for the transfer of infection unless they are done under operating-room conditions. Indeed, from 30 to 80 per cent of cases become infected on hospital wards.

The prevention of the infection that follows contamination at the time of injury is concerned with the "toilet of the wound" and the use of prophylactic antibacterial agents, such as sulfonamides and penicillin. By means of the former, the bulk of the infected material is removed and the conditions for resistance against those that remain are improved. Dressings impermeable to bacteria then reduce the risk of infection from the outside, except during inspection and dressings.

The successful prevention of added infection depends on an appreciation of their source. These may be either air-borne or spread by contact, the latter probably being the more important except in the case of large wounds or burns. One must recognize that the danger from air-borne infection is greatest when dust is stirred up, particularly after

sweeping or bedmaking. It is also necessary to bear in mind that the ordinary procedure of changing a dressing is one of the methods by which a large number of pathogenic bacteria are discharged into the air. Recently the application of oily substances to the floors and bedclothes, to keep down the dust, has proved more effective in controlling infection than have methods of sterilizing the air.

The risks of contact infection are well recognized by surgeons. They do not, however, have the same respect for the open wound on the ward that they have for the clean incision made in the operating room. If both these types of wounds were given the same consideration, Miles believes that the danger of hospital infection of wounds would be almost completely eliminated. He cites instances in which an aseptic routine in handling wounds, with comparative neglect of the air-borne elements, resulted in a striking reduction in the rates of secondary streptococcal and staphylococcal infection. In one clinic, for example, streptococcal infections were reduced from 31 to 2 per cent in this manner.

Surgeons in these busy days are apt to be rather careless in the manner in which they handle wounds and dressings. If the arguments presented by Professor Miles are correct, much time for both the surgeon and the patient would eventually be saved by the aseptic handling of wounds. This would obviously necessitate a considerable change in habits and procedures, but it seems likely that the added effort would be repaid by a reduction in the incidence of secondary wound infection and, hence, by an increase in the rapidity of healing.

MASSACHUSETTS MEDICAL SOCIETY
COMMITTEE ON LEGISLATION

The following letter was sent on May 2 to all members of the Committee on Legislation.

WILLIAM E. BROWNE, *Chairman*
* * *

Dear Doctor:
Realizing that your own district society is probably having a meeting in the near future, and that you might be called on for a report, I am sending you this letter to bring you up to date on legislative affairs.
This session of the Legislature has taken final action on very few bills in which we are interested, although the hearings on most of these bills are finished.
House 973, a bill that we favored, requiring corporations organized for the purpose of conducting medical schools

to file an annual return to the Secretary of State was finally enacted, being signed by the Governor on April 18.

Senate 215 and House 762, bills either to abolish the Division of Occupational Hygiene or to transfer it from the Department of Labor and Industries to the Department of Public Health, were both given leave to withdraw.

Senate 273, a bill relative to the practice of medicine by hospital interns, fellows or medical officers, was rewritten as House 1672, passed and signed by the Governor on April 4.

Senate 54, a bill requiring physicians and surgeons to furnish written statements in certain cases, was given leave to withdraw on February 26; we opposed this bill.

Senate 69, a bill to establish a board of registration in chiropractic, was rewritten as House 1738 and given to the Ways and Means Committee. We plan to oppose it again when it comes up for a hearing.

The three osteopathic bills are House 1394 and Senate 396 and 397. The first bill was withdrawn, but the last two were heard before the Committee on Education early in April. These bills would allow the Board of Registration in Medicine to accept the certificate of the National Board of Examiners for Osteopathic Physicians, just as they now accept the certificate of the National Board of Medical Examiners.

All the following bills, House 754, 755, 858, 859, 860, 1014 and 1396 and Senate 422, were proposed by adherents of either Middlesex University College of Medicine or the College of Physicians and Surgeons to break down the present Approving Authority law. They try to do this by repealing the law, postponing its effective date or making exceptions to it. The proponents of these bills talked for five days before the Committee on Public Health and for two days before the Committee on Education. We answered in two days and one day, respectively. Our side was ably upheld by Dr. H. C. Weiskotten, dean of Syracuse University College of Medicine and secretary of the Council on Medical Education and Hospitals of the American Medical Association, Dr. Lee, Dr. Bagnall, Dr. Mongan and others. What the recommendation of the committee will be, and when it will be announced, we do not know, but it behooves all of us to enlighten our representatives and senators on the true facts of the situation.

Two more bills have been heard by the committees, but no report has yet been made public. These are Senate 421 and 446. The former bill proposes that, if any hospital accepts medical students, it must accept them from all legally chartered schools, and the latter would open every hospital to every physician.

The members of the Committee on Public Health, before whom most of these bills have been heard, have been most patient. We have not tried to coerce anyone, but rather to aid them in arriving at their decisions.

We shall probably have to ask you again to get in touch with your senators and representatives regarding these measures which affect the health of all the people of the Commonwealth.

WILLIAM E. BROWNE, *Chairman*
Committee on Legislation

DEATHS

DUCKERING — William W. Duckering, M.D., of Dorchester, died May 3. He was in his eighty-fourth year.

Dr. Duckering received his degree from Harvard Medical School in 1898. He was formerly on the staff of the Boston Dispensary. He had been retired from practice for seven years.

Two sisters and a niece survive.

KING — Nathaniel C. King, M.D., of Brockton, died January 23. He was in his eighty-fourth year.

Dr. King received his degree from the College of Physicians and Surgeons, New York, in 1884.

MCCARTHY — Eugene A. McCarthy, M.D., of Bedford, died January 1. He was in his eighty-fifth year.

Dr. McCarthy received his degree from Harvard Medical School in 1887.

OBER — Ralph B. Ober, M.D., of Springfield, died April 13 at Sarasota, Florida. He was in his sixty-sixth year.

Dr. Ober received his degree from Harvard Medical School in 1901. He served as a major in the Army Medical Corps during World War I. He was on the senior surgical staff at Springfield Hospital, having been president at one time. He was a fellow of the American Medical Association, a member of the Springfield Medical Club, New England Surgical Society and American College of Surgeons and a diplomate of the American Board of Surgery.

His widow, a son, a daughter and two sisters survive.

PORTER — Charles T. Porter, M.D., of Waltham, died April 19. He was in his fifty-seventh year.

Dr. Porter received his degree from the University of Virginia Department of Medicine in 1912. During World War I, he served with the Harvard hospital unit in France with the British Army. He specialized in otolaryngology, was lecturer on otology at the Harvard Medical School and was associated with the Massachusetts Eye and Ear Infirmary, Massachusetts General Hospital, Waltham Hospital, Children's Hospital, Massachusetts Women's Hospital, Brooks Hospital, Cambridge Hospital and Faulkner Hospital. He was a consultant at the Concord Hospital and Robert B. Brigham Hospital. He was a fellow of the American College of Surgeons and the American Medical Association and a member of the American Academy of Ophthalmology and Oto-Laryngology, American Laryngological Association, American Laryngological, Rhinological and Otolological Society, American Otolological Society and New England Otolological and Laryngological Society. He was a diplomate of the American Board of Otolaryngology.

He is survived by his widow and a daughter.

MISCELLANY

PASSANO FOUNDATION AWARD GIVEN TO DR. COHN

On May 16 in Baltimore, Dr. Edwin J. Cohn, professor of physical chemistry and head of the Department of Physical Chemistry, Harvard Medical School, was honored as the first recipient of the Passano Foundation Award, which carries with it an honorarium of \$5000. The foundation was established in 1944 by the Williams and Wilkins Company, of Baltimore, to aid the advancement of medical research, especially that hearing promise of clinical application. For the encouragement of such research the foundation has established the award as one of its activities. Dr. Cohn is distinguished for his work on the fractionation of blood. Beginning in 1919 with a study of blood and blood proteins, Dr. Cohn's research has progressed until it has yielded a spectacular group of five fractions of blood plasma, which hold untold promise of usefulness in medical science. Following the presentation of the award by Mr. Edward B. Passano, chairman of the Board of Directors, Williams and Wilkins Company, Dr. Cohn read a paper concerning the applications of his work on blood plasma to the field of clinical medicine.

DOCTORS' LAMENT

In spite of all the freedoms that you're fighting for today,
Whatever be your station or position,
For 'most anything that's needed, for your work or for your play,
You must have a little note from your physician.

Now if of creamery butter you're extravagantly fond
And its lack you find impairing your nutrition,
To your pleas the kindly grocer will most pleasantly respond,
If you have a little note from your physician.

It is true that in the winter, when your living room is cold
And the radiator never starts to hissin',
Coal or oil will be provided for not quite its weight in gold,
If you have a little note from your physician.

It may be Sunday evening and your cellar has run dry;
For a long and frosty drink is what you're wishin':
Why, it's simple, for the druggist will replenish your supply,
If you have a little note from your physician.

Suppose on Friday evening that your tank is running low
For the most entrancing week-end expedition;
The solution's very easy: to your ration board you go
With a breezy little note from your physician.

After countless hours of headache, when your income tax is due,
Since you're ill, for time to pay you must petition,
You're forgiven by the Bureau of Internal Revenue
If you have a little note from your physician.

When, at the end, you're pleading with St. Peter at the Gate,
After finishing with pride your earthly mission,
Be quite certain, even then, you impatiently will wait
For that final little note from your physician.

APRENIA ALGERA

CORRESPONDENCE

DEPRIVATION OF LICENSE

To the Editor: At a meeting of the Board of Registration in Medicine held April 11, after a hearing of the case of Dr. Harry B. Bernstein, 100 Boylston Street, Boston, the Board voted to suspend his license to practice medicine in the Commonwealth for three months because of gross misconduct in the practice of his profession as shown by deceit in causing false and misleading advertisements to be inserted in the newspapers.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

TATOOING FOR IDENTIFICATION

A recent confidential report from the man in charge of displaced persons for the United Nations Relief Association in France, makes one sad to hear of the scores of children who carry no means of identification. It is almost impossible to know even their nationality, for some are too young to talk intelligently. Experiments, such as saying "Come here, dear," in various languages and showing motion pictures of certain countries, fail in many cases to help in finding even from what country the children come. Some permanent means of identification should be invented so that none of the children in the United States are lost. For soldiers, this would reinforce the identification tag. It would also be useful in the identification of people who are killed in accidents and of criminals whose source of birth is difficult to place.

To overcome the difficulty of identifying lost people it is suggested that when a birth is reported, a number should be returned to the parents within two weeks and that this number should be tattooed on the child during the first month of life. The number would probably have to start with a letter indicating the country of origin, and the first two numerals in the number could probably be used to indicate the subdivision of the country — in the United States, they might indicate a state. Various parts of the body could be used for tattooing, such as the buttocks, the lower back or the supra-pubic region.

If the above suggestion meets with any approval, the whole matter should be referred to the Children's Bureau in Washington, where the mechanics of numbering the children and deciding the location for tattooing could be worked out, as well as the steps involved in making this a law. If the idea is adopted, experts in tattooing should be trained so that this minor operation could be done in a cleanly fashion and with little discomfort to the baby.

It is to be hoped that many other countries besides the United States will adopt a similar plan of identification.

BOOK REVIEWS

The Trials and Triumphs of the Surgeon, and Other Literary Gems. By J. Chalmers Da Costa, M.D., LL.D. Edited by Frederick E. Keller, M.D. 8°, cloth, 401 pp. Philadelphia: Dorrance and Company, 1944. \$5.00.

Twenty-one addresses and essays of the late Dr. J. C. Da Costa are here collected in book form under the editorship of his younger colleague, Dr. F. E. Keller. The subjects embrace topics in the history of medicine, controversial medical issues, such as vivisection, the medical education of women and polypharmacy, biographical sketches, eulogies and graduation addresses. As Da Costa once said, "During my nearly thirty years of membership in the medical profession, many truths have crystallized in my mind, some as apothegms, some as aphorisms, and some as epigrams"; of these he cites no less than fifty-four in the address before the Philadelphia County Medical Society that gives the title to the book. Charles Dickens must surely have been his literary idol, for he places his lance at rest and tilts against medical shams, hypocrisy, quackery, pretensions and fashions with true Dickensian satire and cynicism. Senior students will do well to expose themselves to these precepts, expressed and implied, and will enjoy the experience; middle-aged doctors will chuckle over and find relaxation in them; but it will be the thousands of his former students in anatomy and surgery at the Jefferson Medical College who will enjoy again listening to the old master, recalling the kindly and warmly sincere nature of the teacher whose words were often so caustic and devastating. To the younger of them will appear again the unconquerable spirit of the man who continued to teach from a wheeled chair, the victim of a painful and disabling disease. And no reader should miss the touching poetical tribute by a friend, beneath the frontispiece picture of Da Costa's desk.

Operations of General Surgery. By Thomas G. Orr, M.D. 4°, cloth, 723 pp., with 1396 illustrations. Philadelphia: W. B. Saunders Company, 1944. \$10.00.

Dr. Orr's purpose in preparing this book is best indicated by a sentence from his preface, "A clear visualization of the steps in an operation is many times more instructive than the descriptive text." Accordingly, he has borrowed from recent textbooks and from surgical monographs and current journals and has added original drawings to a total of nearly four thousand illustrations, a very large number of which occupy the entire page. The text is necessarily brief to be included in the total pagination, and consists of a short description of the anatomy of the region, of the indications for operation and of particular dangers and safeguards, together with a concise enumeration of the operative steps.

The first three chapters constitute an introduction on the subject of wound healing as affected by surgical technic, the treatment of fresh wounds and the indications for various kinds of sutures.

In subsequent chapters the critical reviewer sometimes finds himself not in agreement with the author's judgment of relative values. Interscapulothoracic amputation is dismissed with two small figures showing the skin incision with but twenty-five lines of descriptive text, whereas depressed nipple is accorded two illustrations with almost as much text. A whole page plate with figures of twenty-two varieties of skin incision for radical mastectomy and little or no expressed opinion concerning their respective value must be confusing to the uninitiated. The figures illustrating vascular ligations are inadequate in comparison with others, and this is particularly the case in pulmonary embolectomy. It seems out of proportion to devote sixteen illustrations, most of them full-page, to abdominal incisions. In general, the operations on the abdominal viscera are perhaps the most satisfactorily presented. It seems unfortunate that in picturing four methods of gastrostomy Dr. Orr expressed no opinion concerning their relative merits, and similarly one wishes to know his views about the exact indications and usefulness of posterior gastroenterostomy. In describing proximal temporary colostomy for obstruction one could wish that mention were made of the Miller-Abbott tube, which so often renders this unnecessary. The account of hernia is excellent. The discussion of neurosurgery is limited to fracture of the skull, decompression and the suture and transplantation of nerves. There is an excellent brief analysis of the status of the surgery

of the sympathetic system. In the endocrine system one is surprised at the inclusion of total thyroidectomy for heart disease and angina pectoris, — a procedure that has been largely discarded, — and one notes in the text that in the operation for carcinoma of the thyroid gland "no attempt should be made to preserve the recurrent nerve," whereas the excellent illustration on page 574 shows the nerve to have been carefully preserved. Congenital anomalies and the genitourinary and female reproductive systems are satisfactorily illustrated, but one notes with regret that while the author states that "radical abdominal panhysterectomy includes the complete removal of the uterus with the tubes and ovaries," the six plates and descriptive text indicate that the tubes and ovaries have been preserved. Such discrepancies in a textbook are unfortunate. It could hardly be otherwise than that illustrations from so many sources would be of uneven merit, but most of them are excellent. The value of many is somewhat impaired by the lack of adequate labeling of structures.

The exact place of this handsomely manufactured and expensive volume in the library of the beginner and of the older general surgeon seems to this reviewer somewhat doubtful. He wishes that it reflected more of Dr. Orr's great wisdom and personal experience. It is his opinion that in the serious preparation for the performance of an operation the reader will usually find it necessary to turn to the original monographs and textbooks, to which this volume may be found to be an excellent guide.

BOOK RECEIVED

The receipt of the following book is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Savill's System of Clinical Medicine: The diagnosis, prognosis and treatment of disease for students and practitioners. Edited by E. C. Warner, M.D., F.R.C.P. Twelfth edition. 8°, cloth, 1168 pp., with 185 illustrations and 7 plates. Baltimore: Williams and Wilkins Company, 1944. \$9.00.

This twelfth edition of a standard English work has been thoroughly revised in the light of modern advances in the field of clinical medicine. So much has been rewritten that few pages have escaped alterations, and much new subject matter has been added throughout the text.

NOTICES

ANNOUNCEMENT

Dr. Mark F. Lesses announces the removal of his office from 375 Commonwealth Avenue to 371 Commonwealth Avenue, Boston.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, MAY 24

FRIDAY, MAY 25

*9:00-10:00 a.m. Periarthritis Nodosa and Acute Disseminated Lupus from the X-ray Viewpoint. Dr. Merrill Sosman. Joseph H. Pratt Diagnostic Hospital.

*9:00-10:00 a.m. Medical clinic. Isolation Amphitheater, Children's Hospital.

10:50 a.m. Cardiovascular Syphilis. Dr. Charles Kelly. (Post-graduate clinic in dermatology and syphilology) Amphitheater, Mallory Building, Boston City Hospital.

SATURDAY, MAY 26

*10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, MAY 28

*12:00 m.-1:00 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

THE CIRCUS DISASTER AND THE HARTFORD HOSPITAL*

DONALD B. WELLS, M.D.†

HARTFORD, CONNECTICUT

An emergency anticipated and prepared for ceases to be an emergency.

IN TERMS of sudden death and human suffering, the circus fire of July 6, 1941, is the worst disaster that has overtaken Hartford in the more than three hundred years of her history. In less than fifteen minutes 125 human beings, more than half of them children under fourteen, were burned to death on the lot. One hundred and eighty-three others, of whom 150 were burned, were admitted to the various hospitals, where 43 subsequently died. Some concept of this terrible disaster can be brought to you today.

The Hartford Hospital crystallized from disaster. Ninety years ago, on March 2, 1854, a boiler blew up in the Fales and Gray Car Manufactory in Hartford, killing 19 persons and injuring 23. A coroner's jury promptly placed the blame on the carelessness of the engineer, sermons were preached on the disaster, public recriminations were openly indulged in, and a pamphlet was published and sold for the benefit of the dead and injured. Responsible citizens, however, discussed the need of preparing for a possible repetition of such a disaster, and in May, 1854, two months later, the Hartford Hospital was incorporated. From a modest beginning the hospital has grown during the last eighty-eight years to become the most heavily occupied community hospital in the United States. The physical plant became inadequate, and a new hospital was projected. In April, 1942, the citizens of Hartford pledged for the new Hartford Hospital the largest sum of money ever raised by public subscription for a hospital in the history of the world.

The most essential factor in disaster preparedness that the hospital can provide is adequate shelter for the victims. The first unit of the new Hartford Hospital, the South Building, was opened in July, 1942. Its first purpose is to serve maternity patients and their babies; but the first floor, designed to be used ultimately as an outpatient department,

is constantly maintained as a properly located, adequately protected, completely equipped Triage Room, where a considerable number of casualties of any type can be assembled and definitive treatment instituted in the event of civilian disaster. An adequate drive and ambulance entrance open directly into a large foyer, where are stacked sawhorses and standard stretchers. Immediately adjoining the foyer is the Triage Room, 60 by 40 feet. Here twenty beds are kept constantly made up. At either end are lockers containing all necessary emergency apparatus. The room is equipped with utility hoppers; oxygen is piped directly into it; there is central suction; heavy-duty rubber-covered electric cables with multiple-plug receptacles placed at frequent intervals lie on the floor. Down the corridor from the foyer are two air-conditioned emergency operating rooms with complete pressure-sterilizing equipment, ordinarily used as cystoscopic rooms. Here, and in the regular accident rooms, on the afternoon of the circus disaster, the casualties were admitted and received their initial morphine and plasma, laboratory determinations were made, wounds were dressed, and ultimately the patients were transferred to the wards as these were set up to receive them.

Next to shelter and morphine, the most essential therapeutic agent in civilian disaster casualties, as in war, is blood plasma. The supply must be immediately at hand in adequate quantity. There is no substitute for blood plasma in the treatment of severe burns. The community had recognized this, and on December 15, 1941, eight days after the attack on Pearl Harbor, a proposition for a Hartford County blood-plasma bank of sufficient size and available to all the seven hospitals in the county in the event of civilian disaster was proposed to the six local Red Cross chapters. Responsible citizens accepted the proposal, and the community responded with its blood and money until a cache of 2700 pints of frozen plasma was in storage at strategic points against unexpected sudden demands of civilian disaster. So far as is known, such a cache of blood plasma contributed and paid for by a community,

*Presented at the annual meeting of the New England Surgical Society, Boston, September 20, 1944.

†Visiting surgeon, Hartford Hospital.

is absolutely unique. On the day of the circus fire, the blood-plasma bank paid a large dividend to the community that had had the forethought to set it up: nearly 28 gallons of plasma was injected into the veins of the victims — with only a single mild reaction. Furthermore, up to August 29, volunteers had given an additional 85 pints of whole blood to the victims at the Hartford Hospital. It is interesting to note that a large part of the plasma, blood and electrolyte given the burned patients in the hospital was introduced directly into the femoral veins. Three hundred and thirty-five recorded femoral punctures were done by the house staff during the first three weeks following the fire without an untoward incident — nor were any common femoral veins ligated. One patient, who had sixteen femoral punctures, developed a transient, benign thrombosis of the right deep epigastric vein. In no case was any vein cut down on.

As is true of nearly every other community hospital during this war, the Hartford Hospital is chronically handicapped by a shortage of trained professional personnel. But the hospital as well as the community had prepared for civilian disaster. Five hundred and eighty-five Red Cross nurses' aides had been trained and graduated since the first class was inaugurated in March, 1942. An organized group of volunteer business and professional men known as "medical aides" had been formed at the Hartford Hospital in July, 1942, to meet the crises that had developed because of the disappearance of paid orderlies into the military services and expanded war industries. So far as is known, this is the first group of such volunteer men in the country to train for this type of work. A few of these volunteers were on duty at the Hartford Hospital on the afternoon of July 6. But as the news spread, a trained community flocked to the Hartford Hospital. It came first and continuously in the uniform or dress of its own nurses, staff and employees; then, almost as the victims arrived, it appeared in every professional and volunteer category: as trained nurses, volunteers going to work on the burned cases; as Red Cross nurses' aides, 40 remaining at the Hartford Hospital and 95 being directed elsewhere for service; as male medical aides, 105 of whom reported, 30 being retained for work in the hospital and the remainder going elsewhere for emergency service; as the blue-smocked volunteers; as soldiers from Bradley Field; and as servicemen from the telephone company, who stood by all night.

Burns are a special assignment at the Hartford Hospital, and a majority of all burns routinely admitted come under the care of the Burn Committee. For the benefit of the interns on duty in the Accident Room, the Burn Committee has a typed-out plan for the definitive treatment of such burns as may be assigned to it. Within three minutes of the arrival of the first patient on the day of the disaster the director, in accordance with plans adopted by

the staff and executive committee more than two years previously, declared an "emergency," which automatically placed all the disaster burns on an equal economic level and under the sole professional care of the Burn Committee. As a result, every burn that came into the hospital on July 6 was uniformly treated. The committee's typed-out plan closely follows the so-called "unorthodox method" employed at the Massachusetts General Hospital at the time of the Cocoanut Grove Disaster: immediate intravenous morphine; intranasal oxygen, if necessary; clinical evaluation of impending shock and absolute priority treatment of existing shock with plasma in adequate quantity as determined by frequently repeated laboratory checks; no cleansing or débridement of the local injury; simple protective pressure dressings, using previously prepared sterilized vaseline strips overlaid with dry gauze carefully and smoothly applied; sheet wadding rather than mechanic's waste; and Ace bandages. Folded newspaper splints are applied to extremities, with a second Ace bandage fastened to the newspaper splints with multiple safety pins. Every patient was supposed to receive intravenous sodium sulfadiazine. Each adult received 2 gm. at once, and a majority of the children received 50 mg. per kilogram of estimated body weight. Sulfonamides were entirely discontinued thirty hours after the disaster, when the National Research Council generously made an outright gift to the hospital of 220,000,000 units of penicillin, thus making it available to every victim in adequate dosage not only for therapeutic use but for prophylactic protection against possible infection.

The Burn Committee comprised three surgeons, four physicians, a pediatrician, two pathologists and adjunct members in various specialties. The day has long since passed when any severely burned patient can be considered as adequately cared for when his wound has been covered by some favorite local dressing. It cannot be emphasized too strongly that during the first forty-eight hours burns are a problem in physiologic chemistry and psychiatry; the only necessary surgical procedure in severe diffuse burns is to protect the wounds from infection and further trauma. The recognition and adequate treatment of shock is the all-important therapeutic problem; and in terrible mass catastrophes such as the circus fire severe emotional shock is superimposed on surgical shock. With this in mind, careful social-service investigation was promptly instituted in every case, and psychiatric evaluation and treatment were undertaken in a number of cases.

Fifty-one burned patients are said to have arrived at the Hartford Hospital within thirty minutes. Without the large Triage Room, previously prepared supplies, a reserve cache of frozen plasma, trained volunteer emergency personnel and uniform professional handling, the hospital would have been swamped. In all, 86 living patients were

brought to the hospital. Of these, 19 were dressed in the Triage Room and discharged as ambulatory cases. A total of 67 injured patients were admitted to the hospital, 54 of them having burns. Fortunately, a large surgical ward was in process of being painted, an overflow obstetric ward in the new South Building was not in use, and it was possible to clear other patients from the annex of a third ward. This permitted all the burned cases to be segregated; it simplified medical and nursing care, facilitated laboratory procedures and controlled visitors.

Beginning on the day following the disaster, formal rounds were regularly made at 10 o'clock each morning. All interested physicians were invited. A number of nationally known consultants were invited to come to Hartford, and they added a great deal of interest to the problems presented and discussed on these rounds. The name and the date of the expected visit of each consultant was posted in the Staff Room, and on one day there were thirty-five physicians in the group on rounds. Without exception the patients seemed to appreciate these visits; it made them feel that everything possible was being done for their safety and comfort. Each member of the Burn Committee was expected to speak to every patient as the group passed through the ward, and each consultant was personally introduced.

From the very first, visitors were admitted to the burn wards. During the first fortnight the number of visitors to each patient was limited to two and the duration of the visit to ten minutes; later the number of visitors permitted each patient and the visiting hours were extended to correspond with those on other wards in the hospital. Patients in a critical condition could be seen by members of their immediate family at any time. All physicians, personnel and visitors entering the burn wards were masked, a blue-smocked volunteer being constantly on duty at the door of each ward to enforce the rule. It is the belief of the Burn Committee that no infection was introduced or spread by this free access of professional men and relatives to the victims of the disaster, and there is a definite impression that it did much to maintain a high morale. Not a single patient asked to leave the hospital to secure different professional care, the comfort of special nursing or the exclusiveness of private-room accommodations.

As is so often the case in catastrophes, the burns followed a definite pattern. The vast majority of those who reached the hospital alive were burned solely by hot air. The vertex of the head, the extensor surfaces of the hands and forearms, the lateral surfaces of the arms, the upper back and exposed portion of the legs were uniformly the most severely burned areas. As they came into the Triage Room the victims appeared far more severely burned than eventually proved to be the case. Several had first-

degree burns almost from head to foot. Shock was the outstanding feature as they came in and for the first forty-eight hours after admission. The burned patients were primarily medical cases exhibiting marked physiologic imbalance, which required the closest clinical and laboratory observation, followed by prompt, intelligent and adequate therapy. The immediate results proved the validity of this thesis: not a single burned patient died at the Hartford Hospital of burn shock — a commendable record.

Five days after the fire, at the request of the National Research Council, a group of 7 patients began to have their local wounds dressed with pyruvic acid, followed by succinic acid and early skin grafting. This group was placed under the sole direction of Dr. G. J. Connor, assistant professor of surgery at Yale University School of Medicine, who originated and developed the method. It was a most interesting study and undoubtedly will be the subject of a subsequent detailed report. The local wounds of all the other patients were treated by the standard method — a bland ointment, a massive immobilizing dressing and delayed skin grafting of third-degree areas. It is most difficult to distinguish between deep second-degree and third-degree burns during the first few days; and it was amazing how some of the burns believed at first to be of third degree filled in from little scattered viable islands of epithelium.

Three of the burned patients admitted to the Hartford Hospital died. Each came to autopsy. The first, a twenty-two-year-old woman, died fifty-nine hours after admission. The anatomic diagnoses were second-degree and third-degree burns (10 to 15 per cent of total body surface), acute membranous laryngitis and tracheitis, pulmonary emphysema (bilateral), pulmonary edema (bilateral), diabetes mellitus and tracheotomy. The second, a thirty-five-year-old woman, died six days after the fire. The anatomic diagnosis was extensive second-degree and third-degree burns (50 to 60 per cent of total body surface). The third, a sixty-five-year-old woman, died twenty-eight days after the fire. The anatomic diagnoses were extensive second-degree and third-degree burns (50 to 60 per cent of total body surface), cellulitis, left lower extremity (anaerobic *Streptococcus haemolyticus*), thrombophlebitis, left femoral vein, and operative wound (split-graft donor sites).

* * *

The circus fire as observed at the Hartford Hospital demonstrates that possible civilian disaster requires thoughtful preparation and specific organization on the part of the community, a hospital with adequate physical equipment and trained personnel and, most important of all, an organized professional staff with a clear concept of peripheral vascular failure and the significance of laboratory data, of infection and the limitations of bacterio-

atic agents, of nutrition, of the underlying principles of wound healing and of realistic psychiatry.
) Asylum Street

DISCUSSION

DR. CHARLES C. LUND, Boston: I want to compliment Dr. Wells on a perfectly marvelous job. I was one of those who had the good fortune to visit Hartford, not immediately, but about two weeks afterward, and saw the fine layout and at extremely fine work was being done.

I feel strongly, from the experience in Boston and that Hartford, that every hospital should have typed out and ready a disaster plan, and that this plan should include a plan to administer the care of burns, and probably a different plan to supervise the care of certain other kinds of disasters. How do we know that this morning we may not receive in the hospitals in Boston 200, 300 or 400 patients with any number of complicated fractures, from a train wreck right outside of, say, Readville, perhaps without any burns at all? These things are happening all the time. Owing to Civilian Defense, of course, there are such plans, but very few of them approach the one that Dr. Wells created and had ready in Hartford.

Supposing a disaster strikes, and one is faced with a problem of overloading. What should be done then? The Hartford Hospital was prepared, had plenty of room and was not overloaded. The Massachusetts General Hospital two years ago was not overloaded. The Boston City Hospital two years ago came very close to being overloaded. One hospital in Hartford, in my humble opinion, was overloaded at the Hartford disaster—both in the number of patients and in the severity of the cases. A 170-bed hospital received 100 patients. Fortunately there were 100 vacant beds. The hospital had one intern, it had a part-time staff, the staff rallied around, and they went to work.

If a patient with a fractured skull, injured in the woods of northern New Hampshire, can be safely sent to Boston, it seems sensible for burn patients to be shipped promptly away from a hospital that has its load, and only after all other hospitals in the area have been put in the same position of load—should any further patients go to that hospital. This is a hard thing to do. There is a disaster and everything is in confusion, but the staff of a hospital should put a responsible person on the street, who, when the conditions reach a certain point, should see that incoming patients go somewhere else. Patients were transferred from this hospital to

the Hartford Hospital later, and that corrected some of this overloading.

DR. OLIVER COPE, Boston: I, too, had the opportunity of going several times to Hartford and to the Hartford Hospital. I cannot overemphasize the intelligent care given by the hospital staff. It was one of those fortunate eccentricities of Fate that the circus fire should have occurred so near a hospital so well prepared.

I wish that at least part of the instructions to interns that had been drawn up by the Hartford Hospital Burn Committee could be published. There were several things of interest in them, and they were one of the reasons for the prompt, efficient care. For example, there was a description of how to do a femoral-vein puncture; I do not know of such a good, direct, simple account anywhere in the literature.

Leaving the question of management and foresight, there are other things that have emerged from the handling of this disaster by the Hartford Hospital. Doubt has recently been raised concerning the value of plasma in the treatment of the severely burned patient. There have been references to the substitution of sodium lactate solution. Anyone who had the opportunity to follow the detailed laboratory observations carried out almost hourly could have no doubt about the value of plasma in the treatment of burn shock. The data were beautifully arranged chronologically on a laboratory sheet that had been prepared for such a catastrophe.

The importance of plasma and good shock therapy is shown in relation to kidney function and damage. I visited one of the other hospitals that was less fortunately prepared in many ways and reviewed the laboratory data there. This hospital also did an excellent job in gathering information and taking care of the patients once an adequate force had been gathered. But there was a distinct difference; plasma therapy was delayed, and less of it was used. The Hartford Hospital's therapy was prompt and immediate, as it should be, and one had to search among a great number of extensively burned patients for a nonprotein nitrogen level that was above normal. In contrast, where therapy was even only moderately delayed, the rise in nonprotein nitrogen presumably due to impaired blood flow to the kidney, was dramatic. There was a striking difference in the values at the two hospitals.

There are other points, such as the control of sepsis achieved, that deserve mention in the handling of the burned patients at the Hartford Hospital. I hope that the staff will gather its information and publish it, because it will be useful to everyone in the future.

SALICYLISM ACCOMPANIED BY RESPIRATORY ALKALOSIS AND TOXIC ENCEPHALOPATHY*

Report of a Fatal Case

HENRY W. RYDER, M.D.,† MURTON SHAVER, M.D.,‡ AND EUGENE B. FERRIS, JR., M.D.§

CINCINNATI, OHIO

THE purpose of this article is to report a fatal case of salicylism. The case is of special interest for the following reasons: the drug was given in the usual doses, as determined by symptomatic effect; the course of intoxication was directly shown, by studies of the blood acid-base balance, to be a respiratory alkalosis; tetany and electrocardiographic changes were observed; and at autopsy diffuse toxic encephalopathy was found.

The pH, whole-blood carbon dioxide content and hematocrit determinations were made as follows: Ten cubic centimeters of arterial blood was drawn into a dry syringe and immediately expelled into the cup of a Leeds and Northrup glass electrode potentiometer (No. 7661-A1 assembly), and the pH was determined before clotting occurred. The accuracy of this method is considered to be within ± 0.05 pH.

Another 10 cc. of arterial blood was collected under oil in a chilled container with 10 mg. of dry potassium oxalate powder added. The whole-blood carbon dioxide content was directly determined by the manometric procedure of Van Slyke and Neill.¹ The hematocrit was determined in Wintrobe tubes after centrifuging for one hour at 3000 r.p.m. No correction was made for cell shrinkage with the anticoagulant.

CASE REPORT

I. L. (No. 6961), a 16-year-old Negress weighing 80 pounds, had been observed in the Medical Clinic over a period of several years for attacks of pain in the right lower quadrant of the abdomen. On admission to the hospital on October 18, 1940, the symptoms and physical signs of acute rheumatic fever with pancarditis were present. Briefly, the point of maximal impulse was in the 5th interspace in the anterior axillary line. A booming mitral first sound with a blowing systolic murmur and a rumbling diastolic apical bruit were heard. At the base pulmonic second sound was accentuated and palpable. A friction rub was heard over the 3rd left interspace. A high-pitched early diastolic blow was heard along the left sternal border. The lungs were clear. There was no pulsus paradoxus or peripheral signs of aortic insufficiency. No signs of chorea could be elicited. The reflexes were active without clonus.

The red-cell count was 5,940,000 and the hemoglobin 15.4 gm. per 100 cc. The white-cell count was 15,700, with 75 per cent neutrophils, 11 per cent lymphocytes, 13 per cent monocytes and 1 per cent eosinophils. The platelets appeared normal in number. The erythrocyte sedimentation rate was 11 mm. per hour, and a blood Kahn test was negative. The

urine had a pH of 5.5 and a specific gravity of 1.010; it contained no albumin or acetone; microscopic examination was negative except for an occasional leukocyte. The stool was normal in appearance and negative for occult blood. The electrocardiogram showed a PR interval of 0.20 second and a heart rate of 120 per minute; there was no axis deviation or elevation of the ST segments.

Treatment consisted of bed rest, a soft diet and the administration of 1.3 gm. of sodium salicylate every 3 hours. After a total of 15 gm. had been given, the patient complained of ringing in the ears and nausea with emesis. Fifteen hours later, sodium salicylate was resumed in doses of 1 gm. every 4 hours. During this period — the 4th and 5th hospital days — the fever, pericardial friction rub and all subjective manifestations of the disease disappeared. The blood pressure was 100/60, and two white-cell counts were 8900 and 5250.

On the 6th hospital day, after a total of 26 gm. of sodium salicylate, or 0.7 gm. per kilogram, had been administered, the respirations were noted to be rapid and slightly labored. At noon, the salicylate medication was discontinued because of vomiting. The respirations soon became deep and labored. The patient was restless and tossed about the bed. The muscles were spastic and the reflexes hyperactive with sustained ankle clonus, and positive Trousseau and Chvostek signs appeared. The red-cell count was 5,520,000 and the hemoglobin 13.0 gm. The white-cell count was 6400, the hematocrit 36.5 per cent, the formol-gel test positive, and the sedimentation rate 43 mm. per hour. A specimen of catheterized urine was strongly alkaline, with no albumin, sugar, acetone or blood (benzidine test). The centrifuged specimen showed 10 white cells per high-power field and no red cells or casts. The blood urea nitrogen was 21 mg. per 100 cc. and the carbon dioxide combining power 13.0 millimols per liter (29.0 vol. per cent). At 4 p.m., 4 gm. of sodium bicarbonate was administered by mouth. By 5 p.m., the patient was unresponsive except to painful stimuli. She remained stuporous and continued to hyperventilate throughout the night.

On the 7th day, a lumbar puncture showed an initial pressure equivalent to 220 mm. of water, which fell to 150 mm. on removal of 12 cc. of clear fluid. The fluid contained 13 red cells per cubic millimeter. No leukocytes were seen. A Pandy test was negative. At that time the serum calcium was 10 mg. per 100 cc. and the inorganic phosphorus 4.2 mg.; the white-cell count was 8850, and the catheterized urine showed a pH of over 7.5. One hour after the lumbar puncture the pH of the arterial blood was 7.58, the carbon dioxide content of the whole blood 7.3 millimols per liter (16.4 vol. per cent), and the hematocrit 27 per cent. Three hours later the carbon dioxide content of the whole arterial blood was 6.7 millimols per liter (15.0 vol. per cent). From 1 to 10 p.m. the patient was given 2500 cc. of fluid intravenously containing approximately 25 gm. of sodium chloride, and at 10 p.m. was deeply stuporous. The pH of the urine was 5.5. Respirations were still rapid but shallower than before. The Trousseau and Chvostek signs were negative. Occasional twitches of various muscle groups were noted. The patient was put in a tent supplied with 95 per cent oxygen and 5 per cent carbon dioxide, where she remained until her death. During the night, in the next 7 hours, she was given a total of 0.20 gm. of morphine sulfate with the intent of depressing the respirations without apparent effect. She was incontinent of large volumes of acid urine.

On the 8th day, the pH of the arterial blood was 7.39, the carbon dioxide content of the whole blood 11.8 millimols per liter (26.4 vol. per cent), and the hematocrit 25.4 per cent. There were rales at the bases of both lungs, and much frothy material was aspirated from the throat. The white-cell count rose to 15,750, and the temperature gradually increased (Fig. 1). Culture of a throat swab showed no pneumococci. Sixteen hundred cubic centimeters of 5 per cent glucose

in normal saline solution and containing 2.5 gm. of sodium sulfapyridine was administered intravenously. Twelve hours later, or 66 hours after the hyperventilation was first noted, the pulse became gradually more rapid and feeble and respirations ceased.

The time relations of significant data are shown in Figure 1.

Autopsy. Autopsy was performed 6 hours post mortem. There was gross and microscopic evidence of active rheumatic heart disease with pancarditis, and aortic and mitral valvulitis with mitral stenosis. There was chronic passive congestion of the liver and spleen and toxic changes in all the viscera. The left kidney was absent.

The gross changes encountered in the examination of the brain were confined to patchy subarachnoid effusions of blood, with small perivascular hemorrhages in the region of the 3rd ventricle and occasionally in the inferior portions of the basal

around blood vessels in the distended perivascular spaces. The large nerve cells were markedly diminished in the globus pallidus, and a scattered gliosis was observed throughout the basal ganglions, under the ependyma of the lateral and 3rd ventricles and in patchy areas in the deeper cortex.

No organisms were observed with the bacterial stains.

The anatomical diagnoses were as follows: active rheumatic myocarditis; aortic and mitral valvulitis; pericarditis; mitral stenosis; and nonspecific toxic encephalopathy.

COMMENT

Quincke² in 1882 reviewed the fatal cases of salicylate poisoning following its introduction into medi-

FIGURE 1. Time Relations of Significant Data.

ganglions. Congestion was observed throughout the basal ganglions, substantia nigra and pons and in the floor of the 4th ventricle.

Microscopic examination revealed a generalized swelling and slight chromatolysis of all the nerve cells in the cortex, basal ganglions and brain stem, associated with areas of severe nerve-cell degeneration, scattered particularly in the pyramidal layers of the cortex, basal ganglions and substantia nigra, and to a lesser degree in the nuclear masses of the brain stem. Small perivascular areas of early rarefaction were observed in the deeper layers of the cortex and in the basal ganglions. Hemorrhage and nerve-cell degeneration were most marked in the paraventricular nuclei and in the region of the 3rd ventricle. Many small vessels there and in the cortex contained hyaline thrombi, and in patchy areas in this region, as well as in the basal ganglions and brain stem, the capillaries exhibited moderate endothelial hyperplasia and were generally increased in numbers. The microglia was also increased in many of these areas, and the oligodendroglial cells were swollen throughout and markedly increased in the subcortical white matter and internal capsule. Satellitosis was marked in some areas of the cortex and basal ganglions, with aggregations of these cells

cine a few years before. He believed that dyspnea was characteristic of intoxication and that it was central in origin, because of the autopsy finding of cerebral congestion in his single fatal case. Hurler and Trevan³ in 1916 showed that decerebrate cats with the corpora quadrigemina intact hyperventilated on injection of 0.2 gm. of sodium salicylate per kilogram, whereas if the section was made below the corpora quadrigemina, the response to injection was apnea, followed by resumption of the normal respiratory rate. Veil and Graubner⁴ in 1926 showed that the drug had a uniform central stimulating effect in normal subjects, since all persons showed lowering of the alveolar carbon dioxide tension, increase in the pH of the urine and lowering of the urinary ammonia excretion. Gebert⁵ in 1931 confirmed these results in a similar fashion, noting in

addition the increased calculated pH of the arterial blood, even though there was no detectable clinical change in the breathing with the given doses of 5 to 6 gm. Odin⁶ and Dodd, Minot and Arena⁷ gave excellent discussions of the problem and made similar observations. They each reported several cases of clinical intoxication, although these cases do not conclusively demonstrate the presence of a respiratory alkalosis because of secondary compensatory factors. We have found no complete reports of the course of the acid-base changes in poisoned patients, but Guest and Rapoport³ have noted an increase

The magnitude of these changes resulting from hyperventilation is striking, since the literature reveals no such low values attributable to a primary respiratory alkalosis. Equivalent changes in the carbon dioxide tension have, however, frequently been recorded in salicylate intoxication. In this case, partial correction of the abnormal acid-base balance following administration of saline solution and a return of the blood pH to normal value were not associated with any detectable improvement in the clinical condition.

In view of the finding at autopsy of a diffuse toxic encephalopathy, it appears that the hyperventilation, which was central in origin, and death were related to the encephalopathy. Whether this encephalopathy was caused by the toxic effects of salicylate or by the rheumatic process itself cannot be directly proved, but there is considerable evidence that salicylism was the cause of the acute changes. The onset of the fatal symptoms occurred following the administration of rather large doses of salicylate and during a period when the rheumatic manifestations had completely subsided. Although the dose of salicylate was within the usual therapeutic range, it was definitely above the mean toxic dose for women, according to Hanzlik.⁹ Toxic and fatal manifestations with both larger and smaller doses than were given this patient have been described.^{5, 10} Furthermore, this patient exhibited the classic symptoms of salicylate intoxication, namely, severe hyperpnea and a low carbon dioxide tension of the blood; also, the brain changes in this case are similar to those of the few autopsied cases reported in the literature.¹¹ Since the patient was suffering from subsiding rheumatic fever, it is, of course, possible that the encephalopathy was a part of the rheumatic process. This was the interpretation of Dobbs and de Saram¹² in their report of a patient who followed a very similar course. The encephalopathy of rheumatic fever has recently been studied by Winkelman and Eckel¹³ and by Alpers.¹⁴ Pathologic changes in the brain of the type seen here were reported in 1922 in a case of rheumatic fever by Greenfield and Wolfsohn,¹⁵ who briefly discussed the literature up to that time. Hyperpnea was extreme in their case, but they do not state whether the patient was receiving salicylate.

Apparently the differential diagnosis of chorea, rheumatic encephalopathy and salicylate encephalopathy cannot be made through a morphologic investigation. In this case, however, the time relations of the course of the acute rheumatic fever and the salicylate therapy, the clinical rarity of severe encephalopathy as a complication of acute rheumatic fever and its apparent — although largely unrecognized — frequency as the end stage of salicylate intoxication all strongly suggest that salicylate intoxication was the cause of the fatal encephalopathy. Tetany developing in the course of salicylism has also been observed in 2 cases by Bergmark in his discussion of Odin's⁶ paper.

FIGURE 2. Acid-Base Balance Plotted on Trilinear Co-ordinates (after Shock and Hastings²⁰).

The values for pCO_2 (carbon dioxide tension) and $[HCO_3^-]$ (serum base bicarbonate) at points (1) and (3) were calculated from the pH and carbon dioxide content of the whole blood and hematocrit by the Shock and Hastings nomogram.²¹ Point (2) was approximated from the assumption that the observed decrease in carbon dioxide content of the whole blood was associated with a slight fall in pCO_2 . The normal values given are those of Shock and Hastings²² and agree with our experience. The line marked "CO₂ absorption curve of whole blood" was approximated from the data of Van Slyke, Wu and McLean²³ on oxygenated horse blood with approximately the same HbO₂ (13.4 vol. per cent) as that of the patient (14.9 vol. per cent).

in the pH of the venous blood of patients suffering from salicylate intoxication and have since found a similar rise as the result of controlled salicylate administration.

In the present case, the direction of the changes in the pH of the arterial blood and the carbon dioxide tension, together with the changes in urinary pH, indicate a primary respiratory alkalosis (Fig. 2).

FIGURE 2. Acid-Base Balance Plotted on Trilinear Co-ordinates (after Shock and Hastings²⁰).

The values for $p\text{CO}_2$ (carbon dioxide tension) and $[\text{BHCO}_3]$ (serum base bicarbonate) at points (1) and (3) were calculated from the pH and carbon dioxide content of the whole blood and hematocrit by the Shock and Hastings nomogram.²¹ Point (2) was approximated from the assumption that the observed decrease in carbon dioxide content of the whole blood was associated with a slight fall in $p\text{CO}_2$. The normal values given are those of Shock and Hastings²² and agree with our experience. The line marked "CO₂ absorption curve of whole blood" was approximated from the data of Van Slyke, Wu and McLean²³ on oxygenated horse blood with approximately the same HbO₂ (13.4 vol. per cent) as that of the patient (14.9 vol. per cent).

in the pH of the venous blood of patients suffering from salicylate intoxication and have since found a similar rise as the result of controlled salicylate administration.

In the present case, the direction of the changes in the pH of the arterial blood and the carbon dioxide tension, together with the changes in urinary pH, indicate a primary respiratory alkalosis (Fig. 2).

Of further interest are the changes in the Q-T interval in the electrocardiogram (Fig. 3). The interval became prolonged to the upper limits of normal when tetany was present and the pH of the blood was high, but returned to its original average normal value during the period of compensation when tetany had disappeared and the pH had fallen to within normal limits.¹⁶ Such changes in the Q-T interval in the absence of marked myocardial failure have usually been found in disorders associated with hypocalcemia and with respiratory and metabolic

effect of salicylate in any form is central respiratory stimulation. Partial correction of the acid-base balance caused no detectable improvement in the clinical condition.

Secondary manifestations of primary respiratory alkalosis — that is, tetany, prolongation of the Q-T interval and flattening of the T waves in the electrocardiogram, the secretion of alkaline urine during the development of the alkalosis and acid urine during its regression, and compensatory reduction of fixed base with lowering of the alkaline reserve — are recorded.

FIGURE 3. Serial Electrocardiogram Showing the Changes in the Q-T Interval during the Alkalosis (fifth hospital day).

Lead 1 is reproduced and not Lead 2, as suggested by Shipley and Hallaran,²⁴ because T₂ was isoelectric on the fifth hospital day; K is Bazett's cardiac index.²⁵

alkalosis.¹⁷⁻¹⁹ The serum calcium in this case was normal. Barker, Shrader and Ronzoni¹⁹ noted flattening of the T waves in respiratory and metabolic alkalosis, a finding also present in this case.

The findings in this case, together with the literature cited, do not support the widely held belief that salicylate intoxication is an acidosis.

SUMMARY

A fatal case is recorded in which a primary respiratory alkalosis of extreme degree was conclusively demonstrated following salicylate administration.

The finding is in accord with acceptable data in the literature that indicate that the usual toxic

At autopsy a severe diffuse encephalopathy of the toxic type was found and described in detail.

The relative importance of the salicylate therapy and the acute rheumatic fever in the development of the encephalopathy is discussed.

MEDICAL PROGRESS

ENDOSCOPY (Concluded)*

EDWARD B. BENEDICT, M.D.†

BOSTON

ESOPHAGOSCOPY

Benign Tumor

Harrington and Moersch²⁴ regard benign tumors of the esophagus as potentially malignant, and point out that extensive operative procedures may be required for their removal. They are divided into two main groups: mucosal and extramucosal tumors. The mucosal tumors are often pedunculated and arise from the submucosa. They are usually fibrolipomas or fibromyxomas and are covered by normal epithelium of the esophagus. The extramucosal or intramural tumors arise from the muscle of the wall of the esophagus; they do not involve the mucosa and are usually leiomyomas. The growth of benign tumors of the esophagus is slow, and they may attain considerable size without giving rise to subjective symptoms. This is particularly true of the intramural tumors, which rarely produce obstruction of the esophagus unless they attain great size. The symptoms generally associated with these growths are dysphagia, substernal pain, regurgitation of food, cough and dyspnea. Pedunculated tumors are usually associated with obstructive symptoms, and the diagnosis of these growths is often definitely established by regurgitation of the tumor into the mouth, which may be the first subjective symptom. Regurgitation of these growths into the nasopharynx can imperil life owing to blocking of the trachea, which may result in strangulation. The roentgenographic and roent-

genoscopic examination of the esophagus is of great value in determining the presence of these growths. Esophagoscopy is of the utmost importance in establishing a definite diagnosis, although at times it may be difficult to determine the site of origin as well as the type of growth because of the difficulty in obtaining a specimen for biopsy through the normal esophageal mucosa. The site of origin of the pedunculated tumors can usually be definitely determined. The indications for surgical treatment of benign tumors are not so urgent or so imperative as those for malignant lesions of the esophagus. They depend somewhat on the patient's general condition, the amount of difficulty the tumor is causing and the site of the tumor. Inasmuch as such growths may undergo malignant change, these authors state that surgical treatment should be considered in all cases.

Carcinoma

Bersack³⁵ has reported a case of carcinoma of the esophagus in association with achalasia of the cardia. He is of the opinion that unless careful and repeated esophagoscopies are resorted to, carcinoma is rarely detected early in patients suffering from achalasia. No sharp change in the symptoms marks the appearance of carcinoma, especially when it is located high in the esophagus. This is so mainly because there is no interference with the passage of food. Even at the late stage at which cancer was detected in Bersack's case, no obstruction to the passage of the esophagoscope was encountered. Furthermore, small irregularities and

†Instructor in surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital.

filling defects in the dilated esophagus are often caused by, and are readily attributed to, retained secretion and food particles. In the case that Bersack reports the patient had suffered from a stricture of the cardiac end of the esophagus for ten years. The history revealed that she had been treated with dilatation, which had improved her condition for about five years. For the last four years, the patient regurgitated part of the food and found that food got stuck in the "pit of the stomach." The general condition was fair, and no anemia was present. The roentgenologic examination revealed a carcinoma in the middle of the esophagus and achalasia. The author stresses the fact that this was the first case among 227 cases of carcinoma of the esophagus that was preceded by achalasia. Since both conditions have a similar history, the author emphasizes the importance of an extremely careful examination.

In discussing carcinoma of the esophagus, Bird³⁶ stresses the importance of doing both esophagoscopy and bronchoscopy preoperatively, the object of the bronchoscopy being to demonstrate whether the lesion has extended into the trachea or left main bronchus in which case the lesion is definitely inoperable. Strieder³⁷ and Garlock²⁶ agree that preoperative bronchoscopy is of great importance in determining the operability of carcinoma of the esophagus.

Benign Stricture

The management of benign stricture of the esophagus is a delicate problem. The dangers of blind bouginage cannot be too frequently emphasized. Eloesser³⁸ recalls the case of a benign lye stricture of the esophagus treated by blind bouginage by a local physician. The sound was apparently passed effectually, but still no food got into the stomach through the esophagus. The bouginage had been done some months previously without any obvious deleterious effects. When Eloesser opened the abdomen he found that the sound had been forced down retroperitoneally as far as the sacrum. On opening the chest, he of course found a fistula. Proceeding from there he was able to get a large bougie up into the mouth, and a large bougie was then introduced into the stomach from the upper esophageal segment.

Adams and Hoover³⁹ state that as a sequel to the treatment of carcinoma of the stomach by total gastrectomy and esophagojejunostomy in 68 patients, 6 of them developed a partial stricture at the anastomosis within a few weeks or months after the operation. All responded to repeated dilatations using a swallowed thread as a guide. The technic of successfully traversing a complete occlusion 2 cm. in length of the midthoracic esophagus by combined peroral esophagoscopy, retrograde esophagoscopy and mediastinotomy is described.

Cardiospasm

According to Adams and Hoover³⁹ rapid dilatation with a modified Plummer bag in 2 cases of cardiospasm led to suppurative mediastinitis that required prompt surgical drainage. Both patients recovered. The authors were convinced that such rapid dilatation was too dangerous for further use. Henceforth, they intend to follow their former policy of gradual dilatation, accepting the inconveniences of slow dilatation and the time required rather than risking esophageal rupture. Leakage occurred in one case under general anesthesia, which was given at the insistence of an extremely nervous and temperamental patient. In addition, too great pressure was used. This complication must be classified as secondary to an error in judgment, since the pain reflex should be preserved as a safeguard during esophageal dilatation for cardiospasm.

Another complication of cardiospasm has been discussed by Gray and Jankelson⁴⁰ namely, inhalation pneumonitis resulting from overflow of food or secretions from the esophagus into the trachea. This pneumonitis may be either of the recurrent acute type or of the chronic type with acute exacerbations. The alleviation of the cardiospasm by bouginage improves the general condition and contributes to the cure of the pneumonic process. It is recommended that the esophagus be investigated routinely in all cases of etiologically obscure chronic pneumonitis or recurrent acute pneumonia.

Garlock²⁶ emphasizes the importance of esophagoscopy in cardiospasm. The finding of a smooth conical obstruction at the lower end of the esophagus in the x-ray picture does not necessarily indicate a benign cardiospasm. Esophagoscopy must be carried out. Negative esophagoscopy findings do not exclude completely the presence of a cardiac carcinoma. Repeated endoscopic examinations are indicated if the symptoms persist. No patient should be subjected to operation unless the biopsy specimen obtained by esophagoscopy shows carcinoma. It must be emphasized that the care of a patient with cancer of the esophagus is a co-operative problem requiring the concerted efforts of the roentgenologist, esophagoscopist, anesthetist, operating room staff, bedside nurses, physician and surgeon. Even under the most ideal conditions, the operative mortality is relatively high if the surgeon does not practice careful selection of his operative material.

In discussing the respiratory complication of achalasia of the cardia (cardiospasm) with megaesophagus, Hurst⁴¹ states that it is not generally recognized that symptoms may arise from pressure by the distended esophagus or from aspiration of regurgitated food. In 1 case reported, sudden death occurred from asphyxia.

Hysterical Dysphagia

Gaarde and Olsen⁴² have classified the causes of dysphagia in the upper part of the esophagus. In discussing functional conditions, they distinguish between hysterical dysphagia and functional dysphagia. They regard hysterical dysphagia as a well-defined clinical syndrome that affects elderly women with anemia and is usually accompanied by loss of weight and nutritional deficiency. It is ordinarily referred to as the Plummer-Vinson syndrome. The cricopharyngeus muscle fails to relax and allow passage of food. An esophageal web frequently occurs just below the level of the cricopharyngeus muscle. This web consists of fibrous strands that traverse the esophageal lumen. Whether iron-deficiency anemia or psychic trauma is the antecedent factor in these cases is difficult to determine. The dramatic relief of dysphagia produced by the passage of an esophagoscope or dilating sound suggests that a cure is effected by release of cricopharyngeal spasm, dilatation of any organic stenosis present and the restoration of the patient's confidence in his ability to swallow. The subsequent administration of iron and vitamins should result in permanent relief of symptoms. Attention is called to the frequency with which carcinoma develops at the esophageal introitus in cases of the Plummer-Vinson syndrome.

Functional Dysphagia

Functional dysphagia, on the other hand, according to Gaarde and Olsen⁴² is less clear cut than is the Plummer-Vinson syndrome. Emotionally unstable patients of either sex are likely to complain of difficulty in swallowing. Fear of choking is often the most prominent symptom, and these patients may have equal difficulty in swallowing liquid and solid foods. The diagnosis of functional dysphagia may be dangerous. When dysphagia referable to the hypopharynx or upper part of the esophagus affects a psychoneurotic patient, it is a general practice to make a diagnosis of functional dysphagia. Unless esophagoscopic examination is carried out, errors in diagnosis may readily occur. Organic lesions of the upper part of the esophagus may be confused with functional dysphagia.

Myasthenia Gravis

Blalock,⁴³ in a discussion of thymectomy in the treatment of myasthenia gravis, states that 14 of 20 patients studied complained of difficulty in swallowing. This disease must therefore be considered in patients with dysphagia. Other more frequent causes of dysphagia must be excluded by x-ray and esophagoscopy. The neostigmines (Prostigmin) test is helpful in the diagnosis. The pre-operative neostigmine requirements of these patients varied from 75 to 910 mg. daily. Death in 1 case following thymectomy was due to atelectasis and respiratory failure. In this case Blalock be-

lieves that bronchoscopy and aspiration were definitely indicated. In summarizing the results of thymectomy, performed on 20 patients with severe myasthenia gravis during the last three years, Blalock states that a benign thymic tumor was found in only 2. Four of the patients have died since operation, 3 of the deaths occurring in the early postoperative period. Of the 16 remaining patients, 3 are essentially well, 5 are considered improved, 5 are moderately improved, and 3 have shown little if any improvement. All the 16 surviving patients expressed the opinion that the operation had been helpful.

Peptic Ulcer of the Esophagus

It has been noted by Adams and Hoover³⁹ that a large percentage of patients with peptic ulcer of the lower end of the esophagus have a short esophagus and a small diaphragmatic hernia.

Lust and Peskin⁴⁴ have studied the roentgenologic diagnosis of peptic ulcer of the esophagus, stating that without doubt diagnoses are most accurate when made by direct visualization of the process. Esophagoscopy, however, is a procedure that causes great discomfort, and it should be performed only by those skilled in its technic. Lust and Peskin believe that careful roentgenologic examination can demonstrate the lesion with sufficient accuracy. I take exception to this statement, believing that in any case of narrowing or ulceration of the esophagus, esophagoscopy and biopsy must be performed to exclude carcinoma; esophagoscopy and bouginage may also be necessary for therapeutic purposes. In skilled hands, with a reasonably co-operative patient, the procedure is not one of great discomfort.

Experimental Peptic Ulcer of Esophagus

Brown⁴⁵ fed white rats a long-continued, vitamin-deficient, rice diet and noted frequent lesions of the esophagus consisting of focal ulcerations of the mucosa, with penetrating inflammation, mucosal hyperkeratosis, edema of the submucosa, atrophy and fibrosis of the muscularis and dilatation of the organ. After the administration of synthetic vitamins, the rats gained in weight, the ulcers largely healed and the autopsied animals showed practically no lesions in the internal viscera. The authors concluded that the lesions noted in these animals appeared to be of dietary origin.

Spontaneous Rupture of Esophagus

Collis, Humphreys and Bond⁴⁶ report the spontaneous rupture of the esophagus after a heavy meal occurring in a man forty-one years of age with a previous history of dyspepsia. This condition should be kept in mind when doubt is felt about the diagnosis of perforated peptic ulcer. Deep emphysema in the neck is an important physical sign. Suturing

of the tear in the esophagus, combined with drainage of the pleural cavity on the affected side, offers the best chance of recovery.

GASTROSCOPY

Instruments

Hardt⁴⁷ has described a new flexi-rigid gastro-scope consisting of two parts, a flexible sheath and a removable interior consisting of a rigid optical system comprised of approximately twenty-five optical elements. The optical system is inserted into the sheath when the latter is in place in the stomach. Hardt claims that the advantages of this gastroscope are an increased angle of visualization, a larger image, diminution in the blind-spot areas, a better view of the antrum and less gagging by the patient.

Equen⁴⁸ describes a new magnet for removing foreign bodies in the food and air passages. The magnet is made of cast Alnico and is attached to a Levine tube, through which a metal stilet has been inserted to increase the motility of the tube. The other end of the Levine tube is attached to a rubber bulb, this apparatus being used for inflating the stomach. In the case reported, a bobby pin was successfully removed from the stomach of a nineteen-month-old baby under fluoroscopic visualization. The entire procedure lasted only eight minutes.

The whole foreign-body problem would be greatly simplified if patients vomit foreign bodies as easily as occurred in the case reported by Benedict.⁴⁹ In this very exceptional case, a three-year-old child swallowed an open safety pin a few minutes before entering the Emergency Ward. A few hours later, the patient vomited and the pin was recovered. It measured 2.7 cm. in length. The reason it was vomited so readily was that the point was bent toward the keeper.

Gastritis

Renshaw⁵⁰ believes that the principal value of gastroscopy lies in the diagnosis of gastritis. With rare exceptions gastroscopy is the only clinical means for establishing this diagnosis. Although the true significance of the mucosal changes noted gastroscopically has not been definitely settled, chronic gastritis undoubtedly is a definite entity, which at times produces severe symptoms. A small percentage of cases of unexplained massive hemorrhage from the upper gastrointestinal tract have been shown to be due to chronic gastritis. Renshaw quotes Bockus as stating that unquestionably the flexible gastroscope is opening up new diagnostic channels.

Benedict⁵¹ has written a review of gastroscopy. He concludes that gastroscopy with the flexible gastroscope is an easy and safe procedure, the value of which cannot be doubted. Attention is called to the omni-angle feature and the controllable

flexibility of certain instruments. The simpler technics, including 4 per cent cocaine gargle and small pillows for head support, are preferred to more complicated methods. The indications for gastroscopy are outlined. He states that no stomach that is producing symptoms should be considered normal without gastroscopic study and that the significance of hemorrhage in gastritis has been demonstrated by gastroscopy. Gastroscopic and pathologic findings in gastritis are correlated. The usefulness of gastroscopy in cases of gastritis, ulcer and tumor is critically considered.

Meyer and Steigmann⁵² have discussed the surgical treatment of corrosive gastritis. They state that dysphagia appears oftener and sooner after the ingestion of an alkaline corrosive (lye) than after that of an acid. In fact, in most cases of corrosive gastritis due to an acid, the patients presented themselves not because of dysphagia but because of symptoms of gastric obstruction. Corrosive gastritis may be confused with gastric carcinoma, not only because of the suggestive appearance of the x-ray films but also because of symptoms of continuing vomiting, marked weight loss and achlorhydria. The importance of differentiating the two conditions is obvious from the point of view of treatment, as well as from the point of view of prognosis. Gastroenterostomy may be done rather than resection inasmuch as the dangers of gastrojejunostomy are minimal, since in these stomachs there is no free acidity.

In a study of peptic ulcer, gastritis and psychoneurosis among naval personnel suffering from dyspepsia, Montgomery, Schindler, Underdahl, Butt and Walters⁵³ studied 45 unselected patients, finding 23 cases of duodenal ulcer and 22 cases showing no ulcer. In 11 of the latter the gastric mucosa proved to be entirely normal gastroscopically, but in the remaining 11 cases there were varying degrees of hypertrophic, superficial and atrophic gastritis. In 11 cases, there was a definite psychoneurosis of the anxiety and mixed types sufficiently severe to necessitate discharge from the service. In summarizing the differential diagnoses in this group, it is interesting that among these 22 cases there were 11 in which the diagnosis was made by psychiatric approach. In the other 2 neither psychiatric, gastroscopic nor any other study afforded a satisfactory diagnosis.

In a comparison of the radiologic and gastroscopic findings in 200 dyspeptic soldiers, Guyer⁵⁴ states that the reason for the discrepancies between them is not difficult to determine. The radiologist examines the stomach as a whole, his diagnosis resting on the estimation of function, with an examination of the coarser anatomic details. The gastroscopist, on the other hand, is in a position to examine closely the changes in the mucous membrane, seeing the early inflammatory changes that may be taking place, as well as ascertaining the

more obvious organic lesions, such as ulceration and malignant change. In the study of the duodenum, radiology so far stands supreme, and any changes seen in the stomach by the gastroscopist are merely corroborative and not diagnostic, since the duodenum is at present inaccessible to him. In cases in which radiology has failed to elicit any cause in a complaint of a dyspeptic nature, gastroscopy is of great assistance, mainly in the diagnosis of gastritis, since in this disease the gastroscopic findings are considerably more helpful than is radiology. Two other types of case offer considerable scope for the combination of the two methods of examination, — cases of healed or healing gastric ulcer, which has passed beyond the stage where it was possible to demonstrate it radiologically, and cases in which there is a question of early malignant disease but in which the organic changes are sufficiently marked to allow radiologic demonstration. Gastroscopy in the armed services has obvious limitations. It is considered of use in patients constantly reporting sick with dyspeptic symptoms when all other forms of investigation have been negative. The demonstration of gastritis in a case of this type is important to facilitate the patient's treatment or disposal. Two hundred cases of dyspepsia in serving soldiers were examined radiologically and gastroscopically. Both types of diagnoses are discussed separately, and the combined findings of the two methods are analyzed. The conclusions reached are that the two investigations are complementary to each other, but that in the study of gastritis, gastroscopy gives more valuable information than can be obtained by radiology.

Scheff, Horner and Kenamore⁵⁵ believe the incidence of gastritis in patients with duodenal ulcer, as determined by gastroscopic examination, is higher when the ulcer is complicated by pyloric obstruction. Eighty-six per cent of patients with duodenal ulcer and obstruction showed the mucosal changes of superficial gastritis, whereas 62 per cent of the nonobstructed group gave similar findings. Severe gastritis was found six times more frequently in the stasis group. It appears that retention of gastric contents is associated with inflammatory changes in the gastric mucosa.

Warren and Meissner⁵⁶ are of the opinion that in the severe stages of chronic gastritis the epithelium assumes alterations that are entirely comparable to well-recognized premalignant lesions in the cervix, breast and skin. The most important of these changes are the presence of atypical cells and atypical glands and increased mitotic activity. Only the severe stage of chronic gastritis with these marked epithelial alterations shows the necessary criteria for premalignancy; the mere presence of mucosal infiltration by inflammatory cells and of slight alterations of the epithelium is not sufficient. These authors conclude as follows: chronic gastritis is a

labile condition that may regress and that need not necessarily progress; not all stages or types of chronic gastritis can be considered to be precancerous: the histologic changes in chronic gastritis should be divided into exudative and epithelial, the former having no direct significance as a precancerous lesion; when epithelial changes become severe, they may be comparable to well-recognized premalignant lesions elsewhere in the body; and since one stage of chronic gastritis meets the necessary criteria for a precancerous lesion, it may be assumed that some gastric cancers arise on this basis.

Gastric Ulcer

In discussing the treatment of gastric ulcer, Counseller, Waugh and Clagett⁵⁷ note that they are operating more frequently on gastric ulcer than formerly. The lesions that are not immediately treated surgically are treated medically in the hospital. If the ulcer becomes smaller or disappears, as determined roentgenologically and by gastroscopic examinations, and if occult blood disappears from the stools, medical management is continued. Periodic examinations are strongly advised. When this type of response is not obtained by medical treatment, patients are advised to have surgical treatment at once.

Carcinoma

As regards carcinoma, Counseller, Waugh and Clagett⁵⁷ believe that the general trend of medicine is toward a more and more complete examination, and since early carcinoma can be visualized either at the time of roentgen-ray examination or through the gastroscope or both, it is probable that the more frequent use of these procedures in the future will increase the operability rate of carcinoma of the stomach.

Palmer and Humphreys⁵⁸ discuss 4 cases of peptic ulcer and healing in gastric carcinoma. In all of them, the duration and history were compatible with primary ulcerating neoplasm and gastroscopic evidence of neoplastic infiltration was found at the first examination. In discussing these cases Fitzgibbon reported the case of a penetrating ulcer crater that filled in gastroscopically after eight months of treatment so that the bottom could not be seen. At the end of three and a half months, the lesion was completely covered by mucosa. Surgery had been advised but refused. A few months later, symptoms recurred. Gastroscopy and x-ray examination both showed carcinoma, but the lesion was inoperable, since liver metastases were present.

Lymphosarcoma

Paul and Parkin⁵⁹ made gastroscopic observations on a patient with lymphosarcoma of the stomach. From the standpoint of visualization of the lesion with the gastroscope, they do not believe

of the tear in the esophagus, combined with drainage of the pleural cavity on the affected side, offers the best chance of recovery.

GASTROSCOPY

Instruments

Hardt⁴⁷ has described a new flexi-rigid gastro-scope consisting of two parts, a flexible sheath and a removable interior consisting of a rigid optical system comprised of approximately twenty-five optical elements. The optical system is inserted into the sheath when the latter is in place in the stomach. Hardt claims that the advantages of this gastroscope are an increased angle of visualization, a larger image, diminution in the blind-spot areas, a better view of the antrum and less gagging by the patient.

Equen⁴⁸ describes a new magnet for removing foreign bodies in the food and air passages. The magnet is made of cast Alnico and is attached to a Levine tube, through which a metal stilet has been inserted to increase the motility of the tube. The other end of the Levine tube is attached to a rubber bulb, this apparatus being used for inflating the stomach. In the case reported, a bobby pin was successfully removed from the stomach of a nineteen-month-old baby under fluoroscopic visualization. The entire procedure lasted only eight minutes.

The whole foreign-body problem would be greatly simplified if patients vomit foreign bodies as easily as occurred in the case reported by Benedict.⁴⁹ In this very exceptional case, a three-year-old child swallowed an open safety pin a few minutes before entering the Emergency Ward. A few hours later, the patient vomited and the pin was recovered. It measured 2.7 cm. in length. The reason it was vomited so readily was that the point was bent toward the keeper.

Gastritis

Renshaw⁵⁰ believes that the principal value of gastroscopy lies in the diagnosis of gastritis. With rare exceptions gastroscopy is the only clinical means for establishing this diagnosis. Although the true significance of the mucosal changes noted gastroscopically has not been definitely settled, chronic gastritis undoubtedly is a definite entity, which at times produces severe symptoms. A small percentage of cases of unexplained massive hemorrhage from the upper gastrointestinal tract have been shown to be due to chronic gastritis. Renshaw quotes Bockus as stating that unquestionably the flexible gastroscope is opening up new diagnostic channels.

Benedict⁵¹ has written a review of gastroscopy. He concludes that gastroscopy with the flexible gastroscope is an easy and safe procedure, the value of which cannot be doubted. Attention is called to the omni-angle feature and the controllable

flexibility of certain instruments. The simpler technics, including 4 per cent cocaine gargle and small pillows for head support, are preferred to more complicated methods. The indications for gastroscopy are outlined. He states that no stomach that is producing symptoms should be considered normal without gastroscopic study and that the significance of hemorrhage in gastritis has been demonstrated by gastroscopy. Gastroscopic and pathologic findings in gastritis are correlated. The usefulness of gastroscopy in cases of gastritis, ulcer and tumor is critically considered.

Meyer and Steigmann⁵² have discussed the surgical treatment of corrosive gastritis. They state that dysphagia appears oftener and sooner after the ingestion of an alkaline corrosive (lye) than after that of an acid. In fact, in most cases of corrosive gastritis due to an acid, the patients presented themselves not because of dysphagia but because of symptoms of gastric obstruction. Corrosive gastritis may be confused with gastric carcinoma, not only because of the suggestive appearance of the x-ray films but also because of symptoms of continuing vomiting, marked weight loss and achlorhydria. The importance of differentiating the two conditions is obvious from the point of view of treatment, as well as from the point of view of prognosis. Gastroenterostomy may be done rather than resection inasmuch as the dangers of gastrojejunostomy are minimal, since in these stomachs there is no free acidity.

In a study of peptic ulcer, gastritis and psychoneurosis among naval personnel suffering from dyspepsia, Montgomery, Schindler, Underdahl, Butt and Walters⁵³ studied 45 unselected patients, finding 23 cases of duodenal ulcer and 22 cases showing no ulcer. In 11 of the latter the gastric mucosa proved to be entirely normal gastroscopically, but in the remaining 11 cases there were varying degrees of hypertrophic, superficial and atrophic gastritis. In 11 cases, there was a definite psychoneurosis of the anxiety and mixed types sufficiently severe to necessitate discharge from the service. In summarizing the differential diagnoses in this group, it is interesting that among these 22 cases there were 11 in which the diagnosis was made by psychiatric approach. In the other 2 neither psychiatric, gastroscopic nor any other study afforded a satisfactory diagnosis.

In a comparison of the radiologic and gastroscopic findings in 200 dyspeptic soldiers, Guyer⁵⁴ states that the reason for the discrepancies between them is not difficult to determine. The radiologist examines the stomach as a whole, his diagnosis resting on the estimation of function, with an examination of the coarser anatomic details. The gastroscopist, on the other hand, is in a position to examine closely the changes in the mucous membrane, seeing the early inflammatory changes that may be taking place, as well as ascertaining the

According to Ruiz, Zamanillo and Salar,⁶⁴ the frequency of primary cancer of the liver without cirrhosis as reported in the literature is 1:1000. Primary cancer of the liver without cirrhosis can be differentiated from either primary cancer of a cirrhotic liver or secondary hepatic cancer by the rapid enlargement of the liver, its firmness, a smooth, hard border on palpation, moderate ascites and the acute course of the disease, which varies between four and five months after the onset of the symptoms. I believe that such a differential diagnosis is not possible on the basis of symptoms or physical signs. Even with peritoneoscopic biopsy, such a diagnosis may be difficult.

Kennaway⁶⁵ has examined the incidence of primary carcinoma of the liver in the Negro in Africa, comparing it with the incidence of the same lesion in the Negro in the United States. He concludes that such data as are available suggest that the high incidence of primary cancer of the liver found among Negroes in Africa does not appear among Negroes in the United States and is therefore not of purely racial character. The prevalence of this form of cancer in Africa may be due to some as yet unidentified extrinsic factor. The statistical evidence concerning this question is confused by the inclusion of cancer of the gall bladder in the same category with cancer of the liver

that there were sufficient features to permit identification of the lesion as a lymphosarcoma. The consensus in current radiologic literature is that there are no positive diagnostic points on roentgen-ray examination.

Gastric Diverticulum

Whitehouse and MacMillan⁶⁰ believe that gastroscopy is helpful in the diagnosis of diverticula of the stomach. They believe that one can evaluate the size of the opening more accurately by means of the gastroscope, since the stomach is inflated and the diverticulum ballooned out. In 2 cases reported, they were able to see the interior of the sac almost completely and considered this of value in ruling out an ulcer or tumor in the diverticulum.

PERITONEOSCOPY

According to Benedict,⁶¹ one of the chief uses of the peritoneoscope is in the diagnosis of liver disease. When one considers that many of these patients are seriously ill and that in most of them an exploratory laparotomy is out of the question, the value of a precise diagnosis by peritoneoscopy is apparent. The cases referred for peritoneoscopy because of liver diseases usually fall into one of the following groups.

Metastatic carcinoma. In this group there is a positive or presumptive clinical diagnosis of carcinoma of the breast, bronchus, esophagus, stomach, pancreas, colon, rectum, prostate or the like, and before planning medical, x-ray or surgical treatment, it may be of great importance to know whether or not there is metastatic disease in the liver.

Hepatomegaly. Is one dealing with metastatic or primary carcinoma, cirrhosis, hepatitis, sarcoma, echinococcal cyst, polycystic liver or some other liver disease?

Ascites. Is this due to cirrhosis, carcinoma or tuberculous peritonitis?

Jaundice. Is the diagnosis toxic cirrhosis, biliary cirrhosis, malignant neoplasm, hepatitis or some other infectious process?

Doubtful clinical findings. What is the precise diagnosis?

In conclusion it is stated that peritoneoscopy is an important and well-established method of examining the peritoneal cavity that is especially applicable to the differential diagnosis of liver disease. With biopsy, a suspected diagnosis is made positive. In a series of peritoneoscopies in 435 patients, the examination was undertaken primarily to study the liver in over two thirds of the cases. One hundred and seventy patients were found to have metastatic carcinoma, 73 had cirrhosis, and the remainder had various diseases, including hepatoma, sarcoma, lymphoma, lymphangioma, Banti's disease, cholangitis, polycystic liver, echinococcal cyst and sarcoid.

Wershub⁶² also finds the peritoneoscope of great value in the diagnosis of liver disease, concluding as follows. The peritoneoscope has specific indications for its use, and is especially applicable to the diagnosis of liver disease. The indications previously expressed are definite and in some cases offer the only means, other than exploratory laparotomy, for diagnosis. The diagnosis of portal cirrhosis, which so frequently cannot be accurately determined clinically, can be made with 100 per cent accuracy by the peritoneoscope. In other hepatic disorders, the endoscopic impression may confirm or establish a diagnosis.

Mensh and Hanno⁶³ have discussed a case of hepatoma of the liver with metastasis to bone occurring in a patient known to have had advanced cirrhosis eight years previously. A number of features in this case are worthy of comment. The absence of abnormalities in a number of tests of liver function and of any of the clinical features generally encountered in cirrhosis at a time when the liver of this patient was frankly cirrhotic is of interest. The patient showed a pathologic urobilinogenuria, a slight hypoproteinemia and some retention of dye with the 5-mg. dose of bromsulfalein. On the other hand, the Takata-Ara and the galactose tolerance tests were negative and there was no dye retention with the 2-mg. dose of bromsulfalein. These findings serve to emphasize the now well-known fact that any given test of liver function may be negative despite the presence of a frankly cirrhotic liver. There are to these authors' knowledge no references in the literature to the length of survival of patients following the demonstration of a frank cirrhosis of the liver in the absence of clinical or laboratory evidences of hepatic decompensation. All the figures usually given for the duration of life in patients with portal cirrhosis are calculated from the time of onset of symptoms or findings to which the hepatic disease has given rise. It is important, however, for it is to be realized that the existence of a cirrhotic liver may well antedate by a considerable number of years the manifestations of clinical portal cirrhosis. The relation between malignant primary tumors, especially hepatoma, and cirrhosis of the liver is striking. According to the consensus of a number of observers, upward of 75 per cent of cases of hepatoma are associated with cirrhosis. Whether an antecedent cirrhosis plays a role in the subsequent development of the carcinoma, as is the belief of most observers, whether cirrhosis follows carcinoma, as Wegelin propounded, or whether the two conditions occur independently cannot, of course, be determined by a single case. This report, however, does emphasize the association of the two conditions, and in this one case, at least, conclusively shows that the cirrhosis preceded the hepatoma by at least several years. The presence of metastasis to bone in cases of hepatoma of the liver is generally considered extremely rare.

The caloric and electrolyte needs could scarcely be met in view of the ileostomy loss, which was enhanced by the obstruction proximal to the stoma. His weight fell 21 pounds in four weeks; he became weaker and his skin lesions became worse. This situation, in addition to the development of bleeding from the ileostomy, presumably due to the repeated catheterization, brought about a decision to operate again to relieve the mechanical obstruction, if possible.

At the second operation, one month after the first, the small bowel was found uniformly dilated with no single obstructive point. There was a twist several centimeters proximal to the stoma but no clear-cut obstruction. The serosa, however, was cyanotic, with dilated, almost "varicose" veins in the mesentery. No obstruction to venous return could be found to explain this. On the serosa were several thin white plaques, where the wall of the bowel seemed extremely thin. No change in the ileostomy was made. His general course was little altered by operation.

Two days later the patient was suddenly seized with a severe midabdominal pain that became generalized; the abdomen was board-like, and he went into shock and died in the course of two hours.

DIFFERENTIAL DIAGNOSIS

DR. HELEN S. PITTMAN: This is a long case, and I do not believe that there should be much discussion about the diagnosis. There may be a few atypical features and a few complicating factors, but by and large this is a classic case of chronic idiopathic ulcerative colitis occurring in a young man with a characteristic unhappy social background, which is important. He had a family situation that was thoroughly bad. The patient was an unhappy spontaneous person who did not make close friendships and was the sort of person in whom ulcerative colitis may develop.

Then we go back in the past history and see that at thirteen, five years before entry, he began to have trouble with the gastrointestinal tract. One year after that, at the age of fourteen, he had an appendectomy. Almost surely he did not have acute appendicitis but, rather, ulcerative colitis. I think that it is usually the patient with regional enteritis, rather than colitis, who comes to the hospital after having had a previous appendectomy, and the patient with ulcerative colitis may come after hemorrhoidectomy, both of which are mistaken diagnoses. But I am quite sure that this operation four years before entry was performed because of symptoms due to ulcerative colitis and that it threw him right over into the frank clinical colitis, because on the day following operation he had twenty-five stools. He went along, probably without anyone really understanding what was going on, for quite a long time. It was not until two and a half years later that he went to a hospital for

treatment, and it was at that time that the diagnosis "colitis with infection" was made. He apparently did well on a low-residue diet. He continued to grow, but it seems to me that a great many of these young people with ulcerative colitis have fairly big frames, so there is nothing too surprising about that. He had lost 11 pounds preceding entry, which in an eighteen-year-old boy is quite a lot.

He had pneumonia at the age of seven years, which I put down as a positive finding but not relevant, any more than the "fits," which may have been due to epilepsy or something entirely different.

On examination he was pale, had skin lesions, a dirty mouth and clubbing of the fingers and toes; the last is not an infrequent finding in long-standing ulcerative colitis. He had cold moist hands, a finding perfectly compatible with that disease. He came in with a rather rapid pulse, minimal fever, mild anemia and slight leukocytosis. They happened to catch one stool without blood, but the rest were consistently guaiac positive. Amebas were looked for, but amebic infestation can probably be discarded. On admission the blood chemical values were normal, with a high normal chloride level, which probably means that he had not been having violent diarrhea before he came in. The prothrombin time was prolonged, which is frequent in these patients, all of whom have inadequate nutrition, including a deficiency of vitamin K. A barium enema showed changes characteristic of long-standing extensive idiopathic ulcerative colitis. Do the films show anything additional?

DR. MILFORD D. SCHULZ: This is certainly the typical appearance of ulcerative colitis — shortened rigid walls, which do not collapse well on evacuation, and a granular mucosa. There are only a few ulcers.

DR. PITTMAN: Ulcers lower down were seen through the sigmoidoscope. How big is the spleen?

DR. SCHULZ: The tip of the spleen reaches below the costal margin, but it is not extraordinarily large.

DR. PITTMAN: This boy of eighteen, having been ill for four years, probably five, came in with the advanced irreparable changes of chronic ulcerative colitis; he was carried along medically in an attempt to see what could be done by replacement therapy. He had profuse diarrhea, treated symptomatically, and then was started on sulfasuccidine, which is the drug of choice in afebrile ulcerative colitis, — this boy was essentially afebrile, — and a fairly good caloric intake. Proctoscopic examination showed characteristic lesions — a scarred, fibrotic, granular, hyperemic colon, with many ulcers of various sizes, most of them oozing profusely. A second barium enema suggested that the process was advancing. An ileostomy was then performed. He apparently was in reasonably good shape at that time, and I gather that it was not done in the sense of emergency. Sometimes as such it is a life-saving measure. It was presumably done because it was thought that nothing could be accomplished medi-

CASE 31211

PRESENTATION OF CASE

An eighteen-year-old boy was admitted to the hospital because of severe diarrhea and weight loss.

Five years before admission, at the age of thirteen, the patient began to have episodes of moderately severe epigastric and precordial pain not related to meals; these occurred about twice a week and were usually relieved by belching. There was increased perspiration, and occasional vomiting without nausea. At the age of fourteen he had an appendectomy following a period of unknown duration of severe pain in the right lower quadrant of the abdomen, without vomiting. On the day following the operation he had about twenty-five stools. In the course of a month the number of stools decreased gradually, yet averaged ten to twelve per day, usually with mucus and occasionally with blood. From that time on the diarrhea never disappeared. One and a half years before entry he was admitted to another hospital, where a diagnosis of "colitis with infection" was made. He was treated with a low-residue diet and was discharged moderately improved. He had progressively less pain, tenesmus and urgency during the year before admission. He continued to grow but had lost 11 pounds during recent months.

The boy's parents were divorced when he was three years old. The patient lived with his mother and grandmother. The mother was a shoe-factory worker and was described by the patient as nervous and pessimistic. The patient did not make close friendships. Until he was seven years old he had had "fits" or convulsions about twice a year. He had had pneumonia at seven years of age.

Physical examination revealed an asthenic, poorly nourished but fairly well developed young man. The skin was pale, with "pimples" over the back. The teeth were carious, and oral hygiene was poor. There was clubbing of the fingers and toes, and slight tremor of the hands, which were always cold and moist. The lungs were clear, and the heart was normal. The abdomen showed one small area of slight deep tenderness with minimal spasm in the left lower quadrant. Neurologic examination was negative.

*On leave of absence.

The temperature was 99.5°F., the pulse 90, and the respirations 20. The blood pressure was 105 systolic, 65 diastolic.

Examination of the blood showed a red-cell count of 4,200,000; in the smear there was hypochromia with some poikilocytosis and anisocytosis. The platelets were greatly increased. The white-cell count was 12,750, with 2 to 8 per cent monocytes and some toxic granules in the neutrophils. The urine was normal. The first stool examined was guaiac negative, but later the stools showed +++ guaiac tests. Repeated cultures were negative for pathogens, and no amebas were found. The serum nonprotein nitrogen was 23 mg. per 100 cc., and the chloride 105 milliequiv. per liter. The prothrombin time was 30 seconds (normal, 18 to 20 seconds). A Hinton test was negative.

A barium enema showed the barium to pass rapidly through a tube-like sigmoid and colon into the proximal portion of the terminal ileum. The bowel was extremely irritable, spastic and stiff. The spleen appeared enlarged.

The patient had three to sixteen bowel movements a day for the first six weeks. He received many transfusions of whole blood and plasma. The daily caloric intake was irregular but remained largely between 2000 and 3000 calories. He received sedatives, bismuth subcarbonate and belladonna during the first two weeks, then was given 14 gm. of sulfasuccidine a day. Proctoscopy to the level of the sigmoid revealed an extremely irritable, scarred colon with fibrosis and granularity; in some areas there was marked hyperemia, with large and small ulcerations, most of which oozed blood profusely. A barium enema four weeks after admission suggested advancement of the disease. The ileum did not fill.

Six weeks after admission an ileostomy was performed under local and Pentothal anesthesia. The surgeon noted that the cecum was pale and thickened. The terminal ileum appeared normal. It was divided 10 cm. from the ileocecal valve, and the proximal end brought through the abdominal wall. He drained from 1200 to 4700 cc. daily from the ileostomy and developed severe vomiting.

On the third postoperative day he developed right carpopedal spasm. He had a negative Trousseau sign. The serum calcium was 9.8 mg. per 100 cc., and the phosphorus 4.4 mg.; the sodium was 128 milliequiv. per liter, and the chloride 84 milliequiv. Despite vigorous sodium chloride therapy, the serum chloride rose very slowly. A week after operation the small bowel became distended and abdominal cramps became quite severe. A Miller-Abbott tube brought some relief. It was soon found that there was an intermittent obstruction a few centimeters within the ileostomy and that about six catheterizations of the ileum daily afforded relief of the cramps.

DR. PITTMAN'S DIAGNOSES

Chronic idiopathic ulcerative colitis.
Dietary deficiency, chronic.
Perforation of ileum.

ANATOMICAL DIAGNOSES

Chronic ulcerative colitis.
Acute ulcerative ileitis, with perforation.

that were seen at operation. The entire colon was extremely thick, and the lumen was narrowed — a true "garden hose" variety (Fig. 1). The process in the colon was practically healed, and we were unable to find any extensive acute ulcers. The ileum, on the other hand, was markedly hemorrhagic and very thin, and when opened, there were numerous ulcers measuring 1 to 2 cm. in diameter,

FIGURE 1. Photographs of Sections of the Small and Large Bowel.

A — acute ulcerations of ileum; B — perforated ulcerations of ileum; C — chronic fibrotic lesions of colon.

Acute generalized peritonitis.

Operations: ileostomy; laparotomy

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed an extensive infection of the peritoneal cavity and perforation of several of the thin areas in the terminal ileum

three of which had perforated. These ulcerations occurred only in the proximal loop of the ileostomy. The distal loop of ileum was perfectly normal, showing no evidence of edema, hemorrhage or anything that suggested ileitis. This suggests that the disease that we found in the terminal ileum was not present at the time of the ileostomy but had occurred follow-

cally and that the only thing to do was to put the bowel at rest. At operation the surgeon noted that the cecum was pale and thickened. In other words the patient had changes as far up as the cecum. Whether there was a secondary factor, such as tuberculosis, I do not know. I am inclined to think that there was none and that the process was merely extensive, involving the whole colon.

Following ileostomy the patient got into trouble right away. Carpopedal spasm was present on the third day, with low phosphorus and chloride levels and so forth. I assume that these findings were probably due to the tetany that one finds with vomiting and loss of chloride, although certainly it is not uncommon to see tetany, with a change in the phosphorus and calcium levels, in long-standing intestinal disease of this sort.

Then began the postoperative battle to keep up the intake, and in this case the battle was lost. They began catheterization of the ileostomy, which is a questionable procedure. I believe that Dr. Moore and Dr. McKittrick think that, in general, dilatation of the stoma is safer than catheterization. The patient began to bleed, and it may well have been from the trauma of the catheterization, but we have no data concerning the prothrombin level at that time. The chances are that it was greatly prolonged. He had been losing large amounts of fluid and had not been able to maintain the chloride level. A second operation became imperative, and they found a uniform dilatation of the small bowel without definite obstruction. The serosa was cyanotic, and dilated veins were seen in the mesentery. I do not know what that was, unless edema of the tissues interfered with venous return. The serosal plaques again make one wonder whether to bring in tuberculosis, but I do not believe that it is necessary. They were thin plaques; with little left of the bowel wall, and probably one of these plaques was responsible for the terminal event two days later.

My diagnosis is chronic idiopathic ulcerative colitis, with a chronic deficiency state on entry because of several years of diarrhea. The dramatic episode was acute perforation of the small bowel, likely through one of the thin areas noted at the second operation.

DR. BENJAMIN CASTLEMAN: What do you think the pale areas in the small bowel wall were?

DR. PITTMAN: I think that they were areas of ulceration where the serosa was extremely thin, because they were described as being transparent. I do not believe that they were tubercles.

DR. WYMAN RICHARDSON: I saw this boy once and also saw his blood smear. I might mention that he had a normal or nearly normal red-cell count but a marked hypochromic picture due to blood loss. The hemoglobin must have been low. The polymorphonuclear cells contained toxic granulations, a picture frequently seen in severe ulcerative colitis,

which suggests that the disease is of infectious origin.

DR. ERICH LINDEMANN: We had this boy for four weeks on the Psychiatric Service. In some patients with ulcerative colitis a reduction in emotional tension has been followed by such an improvement in the colitis that psychiatric work has become an important factor in treatment. This, however, usually happens in patients with relatively well-adjusted personalities from the psychologic point of view who have recently undergone a severe emotional disturbance following a crisis, such as bereavement. This patient showed a long-standing personality disorder, the correction of which would have required a considerable period of intensive psychiatric work. The disease was too advanced for this work to be attempted.

On the other hand, we expected a rather severe emotional reaction to the operation, because the patient was haunted by morbid fears in connection with fantasies about violence and destruction. He anticipated the operation with extreme anxiety. Considerable efforts to reassure him and to prepare him for the operation seemed to have but little effect.

DR. FRANCIS D. MOORE: The consensus of those who took care of this boy was that an immediate ileostomy when he first came in might have resulted in a more satisfactory outcome. It is asking a lot of the Psychiatric Service to take the responsibility for holding up operation; such a decision rests with the Surgical Service, which evidently underestimated the extent of the patient's disease.

I should like to comment on one or two things that were said in the discussion. At the present time, following ileostomy we frequently see patients who do not have an inordinate fluid loss from the stoma. In fact any patient who has severe loss of fluid and electrolytes may have either ulceration in the terminal ileum or partial obstruction; possibly this boy had both. So far as catheterization is concerned, Dr. Pittman is absolutely correct. The fewer foreign bodies put in and out of an ileostomy, the better. This boy's obstructive point seemed to be 10 cm. inside the stoma. He was not in shape to operate on again, and catheterization seemed to be the only way out. So far as the last operation is concerned, the areas of discoloration on the bowel were 1 to 2 cm. in diameter, so that the chance of their being real tubercles was relatively small. It was a "sick-looking" bowel, and I had no idea what underlay the changes in the bowel wall or the peculiar dilated veins in the mesentery. I had never seen the latter before and could find no ready explanation for it.

CLINICAL DIAGNOSES

Chronic ulcerative colitis.
Perforation of ileum.

flask of a blood culture grew *Staphylococcus albus*. A number of repeat cultures were negative.

An electrocardiogram on the third day showed a PR interval of 0.15 second, upright but low T₁ and T₂ and a diphasic T₃.

The temperature spiked to 103°F. during the first four hospital days. It was then nearly normal for four days, only to be followed by four more days of spiking between 98 and 105°F. It returned to normal again twenty-four hours after the onset of intramuscular penicillin therapy. He had several episodes of diarrhea and vomiting during the first week. These did not recur after aspirin was withheld.

During the second week the spleen appeared larger, and definite lymphadenopathy was noted. The protein had fallen to 4.4 gm. per 100 cc., with an albumin-globulin ratio of 1.2. On the fifteenth day the patient developed slight jaundice. The van den Bergh reaction was 3.4 mg. per 100 cc. direct and 4.6 mg. indirect. The jaundice, fever, joint pains and splenomegaly definitely improved after the fifteenth day. The prothrombin time, the leukocytosis, the sedimentation rate and the van den Bergh reaction also improved gradually during the third and fourth weeks in the hospital. The anemia persisted and the serum protein did not rise above 4.5 gm. The patient had some edema.

After a month in the hospital the patient was discharged to his home, apparently well except for slight pain in the left shoulder.

Second admission (three weeks later). During these three weeks he had had a constant cold and sore throat. One week after discharge the shoulders, elbows, hips and knees again became stiff and painful. A week later he developed chest pain, which was severest substernally but shifted from side to side and occasionally extended through to the back. This pain was partially relieved by belching. During the week before admission he vomited almost daily and had severe orthopnea and slight fever. He had had no cough or ankle edema.

Physical examination revealed the patient to be pale and emaciated. The heart and lungs appeared unchanged. The left elbow was swollen and fluctuant. The right elbow and both knees were swollen. There was slight tenderness in the left lumbar region.

The temperature was 100°F., the pulse 120, and the respirations 24. The blood pressure was 100 systolic, 70 diastolic.

During the five weeks spent in the hospital the urine and blood picture remained constant. The urine had specific gravity that was never above 1.008 and gave a ++ test for albumin; the sediment contained an occasional hyaline cast and red cell and 5 white cells per high-power field.

The white-cell count varied from 15,000 to 22,000, with about 80 per cent neutrophils. The hemoglobin remained between 7 and 10 gm. per 100 cc. The smear appeared normal. The sedimentation

rate averaged over 3 mm. per minute but returned to normal in four weeks. The serum nonprotein nitrogen was 36 mg. per 100 cc., and the protein 5.8 gm., with an albumin-globulin ratio of 0.78. The prothrombin time was 27 seconds (normal, 18 to 20 seconds), and the cholesterol 258 mg. per 100 cc. Urine and blood cultures were negative.

The temperature spiked to 102.5°F. for three days after admission, after which it rarely rose above 99.

X-ray examination of the bones of the shoulders showed decalcification, the auricular surfaces of the humeri were somewhat irregular, and there seemed to be subcortical absorption of bone.

Although the joint pains and leukocytosis persisted he was discharged to his home for further bed rest and physical therapy.

Final admission (four days later). On the day after discharge he had transient episodes of irrationality and, on the following day, became dyspneic while lying in bed. His physician gave him codeine for joint pain and left pleuritic pain. On the fourth day at 9 a.m. he could not be roused and was readmitted.

Physical examination revealed a pale, thin, dehydrated man. He could be aroused only by painful stimuli. The eyeballs were soft. The neck was not stiff, and a bilateral Hoffmann's sign was elicited. The heart was regular, with a rate of 100.

The temperature was subnormal, and the respirations 16. The blood pressure was 110 systolic, 45 diastolic.

The lungs soon became filled with moist rales and the blood pressure fell to 80 systolic, 20 diastolic. The urine gave a ++++ test for albumin and had a pH of 5.5 and a specific gravity of 1.012. The white-cell count was 30,000, with 90 per cent neutrophils. The serum nonprotein nitrogen was 180 mg. per 100 cc.

The patient became progressively more dyspneic and cyanotic. There were fibrillary twitchings over the body, and he expired about twelve hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM W. BECKMAN: On first glance at this record, one thinks of a bacterial infection of some sort. The patient had fever, malaise, weight loss, a markedly elevated white-cell count and an elevated sedimentation rate. These are the clinical features of bacterial infection. If it were an infection it was of several months' duration. This fact alone, with the cardiac findings and the past history of joint disease, makes one wonder about subacute bacterial endocarditis. In spite of all this evidence I have come to the conclusion that this was not a bacterial infection. In the first place, he was a young man who had had several previous attacks of joint disease and whose present illness was again characterized by joint symptoms in addition to the constitutional manifestations.

ing ileostomy; as Dr. Moore has suggested, this disease in the ileum may have been due to a partial obstruction. Dr. McKittrick, after hearing the results of this case, said that he recalled one other case in which a similar ileitis had occurred following obstruction in the ileum; he wondered whether this ileitis might have resulted from obstruction. You did not find obstruction in the ileum at the time of operation, Dr. Moore? Perhaps there was some other factor, but the fact that the distal loop was not involved suggests that it may have been the mechanical factor of obstruction that contributed some way in the development of this severe acute ulcerative ileitis and death.

DR. MOORE: We did not find obstruction, and yet, as has been pointed out in these meetings before, obstruction of an ileostomy can be due to the interaction of two factors—the caliber of the ileostomy and the propulsive force of the bowel behind it. With even a normal ileostomy stoma, a proximal bowel with deficiency disease cannot push the fecal stream through.

DR. RICHARDSON: What happens is that a lot of digestive juice does not reach the distal ileum. One of the surprising things about human beings is that they do not “eat up their own guts,” so to speak. I think that it may be a factor in cases of ulcerative colitis.

DR. PITTMAN: What about catheterization? Was there really a stenosis of the stoma, and could there have been enough trauma to cause the perforation?

DR. MOORE: The patient died in two hours, obviously from a perforation of a hollow viscus. We were afraid of catheter trauma, but these lesions were about 150 cm. above the stoma.

CASE 31212

PRESENTATION OF CASE

First admission. A twenty-one-year-old machinist was admitted to the hospital with fever, precordial discomfort and inflamed joints.

At the age of eight he had chills and fever and developed warm and red joints and masses on the back of his hands. He was not asymptomatic until the following summer, about eight months later. During the next winter the same illness recurred with fever and warm, swollen, red joints. The joints of the hands were exquisitely tender. He spent that winter in a hospital, where splints were used to correct flexion deformities of the fingers. The following spring his joints suddenly and spontaneously improved, and he walked for the first time in six months. He was said to have no involvement of the heart. Four years later, he had another severe recurrence. He spent almost a year in bed, and he was soon free of symptoms and deformities. He subsequently attended a trade school

for a year, and three years before admission he began to work as a machinist. Until the present illness he had been well and had worked sixty hours each week in a shop. Four weeks before entry he awoke with a sense of precordial and substernal pressure aggravated by deep breathing. A headache was somewhat relieved by elevating the head on four or five pillows. He also began to note considerable malaise. Five days later the temperature was 99.8°F., and it had remained elevated until admission. An electrocardiogram at that time was said to have indicated that he had a “wicked heart.” About three weeks before entry the elbows, shoulders and knees became stiff and tender. At about that time the throat became sore. A week later a physician noted pink spots on the toes. Two or three days before admission he had periumbilical abdominal cramps. On the day before admission he had several more such attacks, accompanied by vomiting and diarrhea. He had lost an unknown amount of weight.

He had drunk three or four bottles of beer and three or four “shots” of whisky every day. He had never had scarlet fever.

Physical examination showed a man with hot moist skin, appearing extremely ill. The heart was 10 cm. to the left of the midsternum in the sixth interspace. There was a regular rate of 110. A mitral diastolic rumble with a presystolic accentuation was thought to be heard. The lungs were clear. The liver was not considered to be significantly enlarged but there was definite tenderness in the region of the liver. The tip of the spleen was palpable on inspiration. The fingers, wrists, elbows and shoulders were painful, tender and stiff. There were several reddish-brown spots, suggestive of petechiae, on the dorsum of the left great toe.

The temperature rapidly rose from 101 to 104.4°F., and the pulse from 90 to 120. The respirations were 20. The blood pressure was 130 systolic, 65 diastolic.

The urine was light amber, cloudy and acid in reaction, with a specific gravity of 1.004 and a +++ test for albumin; the sediment contained 3 white cells per high-power field. There was no sugar, diacetic acid or bile.

Examination of the blood showed a white-cell count of 18,600, with 87 per cent neutrophils and 8 per cent lymphocytes. The hemoglobin was 9.8 gm. per 100 cc. A blood Hinton test was negative. A stool was green and formed; it was guaiac negative. The sedimentation rate was over 2 mm. per minute. The serum nonprotein nitrogen was 34 mg. per 100 cc., the protein 6.1 gm., and the cholesterol 195.0 mg. The chloride was 91 milliequiv. per liter. A van den Bergh test was negative. The prothrombin time was 54 seconds (normal, 18 to 20 seconds). A cephalin flocculation test was + in forty-eight hours. Agglutination tests for typhoid, paratyphoid and undulant fevers were negative. One

sary criteria for the diagnosis of rheumatoid arthritis. The description of the second and third attacks is quite clearly that of Still's disease. I do not believe that anyone would have had difficulty in making the diagnosis. The child was extremely sick, with fever and weight loss. Joint deformities developed that required straightening by means of splints. This is an almost unheard of train of events in rheumatic fever. Furthermore, the present joint manifestations sound classic for rheumatoid arthritis, and the x-ray films, as they are described, are also classic for rheumatoid arthritis. The films of the shoulders are all that we need to see.

DR. MILFORD D. SCHULZ: This film of the left shoulder shows subchondral decalcification and irregularity of the subchondral bone.

DR. BECKMAN: The x-ray film is characteristic of rheumatoid arthritis and, coupled with the clinical course of this attack and the previous ones, makes that diagnosis mandatory. The fever, leukocytosis, anemia, splenomegaly, lymphadenopathy and elevated sedimentation rate are all often seen in rheumatoid arthritis.

Rheumatic heart disease has frequently been found in post-mortem examinations of patients with unquestionable rheumatoid arthritis.^{1, 2} This always raises the unanswerable question. Were the patients suffering from both rheumatoid arthritis and rheumatic fever or from a single process that produced both joint and heart lesions? I am confused about whether the characteristic cardiac findings of rheumatic fever were present in this case, and I shall have to have Dr. Castleman tell me. The typical murmur of mitral stenosis was "thought to be heard" on admission, but in all the subsequent physical examinations the heart was described as "the same." Was there evidence of heart disease?

DR. CASTLEMAN: Dr. Lerman, can you answer that?

DR. JACOB LERMAN: I should say that he did not have evidence of rheumatic heart disease.

DR. BECKMAN: I wondered, because it is difficult to interpret "thought to be."

We apparently do not have to consider rheumatic fever. The marked renal disease, however, cannot be explained by rheumatoid arthritis and suggests another member of "The Group," — lupus erythematosus, — which is characterized by splenomegaly, lymphadenopathy, serous-membrane involvement, fever and renal disease as extensive as this, leading to a nephrotic-like picture and to death. One can categorically say, however, that this patient did not have lupus erythematosus because he did not have the characteristic skin lesions and leukopenia, both of which are essential features of the illness. But the kidney picture does suggest it. Periarthritis nodosa, another member of "The Group" also produces renal disease. It is a generalized vascular disease and as a clinical entity it is characterized by evidence of vascular disturbances,

such as angina pectoris, cerebral accidents, mesenteric thrombosis and so forth. It may occur, however, in association with other members of "The Group." This was eloquently pointed out in 1938 by Dr. Soma Weiss³ in the discussion of a case of clear-cut disseminated lupus erythematosus. It appears to be, as indeed do all the members of "The Group," a response of the body to a variety of stimuli.

The lesions of periarthritis nodosa have been observed in patients suffering from serum sickness and also in patients suffering from sulfonamide intoxication. They have been produced experimentally in animals by the injection of certain fractions of human serum protein. The frequent association of this type of vascular change with the other members of "The Group" makes it likely that the renal disease was on the basis of periarthritis nodosa. Of course I have no way of ruling out an independent lipoid nephrosis or chronic glomerulonephritis, but as I have said, I should prefer to explain all the features of this illness on a single disease process. We also have to consider the possibility of amyloid disease in association with rheumatoid arthritis. This occurs not infrequently. Amyloid disease, however, is usually observed in cases of long duration, and even though I believe that the same process had been present since the first attack, at the age of eight, it is unlikely that amyloid disease developed in this case, because of the eight years of complete freedom of symptoms that he had had before the onset of the present attack.

A word about the liver disease — that also, we think, can be associated with rheumatoid arthritis. We have been studying liver function in patients with rheumatoid arthritis and have been surprised at how many have had one or two disturbed liver-function tests. We have had several autopsies in this hospital on cases of "The Group" in which definite pathological evidence of liver disease was found.

The terminal episode was uremia, although one cannot rule out a vascular accident. It might have been the latter, for it was rather abrupt. This is further evidence of periarthritis nodosa. I shall sum up by saying that the disease lies in the group of syndromes that I have discussed, the likeliest one being rheumatoid arthritis, with features of several of the other members, and that the renal lesions were due to periarthritis nodosa.

DR. LERMAN: I have mentioned the fact that this patient did not have rheumatic heart disease. When he first came in we thought that the underlying disease was subacute bacterial endocarditis, in spite of the fact that the normal state of his heart was against it. We watched him for ten days, and the temperature continued to spike up to 105°F. In fact we were sure that he was going to die. As a last resort we tried penicillin, and the response was dramatic. The temperature fell to normal on the

Therefore, one would like to relate the present illness to the previous ones and to consider it as being an exacerbation of some fundamental process. If the previous attacks of joint disease had been more clearly like rheumatic fever one could relate them, by saying that he had rheumatic heart disease and a superimposed subacute bacterial endocarditis. But actually the description, at least that of the second and the third attack, is not that of rheumatic fever, because he had definite joint deformities of long duration that required orthopedic correction. My conception of rheumatic fever visualizes acute joints, without marked deformity, which rarely if ever become chronic, whereas I believe that the description of the earlier illnesses is exactly what would be expected in rheumatoid arthritis. Another point against any kind of infection is the negative bacteriology throughout the course of the illness. No one knows from the record how many blood cultures were taken but certainly there must have been a great number during the first and second admissions. On one occasion *Staph. albus* grew in one flask, but that can safely be put down as a contaminant. The so-called "response" to penicillin does not appear to have been a true response, and this is further evidence that there was not a bacterial organism susceptible to penicillin. When the fever came down, it looked like a wonderful response, but the same thing had occurred spontaneously eight days before, without penicillin. In spite of the fact that the fever came down, it is obvious that the fundamental process did not improve in any way. He continued to have leukocytosis, an elevated sedimentation rate and joint pains, as well as all the other symptoms of his illness. Therefore I do not believe that it can be called a response.

I should like to know what it means when it says that the tests improved. Does it mean that they were normal or merely went in the direction of normal after penicillin?

DR. BENJAMIN CASTLEMAN: Dr. Berg, can you tell us about that?

DR. ROBERT L. BERG: The van den Bergh test was too low to read, and most of the other tests became more nearly normal. The sedimentation rate, however, remained elevated.

DR. MARIAN W. ROPES: So did the white-cell count.

DR. BECKMAN: The fact that the tests did not return to normal, although they went in the direction of normal, provides further evidence that penicillin did not fundamentally affect the course of the illness. This militates against the diagnosis of subacute bacterial endocarditis.

He had spots on his toes that resembled petechiae, but in subacute bacterial endocarditis of three months' duration I should expect a great deal more evidence of embolic phenomena. Focal emboli to the kidney might explain the albuminuria, but if that were the case a fluctuating urinary picture with

showers of red cells would have been found, rather than a constant one without red cells. It expressly states in the record that the urinary findings were constant. An enlarged spleen can go with bacterial endocarditis, but splenomegaly is by no means diagnostic of this or any disease.

On the basis of these considerations I decided that this man did not have a significant bacterial infection. If any was found at autopsy it probably represents a terminal event that had no particular relation to the course of the total illness.

My ideas about the fundamental process in this case are rather difficult to express. Although I shall not be able to make a single diagnosis that will explain all the signs and symptoms, I believe that he was suffering from a single disease process and that that process can be classified as a member of the group of related syndromes that includes rheumatic fever, rheumatoid arthritis, disseminated lupus erythematosus, dermatomyositis, periarteritis nodosa and so forth. These diseases or syndromes are similar in that they all have marked constitutional symptoms, such as excessive fatigability, weight loss and cold sweating hands and feet. The courses of all of them may be punctuated by fever, although this is less frequent in rheumatoid arthritis. Joint signs and symptoms of varying degree are common to all. Except in lupus erythematosus disseminatus, leukocytosis may be present.

In addition to all these things that are common to the entire group, each member has features not present in the related conditions that dignify it as a syndrome. Rheumatoid arthritis, for example, is characterized by deformed joints, with both x-ray and pathological evidence of bone and joint destruction, whereas rheumatic fever shows characteristic heart involvement. That is to say, there is something in the straight clear-cut syndrome of rheumatoid arthritis that is not present in the syndrome of rheumatic fever, lupus erythematosus or any of the others. The same can be said for each of these related syndromes. Many names have been suggested for this large aggregate of related diseases. Such terms as generalized constitutional disease, generalized connective-tissue disease, mesenchymal disease, generalized vascular disease and neurovascular disease have been employed by various authors. Any one of them, however, is much too limited in scope to describe adequately the widespread nature of this group of diseases. For want of a better name we in the Arthritis Clinic of this hospital have adopted the convention of calling them "The Group." We continue to search for an adequate name and welcome suggestions.

Another reason we believe that these conditions are related is that not infrequently one encounters in a single patient at a given time the characteristic features of two or more of these syndromes. This is well exemplified by this case. In the first place, I think there can be no doubt that he had the neces-

ary criteria for the diagnosis of rheumatoid arthritis. The description of the second and third attacks is quite clearly that of Still's disease. I do not believe that anyone would have had difficulty in making the diagnosis. The child was extremely sick, with fever and weight loss. Joint deformities developed that required straightening by means of splints. This is an almost unheard of train of events in rheumatic fever. Furthermore, the present joint manifestations sound classic for rheumatoid arthritis, and the x-ray films, as they are described, are also classic for rheumatoid arthritis. The films of the shoulders are all that we need to see.

DR. MILFORD D. SCHULZ: This film of the left shoulder shows subchondral decalcification and irregularity of the subchondral bone.

DR. BECKMAN: The x-ray film is characteristic of rheumatoid arthritis and, coupled with the clinical course of this attack and the previous ones, makes that diagnosis mandatory. The fever, leukocytosis, anemia, splenomegaly, lymphadenopathy and elevated sedimentation rate are all often seen in rheumatoid arthritis.

Rheumatic heart disease has frequently been found in post-mortem examinations of patients with unquestionable rheumatoid arthritis.^{1, 2} This always raises the unanswerable question. Were the patients suffering from both rheumatoid arthritis and rheumatic fever or from a single process that produced both joint and heart lesions? I am confused about whether the characteristic cardiac findings of rheumatic fever were present in this case, and I shall have to have Dr. Castleman tell me. The typical murmur of mitral stenosis was "thought to be heard" on admission, but in all the subsequent physical examinations the heart was described as "the same." Was there evidence of heart disease?

DR. CASTLEMAN: Dr. Lerman, can you answer that?

DR. JACOB LERMAN: I should say that he did not have evidence of rheumatic heart disease.

DR. BECKMAN: I wondered, because it is difficult to interpret "thought to be."

We apparently do not have to consider rheumatic fever. The marked renal disease, however, cannot be explained by rheumatoid arthritis and suggests another member of "The Group," — lupus erythematosus, — which is characterized by splenomegaly, lymphadenopathy, serous-membrane involvement, fever and renal disease as extensive as this, leading to a nephrotic-like picture and to death. One can categorically say, however, that this patient did not have lupus erythematosus because he did not have the characteristic skin lesions and leukopenia, both of which are essential features of the illness. But the kidney picture does suggest it. Periarthritis nodosa, another member of "The Group" also produces renal disease. It is a generalized vascular disease and as a clinical entity it is characterized by evidence of vascular disturbances,

such as angina pectoris, cerebral accidents, mesenteric thrombosis and so forth. It may occur, however, in association with other members of "The Group." This was eloquently pointed out in 1938 by Dr. Soma Weiss³ in the discussion of a case of clear-cut disseminated lupus erythematosus. It appears to be, as indeed do all the members of "The Group," a response of the body to a variety of stimuli.

The lesions of periarthritis nodosa have been observed in patients suffering from serum sickness and also in patients suffering from sulfonamide intoxication. They have been produced experimentally in animals by the injection of certain fractions of human serum protein. The frequent association of this type of vascular change with the other members of "The Group" makes it likely that the renal disease was on the basis of periarthritis nodosa. Of course I have no way of ruling out an independent lipid nephrosis or chronic glomerulonephritis, but as I have said, I should prefer to explain all the features of this illness on a single disease process. We also have to consider the possibility of amyloid disease in association with rheumatoid arthritis. This occurs not infrequently. Amyloid disease, however, is usually observed in cases of long duration, and even though I believe that the same process had been present since the first attack, at the age of eight, it is unlikely that amyloid disease developed in this case, because of the eight years of complete freedom of symptoms that he had had before the onset of the present attack.

A word about the liver disease — that also, we think, can be associated with rheumatoid arthritis. We have been studying liver function in patients with rheumatoid arthritis and have been surprised at how many have had one or two disturbed liver-function tests. We have had several autopsies in this hospital on cases of "The Group" in which definite pathological evidence of liver disease was found.

The terminal episode was uremia, although one cannot rule out a vascular accident. It might have been the latter, for it was rather abrupt. This is further evidence of periarthritis nodosa. I shall sum up by saying that the disease is in the group of syndromes that I have termed the "Great One" being rheumatoid arthritis and that the renal lesions were due to periarthritis nodosa.

DR. LERMAN: I have mentioned the fact that this patient did not have rheumatoid heart disease. When he first came in we thought that the heart disease was rheumatic heart disease, in spite of the fact that the normal, and was against it. We wanted to see if the patient was going to die. As a result of the treatment, the response was that the temperature fell to normal on the

second day. Not only was there an improvement in temperature, but his clinical condition also improved. Everyone who saw him agreed that he had made a good response to penicillin. A course of penicillin at the time of his second admission also caused improvement, but the response was not too definite. After a period of time he was able to go home.

DR. J. H. MEANS: I saw this man half an hour before he died and refrained from making a diagnosis, although I did make a correct prognosis. I did not believe that he had subacute bacterial endocarditis, although I thought that it was a possibility. I thought that he had more than uremia to account for his death, and I wondered whether he had had a cerebral vascular accident as a terminal episode.

DR. ROPES: In regard to the response to penicillin, it is true that he improved clinically, but to me at least, it was not a real response because the laboratory signs of activity persisted and the leukocytosis continued to be 18,000 to 20,000 after one of the courses of treatment. In addition, we often see a similar course in this group of diseases without the use of penicillin. In lupus erythematosus and less frequently in rheumatoid arthritis, we frequently observe this picture—a high fever that appears suddenly, lasts a few days and then disappears. During that period the patients often appear moribund and yet recover. In such cases the question often arises whether or not they should receive sulfonamides. In some of them we have thought that the giving of sulfonamides led to death. We did not have that problem in this patient, however, since there is no evidence that penicillin causes similar bad results in patients with these diseases.

CLINICAL DIAGNOSES

Lupus erythematosus disseminatus?
Subacute bacterial endocarditis?
Uremia.

DR. BECKMAN'S DIAGNOSES

Rheumatoid arthritis.
Periarthritis nodosa, involving the kidney.

ANATOMICAL DIAGNOSES

Rheumatoid arthritis.
Amyloidosis of kidneys, spleen and liver.
(Uremia.)
Polyserositis, hemorrhagic.
Bronchopneumonia.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed about 250 cc. of clotted blood in each pleural cavity. We found the same amount of blood in the abdominal cavity but no signs of peritonitis. The heart was normal in size; but on the epicardial surface was a loose, ad-

herent gelatinous material producing interadherence between the parietal and the visceral pericardium. Sections of the pericardium showed microscopically numerous polymorphonuclear cells and fibrin, suggesting an acute or subacute pericarditis. The same reaction was present on the pleura and peritoneum. There was therefore a hemorrhagic polyserositis. The valves of the heart were normal. There was no evidence of rheumatic heart disease, and no thrombi on any of the valves to suggest a nonbacterial thrombotic endocarditis, such as one sometimes sees with lupus erythematosus.

The kidneys were the striking feature of this autopsy. They weighed 600 gm. together, and were quite hard and white. In the gross the condition almost suggested lymphomatous infiltration. Microscopically this whitish infiltration proved to be an extensive amyloid degeneration. Practically every glomerulus and vessel were involved. No wire-loop lesions, which are often seen in cases of lupus erythematosus, were observed. The amyloidosis was corroborated by the findings in the spleen, which weighed 450 gm. and had what is often called a "sago" appearance. Microscopically all the vessels in the centers of the Malpighian corpuscles showed marked amyloid degeneration of their walls.

DR. ROPES: We were unable to examine the joints but did get fluid from the shoulder joint, which contained approximately 70,000 white cells of which 85 per cent were polymorphonuclear cells, and there was also a great deal of what must be called cellular debris, similar to the material we see in cases of rheumatoid arthritis of long duration, where there is a great deal of tissue destruction.

DR. CASTLEMAN: We inoculated the material into various aerobic and anaerobic mediums but were unable to obtain any growth. The blood culture was also negative. I believe that there is little doubt that the joint disease was rheumatoid arthritis.

DR. ROPES: The fluid sugar was high, which one does not find usually with infectious arthritis even following intravenous glucose administration.

DR. CASTLEMAN: I do not believe that the joint lesions were infectious. The patient did have a terminal bronchopneumonia. I still do not understand why there was frank blood in the pleura and peritoneum.

DR. LERMAN: Could it have been associated with the uremia?

DR. BECKMAN: Pleural and pericardial involvement is not infrequent in rheumatoid arthritis.

DR. ALLAN M. BUTLER: How common is amyloid disease in rheumatoid arthritis?

DR. ROPES: It varies; in some small series of Still's disease it has been reported as high as 50 per cent. It has not usually been reported so high as that in this country, and in our group it is relatively low—below 10 per cent. We have had several patients with amyloid disease but the usual

course is a slow downhill one with gradually increasing renal failure.

It is interesting that Carroll and Nelson⁴ have reported a case of rheumatoid arthritis with amyloidosis in which the patient died with hemorrhage in the abdomen.

DR. LERMAN: It is a general principle that new therapeutic agents bring about new clinical pictures as complications or sequelae. For example, thio-uracil causes agranulocytosis, characteristic febrile reactions and adenopathy. The sulfonamides cause a characteristic nephritis. I should like to offer the suggestion that this type of case represents the sequence of events that may follow the use of penicillin and that such cases may occur regularly in the future. Let us assume that this patient had a history of rheumatic disease fifteen years previously. This may have been rheumatic fever or rheumatoid arthritis. He develops a fulminating infection that

behaves in some respects like subacute bacterial endocarditis or septicemia. Penicillin produces a dramatic recovery. The bacteria, however, are not licked — they go underground. The serous cavities are a good hideout, and the infection smolders along there without any serious systemic reaction. Death finally results, not from the infection but from a degenerative process caused by chronic suppuration. An analogous sequence of events takes place in chronic osteomyelitis.

with a determination that we will not so easily forget again.

We must remember the soil that will be forever reddened with the blood of young Americans — at Kasserine Pass and over the hills that fall away to Tunis and Bizerte, in Sicily and at Salerno, at Benevento and Cassino, in the cockpit of Anzio and up the bony ridge of Italy, on the beaches and across the fields of France, and on the plains and by the rivers of Germany.

We must bear in mind certain words that have become part of our spiritual bill of rights — "That from these honored dead we take increased devotion to that cause for which they here gave the last full measure of devotion; that we here highly resolve that these dead shall not have died in vain; that the nation shall, under God, have a new birth of freedom. . . ."

We must remember a new lesson, phrased by Norman Corwin in words written apropos of this event that we now commemorate — "We've learned that freedom isn't something to be won and then forgotten. It must be renewed, like soil after yielding good crops; must be rewound, like a faithful clock; exercised, like a healthy muscle."

And still we must remember that another victory is yet to be won, our power redeployed, another mile traversed, however long, before we can devote ourselves fully to the problems of a peace so hardly won.

VICTORY IN EUROPE

IT SEEMS particularly fitting that our day of victory in Europe should have come in May, for May is the month that we long ago selected in which to have our day of remembrance, and there is much that we must not forget.

We must not forget our grim horror at the tales of Buchenwald, Nordhausen, Belsen and Erla, at prisoners of war murdered in the snow, at unrestricted U-boat sinkings, at Coventry and at the blind rage of rocket bombs. We must remember these things, not with hate, but with a long memory that can outlive the passing of events. We must remember the forgetfulness of the years after 1918,

THE CASE AGAINST FRIED FOODS

AS LONG ago as February, 1944, Dr. Frank Howard Richardson¹ published in the *Journal of Pediatrics* the results of his ardent researches into the digestibility of fried foods. Up to that time it had been assumed, and in those quarters unacquainted with his conclusions it still is assumed, that fried foods are harmful, especially for children. With wartime shortages particularly in mind, Dr. Richardson thought that the soundness of our dietary beliefs should be investigated.

Three sources of authority were open — published records of research, current books and bulletins, and the opinions of living experts in the fields of

nutrition and pediatrics. Surprisingly, only one piece of published research was revealed, and that nearly seventeen years older than the present study: in 1927, Boggess and Ivy² had investigated, on dogs and human beings, the digestibility of potatoes prepared after various culinary patterns. According to their conclusions, the starch of the pan-fried potato is more easily digested than that of the French-fried, and that of the French-fried more easily than that of the boiled specimen. Fat, it was found, actually facilitated the rate of digestion, determined by fluoroscopic observations.

Dr. Richardson found that authoritative textbooks on nutrition, federal and state health bulletins, pamphlets on child care and so forth almost universally condemned all foods prepared after the fashion that made famous, if not popular, the sixth day of the week. No scientific proof was presented for these pontifical opinions: fat may be an excellent food principle, but not the foods that are cooked in it. So far as these tribunals are concerned, the only edible part of the doughnut is the hole. "In frying," according to one of these witnesses, "decomposition products are formed, which are irritating to the digestive tract." And that was that.

Various specialists were then consulted — eleven nutritionists, biochemists and physiologists, seven pediatricians of national reputation, two pediatricians high in the Children's Bureau, two gastroenterologists, one nutrition director of the American Red Cross, two medical editors and two research-bureau heads. Not one of these authorities let the investigator down. The cruelest indictment of fried foods was that overindulgence might be unwise; a differentiation was also made of fried foods properly cooked and those that were simply soaked in hot fat.

And so at last comes vindication, permanent we trust, for the fried spud, the flapjack and the doughnut, the crisp egg — sunny side up or, in the vernacular, "one eye open" — and the Sunday-morning fishball.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BATTERSHALL — Jesse W. Battershall, M.D., of Attleboro died May 4. He was in his fifty-second year.

Dr. Battershall received his degree from Tufts College Medical School in 1916. He had served as medical examiner in Bristol North district for twenty years and as school physician in Attleboro for twenty-three years. In 1943 he was named municipal health officer. He was a member of the Sturdy Memorial Hospital staff.

His widow survives.

LEIB — Edwin R. Leib, M.D., of Worcester, died May 5. He was in his seventy-first year.

Dr. Leib received his degree from Boston University School of Medicine in 1899. He retired as chief of the medical service at Hahnemann Hospital a few months ago but remained on the staff as a consultant. He was also a consultant on the Belmont Hospital staff. For more than thirty years, Dr. Leib had served as epidemiologist in the Worcester Health Department. He was president of the Worcester Blood Bank.

His memberships included the Worcester District Medical Society of which he was past president, as well as a councilor at the time of his death. He was a fellow of the American Medical Association.

His widow and a brother survive.

†Four-year average.

COMMENT

Diphtheria is still at a high point — the highest April for the last ten years. This year's April figure of 24, however, is far below those of Aprils previous to 1935.

Meningococcal meningitis remained well above the seven-year median. It should be remembered, however, that the figures on which this seven-year median was based include several Aprils with extremely low incidences.

Mumps was very prevalent but is beginning to show the usual seasonal decline.

Measles continues at an extremely low point.

All the cases of malaria originated outside the United States.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

- Anterior poliomyelitis was reported from: Boston, 2; total, 2.
- Diphtheria was reported from: Boston, 8; Brockton, 1; Camp Edwards, 2; Everett, 1; Falmouth, 1; Hingham, 1; Lawrence, 1; Lowell, 3; Lynn, 1; New Bedford, 2; Revere, 1; Somerville, 1; Worcester, 1; total, 24.
- Encephalitis, infectious, was reported from: Lexington, 1; total, 1.
- Malaria was reported from: Boston, 2; Camp Edwards, 75; Cushing General Hospital, 9; Everett, 1; Natick, 1; Northampton (U. S. Veterans Hospital), 1; Quincy, 1; Regional Hospital (Waltham), 33; Springfield, 1; total, 124.
- Meningitis, meningococcal, was reported from: Boston, 6; Easthampton, 1; Everett, 1; Haverhill, 1; Hingham, 1; Middleboro, 1; Quincy, 1; South Hadley, 1; Springfield, 4; Stoughton, 1; Sturbridge, 1; Walpole, 1; West Springfield, 1; total, 21.
- Meningitis, Pfeiffer-bacillus, was reported from: Boston, 1; Lawrence, 1; total, 2.
- Meningitis, pneumococcal, was reported from: Boston, 3; Cambridge, 1; Fall River, 1; New Bedford, 1; Reading, 1; total, 7.
- Meningitis, other forms, was reported from: Boston, 1; Weymouth, 1; total, 2.
- Meningitis, undetermined, was reported from: Boston, 1; Springfield, 1; total, 2.
- Salmonella infections were reported from: Boston, 2; Lawrence, 3; Newton, 1; total, 6.
- Septic sore throat was reported from: Boston, 10; Brookline, 1; Cambridge, 1; Haverhill, 1; Lynn, 1; Merrimac, 2; Milton, 1; North Adams, 1; Pittsfield, 1; total, 19.
- Tetanus was reported from: Cambridge, 1; Kingston, 1; total, 2.
- Trichinosis was reported from: Boston, 3; Fall River, 1; total, 4.
- Typhoid fever was reported from: New Bedford, 1; South Hadley, 1; total, 2.
- Undulant fever was reported from: Northampton, 1; Southbridge, 1; total, 2.
- Weil's disease was reported from: Ware, 1; total, 1.

BOOK REVIEWS

Gastro-Enterology (three volumes). By Henry L. Bockus, Vol. II. *The Small and Large Intestine and Peritoneum: Diagnosis and Treatment of Disorders of the Small Intestine, Colon, Peritoneum, Mesentery and Omentum*. 4th, cloth, 975 pp., with 311 illustrations and 53 tables. Philadelphia and London: W. B. Saunders Company, 1944. \$12.00.

This is an excellent book, half of which was written by Dr. Bockus and half by his colleagues in the Graduate Hospital of the University of Pennsylvania. It is easily the best textbook on the subject in English in the past twenty-five years, and fills a real need. The style is pleasing, and the book is well printed and bound and beautifully and copiously illustrated. At the beginning of each chapter there is an index of contents, and a well-chosen list of references is supplied at the end. About one third of the book covers the small intestine, and nearly two thirds considers the large intestine, with the remainder — about fifty pages — on the peritoneum, mesentery and omentum. The material is so varied and extensive that it is hard to single out special chapters for review.

One has only to compare this volume with the standard textbooks of twenty years ago to note the great progress that has been made in the diagnosis and treatment of diseases of the intestine — the free use of the roentgen ray, the use of the Miller-Abbott tube in intestinal obstruction, the better classification of diarrheas, the complete description of ileitis, the use of vitamins, the medical treatment of megacolon, the absence of the usual hundred-page chapter on "intestinal intoxication," and the changes in operability and surgical mortality.

The radiographic illustrations are clear and easy to understand. The color films taken through the proctoscope are really remarkable. The value of examination of the feces is clearly shown. A fuller discussion of peritoneoscopy is promised in the third volume. The description of rectosigmoidoscopy is complete and satisfactory. As is the examination of the feces on an ordinary or a Schmidt test diet, and the use

of barium enemas. The discussions of fluid and salt needs in patients with diarrhea, vomiting and gastrointestinal aspirations are valuable.

The chapter on intestinal obstruction is one of the largest in the book, modern methods of diagnosis and treatment being fully outlined. In the chapter on ileitis the whole subject is brought up to date and is especially well illustrated, and the symptoms and indications for medical and surgical treatment are clear. Mesenteric embolism and thrombosis seem to have been omitted in the differential diagnosis of the acute abdomen, and the value of the urinary diastase level in such cases should be stressed. In the chapter on intestinal carbohydrate dyspepsia, it is surprising that Schmidt and Strassburger, who named and first described the disease in 1901, are not mentioned.

Developmental anomalies of the colon — high and low cecum, redundant colon and so forth — are conservatively dealt with. Modern methods of medical and surgical treatment of megacolon are well outlined. The discussion of the etiology and treatment of one obscure disease, chronic ulcerative colitis, is especially good. The statement that symptoms are present in over 50 per cent of cases of noncomplicated diverticulosis of the intestine seems odd, and suggests that patients with diverticula who have no gastrointestinal symptoms and no roentgenologic examination are not included. The chapters on tumors and granulomas of the bowel are excellent. Chronic appendicitis is treated conservatively.

Tuberculous peritonitis is given one page in contrast to the twenty pages of the older books, which probably corresponds to its lessened incidence.

This book can be highly recommended to the general practitioner and to the specialist.

Synopsis of Neuropsychiatry. By Lowell S. Selling, M.D., Ph.D., Dr.P.H. 12th, cloth, 500 pp. St. Louis: C. V. Mosby Company, 1944. \$5.00.

The book is a simplified manual, well arranged and covering the whole field of neurology and psychiatry. The definitions are clear and concise, and the material is set out in an extremely attractive manner, so that a reference may be easily found. The book is obviously by an expert, with full knowledge of the physiology and pathology of the nervous system, as well as a complete grasp of the clinical aspects. In general, the volume is up to date, in spite of the rapid changes in many aspects of the subject in recent years. There is a good index, but no references to the literature. The book may safely be put in the hands of students, nurses and social workers, provided that they realize that some may differ from the author in the small technical points of a controversial nature.

NOTICES

GREATER BOSTON MEDICAL SOCIETY

A dinner meeting of the Greater Boston Medical Society will be held in the State Suite of the Copley Plaza on Tuesday, May 29, at 6:30 p.m. Dr. Ernst P. Boas, of New York, will speak on the subject "Medical Care in the Postwar Era."

BOSTON CITY HOSPITAL ALUMNI ASSOCIATION

There will be a clinical meeting of the Boston City Hospital Alumni Association on Saturday, May 26, at 10:30 a.m. in the Cheever Amphitheater, Dowling Building.

PROGRAM

The Use of Penicillin Aerosolization in the Treatment of Serious Respiratory Disease. Dr. Maurice S. Segal.
Strangulated Umbilical Hernia. Dr. William A. White, Jr.
Primary Cancer of the Lung. Dr. John W. Strieder.
Penicillin Therapy. Dr. Maxwell Finland.
Postwar Graduate Medical Training. Dr. Harold J. Jeghers.

Physicians and medical students are invited to attend.

Luncheon for the alumni, as guests of the trustees, will be held in the House Officers' Dining Room at 12:30 o'clock.

LIGATION OF THE INFERIOR VENA CAVA IN THE PREVENTION AND TREATMENT OF PULMONARY EMBOLISM*

E. EVERETT O'NEIL, M.D.†

BOSTON

THE interruption of deep venous pathways in the treatment and prevention of pulmonary embolism has come to be a generally accepted surgical procedure. The preferred sites for division when deep venous thrombosis is present, or when pulmonary infarction has taken place without evident thrombosis but the latter is suspected, have been the superficial femoral veins, the common femoral veins and, in a few cases, the external and common iliac veins. In the majority of cases, section of the above-named vessels has been adequate to prevent further extension of thrombosis, with its possible detachment of a fatal or near-fatal embolus. It must, however, be pointed out that there have been occasions when embolism, in a few cases with a fatal result, has occurred after bilateral division of deep veins. The reasons for such fatalities are not always clear. If one has interrupted a vein at a point where a thrombus was present and is not sure that all clot had been suctioned from the proximal segment, it may well be argued that a possible remaining thrombus can produce a fatal outcome; or if the superficial, and not the common, femoral vessels have been interrupted, one may deduce that a propagating thrombus may develop in the deep femoral vein, with subsequent detachment of a fatal embolus. When, however, the first sign of trouble is a sudden pulmonary episode of mild pleuritic pain, with cough and bloody sputum, suggesting a minor embolic process, and inspection of the lower extremities reveals no evidence of the usual stigmas of deep thrombosis, one may postulate a quiet thrombosis in the deep venous plexus of the legs and feel justified in performing a bilateral division of the femoral veins. Operation may reveal no clot in either vein, and a proper division may be done. Despite this procedure a fatal embolism may occur several hours or days later. The obvious query concerns the source of this embolus, and the method of averting it. It is the purpose of this paper to sug-

gest that, in certain selected cases, it may be pertinent to interrupt the inferior vena cava to circumvent the possibility of just such a catastrophe as has been mentioned. It must be admitted that the indications for the employment of such a procedure are limited; nevertheless, they are extremely important.

There appear to be two distinct indications for ligation of the inferior vena cava that have been encountered in a large series of divisions of deep veins: the first exists when the diagnosis of phlebothrombosis is obvious and the site of the lesion is apparent; the second exists when one or more emboli have occurred but their source is obscure. To elaborate further, in the first type of case a synchronous propagating thrombosis may take place in both legs, and when the condition is first observed the thrombotic processes may have extended to the inguinal ligaments or beyond, with or without the production of pulmonary embolism. As a more frequent finding, instead of simultaneous thrombosis in both lower extremities, a phlebothrombosis may occur in one limb, extending to the groin, the thrombus changing in character with the passage of time from a loose, nonadherent clot to a fairly solid mass that partially occludes the main vein. Within a few days the opposite leg may be affected by a typical phlebothrombosis involving the lower leg and thigh, clearly indicating operative interference. The question naturally arises, At what level should the vein be severed? Shall one perform a routine bilateral femoral division and attempt suctioning out the thrombi from the proximal portions of the veins, with the possible danger of leaving in some clot or dislodging it in the process of suctioning? Shall one divide the external or common iliac vein on one side and the common femoral vein on the other? The simplest solution to the problem appears to be to interrupt the inferior vena cava. The following case illustrates this point quite clearly.

CASE 1. M. S., a 34-year-old, married woman, had a pelvic operation performed on June 6, 1944. A moderate-sized cyst was removed from the right ovary and numerous

*Presented at the annual meeting of the New England Surgical Society, Boston, September 20, 1944.

†Clinical professor of surgery, Boston University School of Medicine; chief surgeon, Boston City Hospital.

adhesions were freed. The patient was discharged 2 weeks after an uneventful postoperative course. Ten days later she experienced moderate pain and swelling in the left leg and thigh. She was returned to the hospital, where shortly after admission she suffered a major pulmonary embolism. This was characterized by sharp substernal pain, cyanosis, a rapid, thready pulse, expectoration of bloody sputum and fear of impending death. Examination of both lower extremities revealed signs of deep venous thrombosis, the left more advanced than the right, extending to the groins. A diagnosis of bilateral, nonobstructive venous thrombosis, probably reaching into the iliac vessels, was made.

Under ether anesthesia, the inferior vena cava was exposed through a right lumbar incision. Two heavy braided-silk ligatures were applied to the lower vena cava, care being taken to avoid the lumbar veins. No attempt was made to search for intravenous clot. The patient's condition remained poor for 48 hours, but she gradually improved and was discharged from the hospital within 10 days. When last seen 2 months after the operation, she appeared to have undergone no ill effects from interruption of the vena cava. She experienced moderate discomfort in both legs after long periods of standing. Walking did not disturb her, and she carried on her usual household duties. Objectively there was no swelling in either leg.

In the second group of cases that may call for a ligation of the inferior vena cava, the indications are not quite so well defined, particularly since the source of the embolus may be entirely unknown and no clinical evidence of thrombosis may be available. Pathological and clinical observations preponderantly favor the role played by deep venous thrombosis of the lower leg in the production of pulmonary embolism. This phlebothrombosis may be very quiet and yet lethal in its manifestations, exhibiting no evidence of its presence until death ensues. Or the first intimation that such thrombosis exists may be the familiar signs of a pulmonary infarction, — evidence sufficient perhaps to justify division of the femoral vein. But if emboli continue to recur after such an operative procedure, is it correct to assume that thrombosis in the lower leg has been the instigating factor, even though there is no subsequent clinical manifestation of thrombosis? How perplexing this problem may be is shown by the following case.

CASE 2. M. O'B., a 52-year-old unmarried woman, had three minor pulmonary episodes, diagnosed as pulmonary infarctions, during a 4-week interval following the performance of a cholecystectomy. Search for a focus of thrombosis in the lower extremities was nonrevealing. A phlebogram was negative for obstruction in the deep veins of the leg. Despite all negative findings, bilateral division of the common femoral veins was done. No intravenous thrombus was discovered, and free bleeding was observed from the distal and proximal vein segments on both sides.

Two days following the operation, the patient presented a classic picture of sudden pulmonary embolism, with chest pain, marked dyspnea and cyanosis and expectoration of bloody sputum. Supportive treatment was instituted and the patient recovered. A subsequent electrocardiogram was negative. Within the following 12 days, two similar attacks, both almost lethal, occurred. Interruption of the inferior vena cava was contemplated, but the patient's condition interdicted any operative interference. She slowly responded to conservative measures and left the hospital within 4 weeks of the last attack. At no time during the hospital stay or since discharge has any clinical evidence of venous thrombosis been present in either leg.

Furthermore, there have been other cases in which repeated attacks of pulmonary embolism have occurred and no treatment except rest and seda-

tion was instituted, yet at no time during or after these attacks has any evidence of deep thrombosis in the lower limbs been present, even though the most painstaking search, including phlebography, was carried out.

One may thus postulate a propagating thrombus arising from some other source, such as the prostatic or uterine plexus, wending its sinister way through the hypogastric vein and the common iliac vein into the inferior vena cava. Anyone who is familiar with surgery of the female pelvis is aware of the tremendous size that the veins of the uterine plexus may attain. Their engorgement during pregnancy, in the presence of pelvic disease or in the course of routine postoperative convalescence, with its attendant immobilization, creates a most favorable medium for the formation and propagation of a silent thrombus. Likewise, in the male, the prostatic plexus gives a similar picture. This plexus of veins, sometimes termed the "prostaticovesical plexus," surrounds the prostate gland and the neck of the bladder. It receives the deep dorsal vein of the penis and veins from the seminal vesicles and empties into the hypogastric vein. All these veins may enlarge to considerable dimensions and become varicose and thrombosed. Hence, when the

FIGURE 1. Sketch Showing Origin and Cause of Deep Venous Propagating Thromboses.

The thrombus may be initiated in the lower leg veins, or in the deep femoral system, or in the deep pelvic veins, such as the uterine or prostatic venous plexuses.

presence of so-called "silent thrombosis" is suspected the thrombotic process may well exist in one or several groups of deep veins, namely, the venous channels of the lower leg, the deep femoral veins and the venous plexuses of the pelvis (Fig. 1). When

the source of the embolus is unknown, the best guarantee of safety appears to be interruption of the inferior vena cava, such as was performed in the following case.

CASE 3. L. D. O., a 65-year-old, married woman, had a cholecystectomy performed on June 13, 1944, at which time an acute gangrenous gall bladder was removed. The convalescence was essentially uneventful and afebrile until the 19th postoperative day. During the next 4 days the pulse, temperature and respirations were elevated, and signs of pulmonary infarction were found in the right chest. X-ray studies confirmed this diagnosis. A repeat chest plate taken several days later showed a much larger area of infarction than at the first observation. The clinical course and x-ray findings suggested repeated pulmonary embolisms. There was no evidence of thrombosis in either lower extremity. Because of this negative finding, interruption of the inferior vena cava was performed under Pentothal-cyclopropane anesthesia through a right lumbar incision. The postoperative course was excellent, save for one or two gastrointestinal upsets. Except for a sense of heaviness and minimal swelling in both legs when standing, the patient has no complaints.

In the above case, an equally good result might have been obtained by bilateral division of the common femoral vein, but previous experiences in which repeated embolisms have occurred after such a procedure, with the belief that a silent propagating thrombosis might exist in the pelvic vessels, influenced me in ligating the inferior vena cava.

Several considerations present themselves in a discussion of ligation of the inferior vena cava. They include the pattern of the collateral circulation that follows on such an interruption, and the operative procedure and the state of the venous return from the legs after occlusion of the vena cava.

In a recent communication, Homans¹ has demonstrated the more satisfactory collateral circulation available when the common iliac vein, rather than the common femoral vein, is divided. A further significant clinical observation is made by the same writer, to the effect that there is much less venous congestion and swelling of the extremities following such a division. It should be pointed out that a parallel situation exists when the inferior vena cava is occluded. There is equally as rich a collateral venous pattern set up after such interruption as after division of the common iliac vein. The theoretical disadvantage of the former procedure, in relation to return blood flow from the legs, is the interference with shifting of blood from one side of the pelvis to the other — a situation that does not obtain when only one common iliac vein is obstructed. This apparent disadvantage, however, is not borne out by any serious clinical aftereffects with which I am familiar.

The collateral pathways available after ligation of the lower vena cava fall roughly into three groups — the superficial, the deep, and those of the ascending lumbar trunks. The first of them comprise the superficial circumflex iliac and the superficial epigastric veins, which connect the saphenous system with the superficial thoracic vein and those of the upper abdominal wall. The deep pathways are formed by the anastomosis of the deep circum-

flex iliac, superior epigastric and lumbar veins, thereby connecting the external iliac veins with the internal mammary and ascending lumbar veins. The ascending lumbar trunks begin in the pelvis on either side of the promontory of the sacrum and communicate with the sacral, common iliac, hypogastric and iliolumbar veins. As they ascend they connect with the lumbar veins, the inferior vena cava and the right renal vein. The right lumbar trunk becomes the azygos vein and terminates in the superior vena cava; the left continues as the hemiazygos vein and eventually enters the right azygos vein. Figures 2, 3 and 4 — the first two taken from

FIGURE 2. Diagrammatic Representation of the Venous Return and Collateral Blood Supply following Division of the Common Femoral Vein. (Reproduced from Homans¹ with permission of the publisher.)

the description by Homans — portray the essential differences in the collateral channels at various levels of interruption of deep veins.

Technically, the exposure and ligation of the lower vena cava is not so hazardous or so difficult as would first appear. Heretofore, the majority of ligations have been carried out as emergency procedures following operative accidents, particularly after nephrectomy. For obvious reasons, approach to the vena cava under such conditions is extremely formidable. Such a problem, of course, does not exist in an elective operation. Interruptions of the vena

cava have also been performed because of septic thrombosis in the deep pelvic veins.² The approach in these cases is always transperitoneal, because of the necessity of ligating the ovarian veins as well as

FIGURE 3. Diagrammatic Representation of the Rich Collateral Venous Circulation after Interruption of the Common Iliac Vein. (Reproduced from Homans¹ with permission of the publisher.)

the inferior vena cava. The left ovarian vein enters the left renal vein; the right ovarian vein flows directly into the inferior vena cava. In the presence of pelvic infection and septic thrombosis, possible dissemination of septic emboli by way of the blood stream into the kidneys and lungs demands the division of these vessels. In aseptic thrombosis or phlebothrombosis, this indication does not obtain. The ovarian veins are small, and very likely do not dilate enough to harbor a propagating thrombus of sufficient size to produce a major embolism. The approach to the inferior vena cava may therefore be entirely extraperitoneal.

One of two incisions may be employed. The first (Fig. 5) is that customarily used in exposing the right iliac vessels, and is made approximately parallel to the inguinal ligament extending laterally toward the flank. After retraction of the peritoneum mesially, the right common iliac vein is clearly brought into view; further retraction up-

ward and inward discloses the lower inferior vena cava. The alternate incision (Fig. 6) is placed higher up in the flank. It is the approach usually employed in the operation of lumbar sympathectomy. It gives ready access to the vena cava, and appears to be the preferable route. If troublesome bleeding is encountered, the better exposure rendered by the lumbar incision makes control of such a complication less difficult. Also, little manipulation is required in tying off the vena cava through this incision, a consideration if much thrombus is present in the iliac vessels. Actual ligation of the vena cava is done with two heavy braided-silk ligatures placed about the vessel 2 or 3 cm. apart. Caution should be used when placing these ligatures in the region of the lumbar veins. These veins, four in number, on either side of the lower vena cava may easily be injured in the maneuver of sliding the ties under the main venous trunk. It is necessary neither to open nor to divide the inferior vena

FIGURE 4. Diagrammatic Sketch Illustrating the Abundant Collateral Venous Supply following Ligation of the Inferior Vena Cava.

The venous return is comparable to that obtained when a bilateral common-iliac-vein interruption is performed.

cava. If a thrombus is contained within the vessel, not enough will be detached to be dangerous. Ligation will serve the purposes of interruption equally as well as division.

The determination of venous pressures in measuring the status of venous return

ing ligation of the inferior vena cava, is probably of considerable value. It is apparent that venous pressure is considerably raised following occlusion of a

rapidly after interruption of the vena cava. Theoretically, in cases of advanced age with failing myocardium, caution should be used in ligating the in-

FIGURE 5. *The Abdominal Extraperitoneal Operative Approach to the Lower Inferior Vena Cava.*

main venous trunk, without, however, causing any undue effect on a normal heart muscle. If pressure in the great veins becomes excessive, the heart muscle responds by contracting more vigorously.

inferior vena cava. Further studies are necessary for fuller understanding of this problem.

Clinically, both the immediate and the remote effects of caval ligation are satisfactory. Eight cases

FIGURE 6. *The Lateral Extraperitoneal Operative Approach to the Inferior Vena Cava.*
The incision is the one customarily used in lumbar sympathectomy.

propelling more blood into the arterial tree and thereby lowering venous pressure and maintaining it at a normal level. It is thus evident that venous pressure should return to normal quite

of interruption of the inferior vena cava have been performed in this series. In 5 of these, there had been obvious thrombotic involvement of the lower extremities; in 3, pulmonary embolism had oc-

curred but no source was evident. In no case have there been any untoward postoperative effects. Minimal discomforts, such as heaviness, numbness and moderate swelling, have been observed by patients, but are not of sufficient magnitude to interfere with their usual everyday duties. Edema of the legs, which at first thought seems to be of outstanding importance, is not so frequent or so pronounced as after division of the femoral vein, and with the passage of time usually clears up.

CASE 4. J. McC, a 41-year-old man, was brought to the hospital in December, 1939, following an unusual accident 8 weeks previously. He had been struck in the backs of both knees by an automobile bumper, suffering extensive contusions and abrasions but no fractures. Considerable swelling, coldness, numbness and mottled discoloration of both lower legs followed. On examination the pedal, popliteal and femoral pulsations were absent in both legs, which were markedly swollen and still showed signs of hematomas in both popliteal spaces. The feet were cold and cyanotic, but the patient could move his toes and feet without difficulty.

A transperitoneal exploration of the pelvic vessels was performed. Extensive thrombosis was observed in both right and left common iliac arteries and veins, leading up to the bifurcation of the aorta and vena cava. A left common iliac arterectomy, with removal of a 5-cm. segment of the vessel, was done. It was decided to tie off each common iliac vein, but profuse bleeding from one of the lower lumbar veins dictated an interruption of the inferior vena cava above the bleeding point. The patient recovered after a stormy and protracted convalescence. The immediate effect on the swelling of the legs was striking. Within 48 hours the edema began to subside and did not reappear even on standing. The legs have remained free of swelling since the operation (Fig. 7).

This case illustrates the rapid collateral anastomoses that are effected after interruption of the inferior vena cava, even in the presence of a fairly well-advanced venous thrombosis.

SUMMARY AND CONCLUSIONS

Two indications for interruption of the inferior vena cava have been suggested: when concurrent phlebothrombosis exists in both lower extremities and has extended to or above the inguinal ligament; and when pulmonary embolism has occurred and its source is not evident.

In one's enthusiasm for diagnosing lower-leg thromboses as the *bête noir* in pulmonary embolism, the fact that aseptic thrombosis may exist in the large pelvic vessels and initiate a serious embolism

should not be overlooked. If one is to operate on cases of deep venous thrombosis on suspicion alone, the best assurance that can be given for the patient's

FIGURE 7. Photograph of the Patient's Legs (Case 4) Five Years after Ligation of the Inferior Vena Cava.

Note the absence of swelling. At no time following operation was any swelling apparent in either extremity.

safety is the highest possible ligation compatible with adequate venous return.

THE CRUVEILHIER-BAUMGARTEN SYNDROME*

Report of a Case

ALEXANDER BLAIN, III, M.D.,† AND MUIR CLAPPER, M.D.‡

DETROIT

INFREQUENTLY a venous hum or bruit occurs in the dilated collateral venous channels that may develop in portal obstruction. In 1942, Armstrong et al.¹ reviewed the 53 published cases of this phenomenon and added 2 cases of their own. Actually, 5 of the cases — including 1 of Armstrong's — showed persistence of a patent umbilical vein without portal obstruction. Since the review of Armstrong, several additional cases of portal obstruction associated with a venous hum heard over the dilated collateral veins have been reported, mainly by English and French authors.

HISTORICAL CONSIDERATIONS

Pégot^{2,3} in 1833 observed a patient who had dilated veins in the abdominal wall, a caput medusae and a loud venous hum at the umbilicus. Post-mortem examination revealed a widely patent umbilical vein associated with a small liver and spleen that were grossly normal in appearance. This case was again reported in 1835 by Cruveilhier,⁴ who postulated that the patient had a congenital defect of the umbilical circulation with atrophy that was probably secondary to this defect. Baumgarten⁵ in 1907 reported the case of a sixteen-year-old boy who had distended abdominal veins, ascites, splenomegaly, anemia and leukopenia. Post-mortem examination revealed a widely patent umbilical vein, splenomegaly "not of the Banti type" and an atrophic liver, with subcapsular increase in interlobular connective tissue. It was Baumgarten's belief that the disease was due to congenital failure of obliteration of the umbilical vein with hypoplasia of the liver. He emphasized the absence of a well-developed cirrhosis. Sappey,⁶ however, in 1859 stated that the large vein found in the falciform ligament in some cases was independent of the umbilical vein.

Thayer's⁷ review of the 19 cases published up to 1911 demonstrated that a majority of the cases that presented a venous hum had good evidence of cirrhosis of the liver without a patent umbilical vein. Thayer added a case from the Johns Hopkins Hospital in which the venous hum was definitely associated with a dilated collateral circulation due to portal obstruction in a patient with hepatic cirrhosis.

Hanganutz⁸ in 1922 collected 6 cases of partial or total persistence of the umbilical vein in what he

termed "Cruveilhier-Baumgarten cirrhosis." Several authors subsequently published case reports under this title. Later Fiessinger and Michaux⁹ analyzed the reported cases together with their own cases and concluded that Cruveilhier-Baumgarten cirrhosis was not truly a disease entity.

Armstrong et al.¹ accepted the term "Cruveilhier-Baumgarten syndrome" as applying to those cases having a clinical picture of portal obstruction featured by a loud abdominal murmur and thrill and periumbilical venous distention. After analyzing the data of the published cases, they accepted only 4 as having the true congenital abnormality that results in Cruveilhier-Baumgarten disease as originally described. They were able to add 1 case of their own from the Los Angeles County Hospital.

In differentiating the true Cruveilhier-Baumgarten disease, a very rare congenital anomaly of which only 5 well-proved examples are known, and the Cruveilhier-Baumgarten syndrome, which is usually the result of cirrhosis of the liver, Armstrong states:

... any patient having portal hypertension, generally with splenomegaly, and in whom evidence in the form of visible veins, murmurs and thrill of excessively prominent umbilical circulation exists, merits the diagnosis of *Cruveilhier-Baumgarten syndrome*. . . . Those cases which show at necropsy patency of the umbilical vein itself together with atrophy and little or no fibrosis of the liver would then be considered as examples of *Cruveilhier-Baumgarten disease*.

Lutembacher¹⁰ in 1936 reviewed the subject of the genesis of the venous hums and proved that they arise from veins, being most intense at the point where a small vein enters a dilated vein. The bruits have most often been heard either in the epigastrium over the course of the falciform ligament (containing dilated periumbilical veins) or over dilated superficial veins. They have also been heard in the splenic area, over dilated coronary veins and over the liver. The murmurs heard in the Cruveilhier-Baumgarten syndrome have been described as "the roaring of a wind through a cave or humming of a top" (Gambarati, quoted by Thayer⁷) and, in 1 case (Catti¹¹), as "a musical ringing sound like that of an Aeolian harp."

The murmur in the following case was continuous in nature and sounded somewhat like a hurricane. It was best heard over a prominent superficial varicosity near the umbilicus.

CASE REPORT

A. M., a 46-year-old man of Rumanian birth, was admitted to the Detroit Receiving Hospital on March 23, 1944, complaining of swollen legs and a distended abdomen of 8 months'

*From the Medical Service, Detroit Receiving Hospital, and the Department of Medicine, Wayne University College of Medicine.

duration. The past history revealed chronic alcoholism of long standing. He had been imbibing three or four bottles of beer and several drinks of whisky daily since the age of 14. It is of unusual interest that the abdomen had been tapped for ascites 23 years previous to the present illness after a progressive enlargement of 3 months' duration. Four thousand cubic centimeters of fluid was removed. Following the paracentesis there was no abdominal distention until the onset of the present illness. In July, 1943, the patient noticed a slight swelling near the umbilicus, just under the skin and easily reducible with a finger. This mass was "blue" (apparently a vein) and marked the onset of a gradual and generalized enlargement of the abdomen that progressed until the time of admission. The abdominal swelling was painless until 1 month prior to admission. Edema of the ankles had been present for 5 months. There was no cough, dyspnea, palpitation, hematemesis, tarry or bloody stools or the like. A thorough dietary history revealed no specific nutritional deficiency but rather a generally poor food intake.

Physical examination revealed a well-developed, slightly icteric man with a markedly distended abdomen and pitting edema of the ankles. Over the tense abdominal surface were many large dilated veins that filled from below upward. These veins fused about the umbilicus to form a classic caput medusae (Fig. 1). Numerous spider angiomas were present over the shoulders, back and abdomen. The tongue was smooth and of a striking magenta color. The head and neck were otherwise normal. Examination of the chest revealed a few moist crackling rales at the lung bases. The heart was slightly enlarged to the left, and there was a soft blowing systolic murmur at the apex. Abdominal examination revealed shifting dullness and a fluid wave. A continuous thrill was easily palpated over the large dilated vein just above and to the right of the umbilicus (Fig. 2). Auscultation in this area revealed a continuous murmur that was extremely loud but varied in intensity ("like a hurricane"). Pressure on the vein below this dilatation obliterated the venous hum and thrill. The scrotum and the lower extremities from the hips down exhibited marked pitting edema.

FIGURE 1. Infrared Photograph Showing the Caput Medusae.

The liver and spleen could not be palpated. The rectal and neurologic examinations revealed nothing significant.

The serum albumin level was persistently low, varying from 1.6 to 2.6 gm. per 100 cc. in six determinations. The lowest serum globulin level was 4.2 gm. per 100 cc., and the highest 4.7 gm. The amount of urobilinogen in the urine on repeated examination was markedly increased as measured by a rough dilution method, positive tests being obtained

on urine diluted as much as 1:400. After the oral administration of 6 gm. of sodium benzoate in the performance of the hippuric acid test, an amount of hippuric acid equivalent to 1 gm. of benzoic acid was excreted in a 4-hour urine specimen. Repeated icterus indices varied from 10 to 50 units

FIGURE 2. Photograph Showing the Varicosity near the Umbilicus over Which the Intensity of the Venous Hum Was Greatest.

The van den Bergh reaction was direct, immediate and positive. The serum bilirubin was 0.9 mg. per 100 cc. Hematologic studies revealed a hemoglobin of 11 gm. per 100 cc. and a red-cell count of 3,810,000. This gave a color index of 1.01. The white-cell count was 9950, with 82 per cent neutrophils (68 per cent filamented), 9 per cent lymphocytes, 7 per cent eosinophils and 2 per cent monocytes. The neutrophils contained toxic granulations. The platelet count was 297,000. The bleeding time was 2.5 minutes, the coagulation time 2.5 minutes, and the prothrombin 78 per cent of normal. Clot retraction began in 45 minutes and was complete in 4 hours. Urinalyses were persistently negative. Repeated stool examinations were benzidine-positive and contained bile. Over 1000 cc. of ascitic fluid was aspirated in each of three paracenteses. This fluid was negative for neoplastic cells, blood and tubercle bacilli. Its specific gravity of 1.016, and an albumin content of 8.4 gm. per 1000 cc. showed it to be a transudate.

An electrocardiogram revealed a sinus tachycardia and evidence of myocardial damage—early left ventricular in type. A stethogram recording made simultaneously with the electrocardiographic tracing showed a continuous murmur the intensity of which was greatest at the umbilicus. A chest x-ray film showed elevation of both leaves of the diaphragm due to the abdominal distention by fluid. Above the diaphragm there were patchy areas of atelectasis at both lung bases. The venous pressure in the right antecubital vein was equivalent to that of 6 cm. of saline solution, as contrasted with a venous pressure of 17 cm. in a dilated superficial vein near the site of origin of the venous hum.

On April 18, the patient suddenly became drowsy and lapsed into coma. He vomited and developed Kussmaul breathing, and died on the following day.

Unfortunately, permission for autopsy could not be obtained.

This patient's long history of chronic alcoholism, together with the hypoproteinemia, icterus, abnormal benzoic acid excretion, urinary urobilinogen and the findings of portal obstruction, established the diagnosis of cirrhosis of the liver. The demon-

stration of a venous hum in association with proved cirrhosis of the liver suggests strongly that this case is an example of the Cruveilhier-Baumgarten syndrome rather than Cruveilhier-Baumgarten disease, in which the venous hum is due to a persistence of a patent umbilical vein. In the absence of post-mortem examination we cannot be absolutely certain that a patent umbilical vein was not also present, but the rarity of this anomaly makes this possibility quite unlikely.

SUMMARY

A case of hepatic cirrhosis presenting the features of the Cruveilhier-Baumgarten syndrome is reported. A brief history of this syndrome and its relation to the extremely rare congenital Cruveilhier-Baumgarten disease are discussed.

MEDICAL PROGRESS

ECZEMA*

FRANCIS M. RACKEMANN, M.D.†

BOSTON

A DIAGNOSIS of "eczema" is never a sufficient one. In recent years the term has come to be used more and more for those cases in which there is a suggestion that the cause of the dermatitis is allergy, and that the eczema depends on a sensitiveness to one or another foreign substance that affects the patient either by ingestion, by inhalation or by direct contact.

The present conception of eczema is remarkably new. In 1892, Besnier¹ wrote a "*Première note et observations préliminaires pour servir d'introduction à l'étude des prurigos diathésiques*." He recognized that certain dermatoses that came and went in attacks depended on something wrong with the body as a whole and were not merely a disturbance that was limited to the skin itself. It was twenty-two years later, in 1914, that Rasch,² a Norwegian, named eczema of a certain variety "prurigo of Besnier." The description referred to the type of eczema which occurs in older children and young adults, and in which the distribution of lesions to the face, neck and antecubital and popliteal spaces is particularly characteristic. Brocq called it "neurodermite," as Hill³ has explained, but in more recent years it has passed under the name of "flexural eczema" and sometimes of "eczema with lichenification." Nowadays it is best designated as "atopic" dermatitis or perhaps "allergic dermatitis" or "atopic eczema," the adjective "atopic," proposed

by Coca,⁴ referring to the factor of inheritance, as well as to a mechanism comparable to that of hay fever and asthma.

Meantime, Schloss's⁵ study of the baby sensitive to eggs, almonds and oatmeal was published in 1912. Goodale⁶ described horse asthma in 1914, and in 1916 came the first comprehensive paper on human sensitization — that by Cooke and Vander Veer.⁷ Also in 1916, Blackfan⁸ tested eczematous infants with various substances and demonstrated that a high proportion of them were skin-sensitive to egg white. This paper furnished the first real evidence that allergy may be a factor in infantile eczema. The comprehensive studies of Walker⁹ on asthma began in 1917. In 1920, Ramirez¹⁰ likewise made skin tests on infants with eczema and showed that 30 of 78 cases were skin-test-positive. At the same time he pointed out that those children who suffered also from asthma and hay fever were likelier than others to show positive skin reactions.

Treatment on the basis of eliminating certain foods, especially eggs and cow's milk, from the diet began. In 1923, O'Keefe¹¹ found that the diet treatment was successful even though he was unable to demonstrate positive skin tests, and he first pointed out that "variations in the threshold of sensitivity in various tissues may be the factor which determines whether hay fever, asthma or eczema will result from foreign proteins with which the tissues are brought in contact."

In the meantime, another type of eczema was in process of description when Bloch¹² found that

The liver and spleen could not be palpated. The rectal and neurologic examinations revealed nothing significant.

The serum albumin level was persistently low, varying from 1.6 to 2.6 gm. per 100 cc. in six determinations. The lowest serum globulin level was 4.2 gm. per 100 cc., and the highest 4.7 gm. The amount of urobilinogen in the urine on repeated examination was markedly increased as measured by a rough dilution method, positive tests being obtained

on urine diluted as much as 1:400. After the oral administration of 6 gm. of sodium benzoate in the performance of the hippuric acid test, an amount of hippuric acid equivalent to 1 gm. of benzoic acid was excreted in a 4-hour urine specimen. Repeated icterus indices varied from 10 to 50 units

FIGURE 2. Photograph Showing the Varicosity near the Umbilicus over Which the Intensity of the Venous Hum Was Greatest.

The van den Bergh reaction was direct, immediate and positive. The serum bilirubin was 0.9 mg. per 100 cc. Hematologic studies revealed a hemoglobin of 11 gm. per 100 cc. and a red-cell count of 3,810,000. This gave a color index of 1.01. The white-cell count was 9950, with 82 per cent neutrophils (68 per cent filamented), 9 per cent lymphocytes, 7 per cent eosinophils and 2 per cent monocytes. The neutrophils contained toxic granulations. The platelet count was 297,000. The bleeding time was 2.5 minutes, the coagulation time 2.5 minutes, and the prothrombin 78 per cent of normal. Clot retraction began in 45 minutes and was complete in 4 hours.

Urinalyses were persistently negative. Repeated stool examinations were benzidine-positive and contained bile. Over 1000 cc. of ascitic fluid was aspirated in each of three paracenteses. This fluid was negative for neoplastic cells, blood and tubercle bacilli. Its specific gravity of 1.016, and an albumin content of 8.4 gm. per 1000 cc. showed it to be a transudate.

An electrocardiogram revealed a sinus tachycardia and evidence of myocardial damage—early left ventricular in type. A stethogram recording made simultaneously with the electrocardiographic tracing showed a continuous murmur the intensity of which was greatest at the umbilicus. A chest x-ray film showed elevation of both leaves of the diaphragm due to the abdominal distention by fluid. Above the diaphragm there were patchy areas of atelectasis at both lung bases. The venous pressure in the right antecubital vein was equivalent to that of 6 cm. of saline solution, as contrasted with a venous pressure of 17 cm. in a dilated superficial vein near the site of origin of the venous hum.

On April 18, the patient suddenly became drowsy and lapsed into coma. He vomited and developed Kussmaul breathing, and died on the following day.

Unfortunately, permission for autopsy could not be obtained.

This patient's long history of chronic alcoholism, together with the hypoproteinemia, icterus, abnormal benzoic acid excretion, urinary urobilinogen and the findings of portal obstruction, established the diagnosis of cirrhosis of the liver. The demon-

including the importance of skin tests. In the next year he with Pratt²¹ showed that in those infants sensitive to cow's milk the lactalbumin caused more trouble than the casein. It is to be wondered whether cottage cheese might not be a useful addition to an otherwise restricted diet.

In the meantime, Hampton and Cooke²² and later Simon²³ discovered that human dander contains an allergen to which certain human beings become sensitive and that in certain infants the eczema depends on an allergy to human dander. Hampton and Cooke found that skin reactions to human dander were positive in a few cases but not in enough to support the idea that this dander is a frequent cause of eczema. Simon, on the other hand, found that skin tests by the patch method applied to young children with eczema showed positive reactions to human dander in 15 of 20 cases, whereas in 23 non-eczematous children of the same age there was only a single positive reaction. In a few cases, the prompt improvement that followed the avoidance of contact with human dander was striking. Finally, Simon was able to show that the lesions could be reproduced when, for example, the mother rubbed her hair on the lower abdomen of her child. In another paper he²⁴ found that extracts made from the scales of patients with seborrheic dermatitis gave reactions quite like those of human dander, whereas the scales from patients with psoriasis or exfoliative dermatitis showed nothing. All this work was done by the patch method of testing, since the scratch test remained negative.

One may conclude that in infantile eczema the factor of allergy is present, and in certain cases the lesions disappear when contact with the food or possibly with the dust is removed. On the whole, however, it is recognized more and more that in these children there is some fundamental disturbance that remains unexplained.

Several papers suggest the new trend. Engman and MacCardle²⁵ found that albino rats when fed a diet deficient in magnesium developed lesions similar to those of neurodermatitis. The vitamins have been studied, as might be expected. Kunz²⁶ examined the riboflavin metabolism in 2 cases. Harris and Gay²⁷ treated 20 cases of infantile eczema with large doses of vitamin B complex. In 2 of them there was complete healing and in 11 there were various degrees of improvement, but in 7 cases there was no change. The absorption of vitamin A was found by di Sant'Agnese and Larkin²⁸ to be impaired in 4 cases, but each patient was in extremely poor general condition, besides having severe eczema. On the other hand, Frei²⁹ varied the amount of vitamin A (carotene) in the diet of guinea pigs and studied the ability to sensitize them to old arsphenamine. No significant influence could be demonstrated.

More promising, perhaps, is a new suggestion about fat in eczema. Burr³⁰ showed pictures of a

child before and after treatment with two or three teaspoonfuls of lard each day for a month. The eczema cleared entirely, and the author explains that fat has a sparing action on vitamin B₆, that linoleic acid is important to the health of the skin, and that rats fed on a fat-free diet develop scaly skin with retarded growth, and later kidney lesions. This paper is reminiscent of older theories that eczema depends on too much fat in the diet.

ATOPIC DERMATITIS IN YOUNG ADULTS

In the Army and Navy, eczema is always troublesome, although fortunately the number of cases is not great. In 1943, French³¹ reporting on allergy clinics in the Fourth Service Command, included 1100 cases of eczema as against 8500 cases of asthma and 5300 cases of hay fever. In the Navy, on the other hand, allergic skin diseases, according to Sulzberger,³² comprised 8875 cases, whereas asthma and hay fever together numbered only 1257 cases. There were altogether 33,539 cases of skin diseases in the area described. Hampton and Rand³³ studied those men who were examined for certificates of disability for discharge on account of diseases of allergy. Of 1633 subjects, 286 had asthma, and 86 of them were discharged; 448 had hay fever, and 1 was discharged; 117 had urticaria, and 7 were discharged; 24 had atopic eczema, and 2 were discharged; and 35 had contact dermatitis, and 1 was discharged. Gold and Bazemore,³⁴ of Camp Blanding, give the clinic admission rate for asthma as 9.5 per 1000, for hay fever 3.3 and for eczema 12.3. The considerable variation of these figures is interesting; in some areas asthma seems much more important than eczema, whereas in other places the conditions are reversed. Presumably, the discrepancies depend on the difficulty of accurate diagnosis or on the classification used.

In the atopic dermatitis of adults, hypersensitivity to foods plays a part in not over 10 or 15 per cent, according to Osborne, Jordon and Hallett.³⁵ In their paper, stress is laid on external contact and environmental allergy pointing to wool, silk, feathers, other epidermals, soaps and laundry chemicals. As they say, a visit to the home of the patient is indispensable. Stroud³⁶ has commented on this, writing, "Success in the treatment of allergic dermatitis is proportionate to knowledge of the causative factors." Hill³⁷ has shown that with increasing age the importance of environmental allergy (dust substances) rapidly increases. Scratch tests with dusts were positive in only 10 per cent of 38 eczematous infants, but after the age of one they became positive in 37 per cent and after two in 50 per cent. Feinberg³⁸ stresses the molds, describing 14 cases in which the eczema became much worse during the pollen and mold seasons. In a number of patients, I have found that the eczema cleared when the patient went away from home and recurred on his return. Such a history is always im-

when certain chemical substances like quinine, iodoform and turpentine were applied to the unbroken skin and were held in contact for some hours, areas of typical eczema developed on the test site. He came to the conclusion that the so-called "constitution of the skin" was the decisive factor in producing the reaction. Thus, when a patient with horse asthma was tested by this patch test with horse protein, an area of eczema developed in the arm, whereas when normal persons were tested in the same way, no reaction resulted. For some years it was not appreciated that the kind of eczema associated with asthma and hay fever and dependent on a factor of inheritance was quite different from the other kind of eczema that was localized to exposed surfaces and dependent on direct sensitization of a small area of exposed skin.

Recently, Cooke¹³ has questioned the propriety of distinguishing so sharply between atopic eczema and contact dermatitis. Whereas it is quite true that both disorders depend on allergy, the facts, first that atopic eczema is often associated with other evidences of allergy whereas contact dermatitis is not, second that atopic eczema is not nearly so frequent as contact dermatitis, — the incidence of poison ivy, for example, is admittedly high, — and third that passive transfer antibodies (reagins) can be demonstrated in atopic eczema but not in contact dermatitis, make it reasonable to distinguish them.

CLASSIFICATIONS

Many authors have classified eczema. Several old names based on the clinical appearance — the morphology of the eczema — have been given up, and new names have been added. Seborrhea, with its oily skin and distribution to the hair line, the face and the upper portions of the chest and back, probably does depend on a disturbance of the skin itself.

Fungus disease, often hard to distinguish from eczema, is found oftener on the feet and hands, in the crotch, in the axillas and sometimes on the neck. In most cases it is possible to recognize the two types of eczema due to allergy. In atopic dermatitis, the characteristic feature is the typical distribution of the lesions to the face, neck and cubital and popliteal spaces. Skin tests made by the scratch or intradermal method show immediate positive reactions of the wheal and erythema type, and reagins that can transfer the skin sensitiveness to a local test site on the arm of a normal person are found in the blood. In contact dermatitis, the lesions are on exposed parts — usually the hands and face. Here the foreign substance reaches the skin by direct contact and not through the blood stream underneath. Whether this type depends also on heredity is not clear; the majority of people are sensitive to poison ivy, and in industry the frequency of dermatitis that involves the hands and

sometimes the face is greater than that of hay fever or asthma.

Atopic dermatitis can be divided for convenience into the infantile and adult types. In both, itching is the most significant feature. In infancy the lesions are on the face, where vesiculation and later oozing and crusting are characteristic. In older children and young adults vesiculation is not so marked, and in place of it comes lichenification, with thickening of the skin and later pigmentation. Although it is probably true that the two kinds of eczema differ chiefly in the location and concentration of sensitizing antibodies and so in the degree of clinical involvement, and that the differences may be greater in quantity than in kind, it is of practical importance to distinguish them, if only because in the one type the investigator looks for food or dust as the cause, whereas in the other he considers cosmetics, soaps and dyes, as well as chemicals in wide variety.

ATOPIC ECZEMA IN CHILDHOOD

Hill¹³ has written, "To talk about eczema is easy; to cure the patient is quite another matter." In 1935 he¹⁴ wrote an extremely interesting paper on the evolution of atopic dermatitis. He showed how the infantile form may subside of itself within a year or two when the child outgrows his sensitiveness, whereas in other cases this early type merges by slow degrees into the adult type, with thickening in place of weeping. Hill believes that the presence of a positive skin reaction to egg, which is observed in at least half the cases, is easy to explain. Egg is a protein easily digested by the adult; it is a common food, and it has been shown that egg can pass unchanged through the intestinal wall and the placenta so as to sensitize the fetus in utero. The significance of the positive skin test is not quite so easy to explain. In some cases there is great improvement when egg is withdrawn from the diet, but in most it is impossible to demonstrate any clinical relation between the elimination of egg and the improvement of the eczema: indeed, most of the infants have never had egg. Moreover, as Hill explains, it is not possible to produce atopic sensitization in a normal nonatopic person no matter how much egg white may have been given by injection. "Precipitins," he writes, "are produced but never eczema, asthma or hay fever. . . . The infant is prepared for eczema by his sensitivity to egg, but the actual eczema may be brought about by other causes of which nothing definitely is known." Smyth et al.¹⁵ were able to produce striking relief in 47 of 160 cases by changes in diet based on the finding of positive skin reactions to foods.

After 1935 there was a hiatus in the study of infantile eczema. Sulzberger and his co-workers¹⁶⁻¹⁹ did much to clarify the relations between this and other forms of skin disease. In 1940, Hill²⁰ presented a useful discussion of the diagnosis and treatment,

aneous hypersensitiveness to the drug, and he cautions against the indiscriminate use of sulfonamides in local treatment, which may sensitize the patient and so preclude the subsequent use of these drugs should serious illness supervene. Shaffer, Lentz and McGuire⁵⁴ have also found that sensitiveness to sulfathiazole can be induced by local therapy and subsequently elicited by oral medication.

As a test for sulfonamide hypersensitiveness, Leftwich⁵⁵ has made an important contribution. In tests for drug allergy, the application of most drugs by themselves to the skin produces no local reaction. The reaction must depend on a chemical combination between the drug and the serum protein. Leftwich found that the serum of patients who are saturated with the sulfonamide drugs and whose blood level is therefore high is an extremely useful testing agent. It is important that the donor patient shall have received the drug for at least five days and that the serum be used fairly soon after its separation. It is also important that the serum from a normal person be drawn at the same time and be kept under the same conditions so that the observations can be controlled. Leftwich reports that when the sulfonamide-bearing serum was injected intradermally into 30 patients who were clinically sensitive to the sulfonamide drugs, the results were positive in 28, with a wheal and erythema reaction that appeared in fifteen minutes. This may be significant particularly if the findings can be confirmed.

The legal aspects of contact dermatitis, especially in connection with industry and occupation, are sometimes complex. The employer has provided the specific substance, but the worker has provided the kind of tissue that is capable of developing a sensitiveness to that substance. Each of the two factors is necessary, and it is not always easy to separate them. Downing⁵⁶ has discussed the matter in an interesting paper.

* * *

To repeat, the diagnosis of eczema is never a sufficient one. The problem is always complicated, but if one tries to visualize the probable mechanism that is operating in the particular patient, it is easier to find the cause through a better classification of the possible factors. As usual in the study and treatment of all the diseases due to allergy, it is the clinical history taken from the point of view of the detective more than from that of the physician that leads to the proper solution. In doing this, however, one must at least know what the possibilities are. In the background of all these cases there is a fundamental disturbance of normal physiology; this is a platitude that cannot be disregarded.

portant and emphasizes once more the need for great care in history taking. It is always worth while to repeat the two most important points. First, one should record the passage of time and the relation to various foods and events by the actual dates on which they occurred and try to explain the end of the attack just as carefully as the onset. Secondly, one should account for all the time from the beginning of the disease to the present. If there was an interval of a year or two or perhaps of only a few months in the summer when the skin was quite clear, it is essential that this fact be noted in the history. Often such knowledge leads to the discovery that during the free period the patient was sleeping in a different house or perhaps living and sleeping in a different room in his own home.

Some years ago, Becker³⁹ laid stress on the fact that treatment of the patient as a whole was quite as important as treatment of his eczema. A woman who had had an eruption on the neck was playing thirty-six holes of golf every day and was in a state of chronic fatigue. With proper advice directed toward the improvement of general hygiene, the eczema cleared, even though contact with necklaces, dresses and a mink coat were the same after as before her visit to the physician.

The treatment of atopic eczema in adults is not easy; there is no specific treatment. Local treatment is necessary, but one should realize that the ointment or wash that does good in one case may be useless in the next. All too often one finds that too much local treatment does more harm than good. Potassium chloride, extra vitamins and nonspecific therapy of various kinds have all been used with success in certain cases but without effect in others. The ingestion of lard mentioned above for infantile eczema has been tried in older patients by Finnerud, Kesler and Wiese⁴⁰ with little evidence of success.

CONTACT DERMATITIS

In writing a review of the literature of drug allergy, I⁴¹ was impressed by finding that in different patients the same drug might cause a variety of manifestations. Arsenic, for example, might cause in different cases a diffuse generalized dermatitis medicamentosa, asthma, agranulocytosis or a local contact dermatitis. This finding was an excellent demonstration that sensitiveness depends on the concentration of antibodies in certain tissues that are more sensitized than others. As described above, the principles of contact dermatitis are somewhat the same as those for atopic eczema, but they vary in degree; the sensitiveness is not general but is often confined to one area of the skin. The so-called "fixed drug eruptions" are particularly interesting, for in this condition the patient has a certain spot, perhaps on the thigh, face or arm, that always flares up when the drug is taken by mouth or by hyperdermic needle. This is hardly a contact dermatitis,

but it illustrates the principle of localized tissue sensitiveness.

Contact dermatitis becomes increasingly important in industry as more and more complex chemical substances are devised. In contact dermatitis, the typical lesions are often on the hands; the backs of the fingers flare when the surgeon puts on the wrong kind of rubber gloves or the pharmacist or dentist comes in contact with novocain or quinine or other chemicals. They may be on the face, much trouble arising from cosmetics. Hazen⁴² declares that the most frequent cause of dermatitis of the eyelids is nail polish. Howell⁴³ found that all brands of nail polish could cause the trouble, and Shelton⁴⁴ incriminated the nail-enamel foundation. Epstein⁴⁵ described the case of a mother and two daughters, aged four and six, who developed a contact dermatitis from hair lacquer pads. In the children the lesions at first suggested mumps because of the distribution and swelling, but later on, patch tests with the lacquer pads gave positive reactions. Pyle and Rattner⁴⁶ report the case of a medical officer who developed an inflammation of the eyelids and conjunctivas while preparing solutions of penicillin. Schwartz⁴⁷ has described 1904 cases constituting 30 per cent of those who worked in an explosive factory producing tetryl. The face, neck, eyes and all parts touched with the soiled hands are involved, and if exposure continues anemia and leukopenia may follow. Schwartz, Peck and Dunn⁴⁸ describe a dermatitis that depends on ureaformaldehyde and phenolformaldehyde resins, and Peck⁴⁹ finds that certain cutting oils and solvents that remove the fats and oils and dry the skin cause a local dermatitis. Baker's eczema is not frequent. At first it was thought that the trouble came from the ammonium persulfate and other substances added to the flour to make it easier to handle, but patch tests with these substances showed no reactions, and Van Vonno and Struycken⁵⁰ concluded that the trouble depended on the wheat flour itself.

The reactions that come from the sulfonamide drugs are of more practical interest. These are of great variety, ranging from a severe generalized exfoliative dermatitis in the case described by Johnson⁵¹ to a local reaction when a drug is applied for local treatment. Kasselberg⁵² described the case of a young man who had been treated with sulfathiazole for gonorrhea. Twenty days later the drug was changed to sulfamerazine, and after forty-eight hours a generalized macular eruption appeared, which three days later turned into a pemphigus-like disease, with numerous bullas and blebs filled with straw-colored fluid. One forgets that to produce sensitiveness, either local or general, one must follow the principles of the classic anaphylaxis experiment with its three factors — first the sensitizing dose, second a time interval and third the test or shocking dose. Park⁵³ has described 12 cases in which local sulfonamide therapy resulted in a cu-

became gradually elevated to 20,000, with 75 per cent neutrophils, 9 per cent lymphocytes and 16 per cent monocytes; toxic granules were prominent. Despite repeated transfusions the red-cell count could not be maintained above 3,000,000. The urine showed increasing amounts of bile, with a ++ to +++ test for albumin and considerable sugar during intravenous glucose therapy. The patient had frequent chills, with occasional fever, while receiving amino acids (Amigen) intravenously. The size of the liver remained unchanged, but it became more tender.

During the third week the patient developed a mousy odor to her breath and the jaundice deepened, with the appearance of dullness and rales at both bases, ascites and sacral edema. She became depressed, stuporous and finally semicomatose, with an erratic temperature and pulse. She had three days of subnormal temperature and expired quietly on the twenty-third day.

DIFFERENTIAL DIAGNOSIS

DR. JOSEPH C. AUB: Here is a woman who had epigastric fullness and discomfort, which suggest increased portal pressure because of the association with occasional gastrointestinal bleeding. The record implies that there was nothing wrong above the diaphragm and that all the difficulty lay in the abdomen. We are dealing with a large liver, possibly an enlarged spleen and an epigastric mass.

I should like to see the x-ray films, with particular reference to the epigastric mass that is mentioned, as well as the condition of the bones. My interest in the bones is based on the extraordinary albumin-globulin ratio, which discloses such a high level of globulin that one must consider the presence of multiple myeloma.

DR. MILFORD D. SCHULZ: These films show the liver edge extending below the crest of the ilium. The right kidney apparently has rotated and overlies the crest of the ilium.

DR. AUB: You see no evidence of the epigastric mass?

DR. SCHULZ: No. The spleen does not seem large; you can see its tip about where that of the normal spleen usually appears.

I do not believe that the chest is normal. There is something in the right apex. I cannot be sure whether it is in the lung or in the pleura. It is what has been called thickened apical pleura, but may represent atelectasis in the upper lobe. The bones, so far as one can see, are quite all right.

DR. AUB: The patient had an erratic temperature, which suggests sepsis. One or two times it went up to 104°F., apparently owing to the injection of amino acids.

Here then is a woman with a fever, who had had symptoms for five years, and who entered the hospital with a big liver and no intense amount of liver damage. The liver deteriorated rapidly, according to the history, and she died with evidence

of severe liver damage. I think that one can rule out obstructive jaundice or difficulty with the bile ducts on that basis. I believe that this woman had severe damage to the hepatic cells themselves, and that she died of cholemia.

The albumin-globulin ratio in the blood interested me, for there was a high total protein, made up mostly of globulin, the albumin being extremely low. One must discuss four diagnoses: myeloma, amyloidosis, hemochromatosis and cirrhosis.

This woman had severe liver damage, but the blood changes were so marked that one wonders whether they could have been due to liver damage. The alternative is to think of myelomatous lesions in the bones. Bone lesions are not essential, however, since this tumor may be found only in the liver. Later in the disease she had a great deal of albuminuria but no Bence-Jones protein in the urine. There is also the queer finding of a couple of metamyelocytes in the blood, which might have been a misdiagnosis of the plasma cells found in multiple myeloma. I should like to make a diagnosis of multiple myeloma but it is unwise to do so, because it is a rare disease and because there is not enough evidence for it in this record.

The next thing that occurred to me was amyloid disease. Albumin in the urine, without abnormality of the sediment, always suggests amyloid disease to me. Was a Congo red test done?

DR. BENJAMIN CASTLEMAN: No.

DR. AUB: The spleen was not particularly large, but I have seen many cases of amyloid disease in which there was no justification for making the diagnosis. It is an interesting point, but without the Congo red test I am incapable of making the diagnosis.

This record does not contain evidence of jaundice sufficiently severe to justify the diagnosis of acute yellow atrophy of the liver. In other words, the diagnosis that must be made involves a big liver that was not functioning. It could have been a fatty liver, early in cirrhosis, but I do not believe that that is likely. She had several other noteworthy findings, namely, an extremely low cholesterol and no cholesterol esters in the blood, which imply severe liver damage, and a normal phosphatase, indicating, however, that the liver cells were not being rapidly destroyed. Amyloid disease should be entertained as a serious possibility.

In favor of hemochromatosis is the sugar in the urine even though the blood-sugar level is not given.

DR. CHESTER M. JONES: But that was following intravenous glucose therapy.

DR. AUB: The urine is reported to have given a green reaction with Benedict's solution on entrance to the hospital, but this is not adequate evidence for hemochromatosis.

The fourth thing is cirrhosis. I think that she had a mild cirrhosis, not enough to give ascites and therefore not a severe cirrhosis. With an albumin-

EDITH E. PARRIS, *Assistant Editor*

CASE 31221

PRESENTATION OF CASE

A fifty-five-year-old Polish woman was admitted to the hospital complaining of anorexia, weakness and intractable vomiting.

For the past ten years she had had vague epigastric discomfort, with a feeling of tightness across the abdomen. During this same period she took laxatives frequently for constipation. There had been insidious weight loss for probably a long period. During the past five years the epigastric discomfort had become distressing, with occasional nausea and vomiting. For the past four years there had been infrequent episodes of bright-red bleeding from the rectum. About one and a half months before admission she began to vomit frequently. The vomiting was preceded by epigastric distress varying from a feeling of fullness to moderately severe pain. Vomiting always brought relief. Malaise was pronounced during the month before entry. For about three weeks she had coughed up small amounts of bright blood on occasions.

She had had pneumonia one year before admission, from which she recovered uneventfully. She was seven years postmenopausal.

Physical examination revealed a pale, thin, slightly icteric woman with evidence of a moderate amount of recent weight loss. Many teeth were absent, and the remainder carious. The heart size and rhythm were normal. A mild systolic murmur was heard at the apex. The lungs were clear and resonant. The abdomen was flat. There was a

moderately enlarged, tender liver, extending five fingerbreadths below the costal margin. On inspiration a questionable, firm, tender mass was felt in the epigastrium. The tip of the spleen was just palpable beneath the costal margin on inspiration. Pelvic and rectal examinations were negative.

The temperature was 101°F., the pulse 90, and the respirations 20. The blood pressure was 120 systolic, 65 diastolic.

Examination of the blood showed a white-cell count of 11,000, with 64 per cent neutrophils, 28 per cent lymphocytes, 6 per cent monocytes and 2 to 3 per cent of what were thought to be metamyelocytes. Examination of the urine showed a specific gravity of 1.030; it contained no albumin, and a test for sugar was green to orange with Benedict's solution. The sediment showed an occasional red and white cell. The stool was guaiac negative. A Hinton test was negative. The serum protein was 7.95 gm. per 100 cc., with an albumin-globulin ratio of 0.5. The chloride, nonprotein nitrogen and van den Bergh test were normal. The phosphorus was 2.7 mg. per 100 cc., and the alkaline phosphatase 2.1 Bodansky units. The prothrombin time was 35 seconds (normal, 18 to 20 seconds).

X-ray examination of the chest and a gastrointestinal series were normal. An intravenous pyelogram showed a large liver extending to the level of the iliac crest. The right kidney was unusually low in position but was normal in shape and function; the left kidney was normal. A barium enema showed the hepatic flexure to lie extremely low in the abdomen. Proctoscopic examination showed intrinsic disease of the rectum and lower sigmoid.

On the first day the patient passed a small blood clot with her bowel movement, but no bright blood, the stool was of normal color. Occasionally she vomited bile-stained material. Further serum studies a week after admission showed a total protein value of 7.16 gm. per 100 cc., with an albumin-globulin ratio of 0.28. The cholesterol value was 53 mg. per 100 cc., with esters too low to read. The van den Bergh reaction was 17.6 mg. per 100 cc. direct and 28.4 mg. indirect. The cephalin flocculation test was ++++, and the prothrombin time 49 seconds (normal, 18 to 20 seconds); later the prothrombin time increased to 54 seconds. The white-cell count

*On leave of absence.

mediate cause of death, the certificates having been returned. It seems to me that we see a great many persons in whom, without an autopsy, it is impossible to make a diagnosis of the exact type of underlying liver disease and yet the cause of death is undoubtedly hepatic failure. There is an occasional tendency to say that this should be called acute yellow atrophy. In some cases there is a lot of destruction of liver cells, and in others, diffuse carcinomatosis or a similar infiltrative process. One can get this picture with cholemia and yet have no appreciable amount of necrosis. I think that hepatic failure is a good descriptive term for such a final event, just as uremia is in a patient with renal disease.

CASE 31222

PRESENTATION OF CASE

First admission. A fifty-five-year-old business man was admitted to the hospital because of jaundice.

He appeared to be in excellent health until three weeks before admission, when he noticed that his urine had become dark, and his stools pale slate colored. The following week he developed anorexia and had frequent soft stools. The urine remained dark and the stools clay-colored until admission. Twelve days before entry it was first observed that he was jaundiced. He felt fairly well and on the following day played tennis; a day later he developed slight nausea. No pain, malaise, chills or fever was noted at any time. He was examined by his physician ten days before he was admitted. At that time the temperature, pulse and respirations were normal. There was marked icterus of the skin and scleras. He had lost no weight recently. The abdomen was negative. The liver and spleen could not be felt. An x-ray examination revealed no gallstones. The stool was negative for bile, and a cephalin-flocculation test was negative. The icteric index was 42 units. He was placed on a high-carbohydrate, low-fat diet supplemented with vitamins. The patient insisted on continuing his work at the office, where he worked until noon each day. During the week before admission he had three soft clay-colored stools a day and lost approximately 10 pounds in weight.

Six years before admission he had an "ulcer," which recurred a year before admission; both times he responded well to medical therapy. His bowel habits had been normal.

Physical examination revealed a well-developed, fairly thin man who was deeply jaundiced but not bronzed. There was no lymphadenopathy. The lungs were clear, with good expansion. The right half of the diaphragm was quite high. The heart was normal in size, rate, rhythm and sounds. The liver edge could be felt three to four fingerbreadths below the costal margin; it was smooth, rounded and nontender. The spleen was not felt. There was

no ascites or edema. Rectal and neurologic examinations were negative.

The temperature, pulse and respirations were normal. The blood pressure was 120 systolic, 80 diastolic.

The urine was dark, with a specific gravity of 1.026, gave a +++ test for bile, and showed traces of albumin and sugar, with an occasional white cell, red cell and cast in the sediment; the test for urobilinogen was plus in dilution of 1:8. Examination of the blood showed 4,400,000 red cells, with 90 per cent hemoglobin (Sahli), and 8500 white cells. The stool was clay-colored and guaiac negative and contained no bile. The van den Bergh reaction was 11.8 mg. per 100 cc. direct, and 16.7 mg. indirect. The serum nonprotein nitrogen and protein and the prothrombin time were normal. The phosphorus was 3.0 mg. per 100 cc. The alkaline phosphatase was 10.2 units per 100 cc., and a cephalin-flocculation test was negative in forty-five hours.

X-ray examination of the gastrointestinal tract revealed the esophagus to be normal. The stomach contained a moderate amount of secretion and showed slight thickening of the mucosal folds. The duodenal cap was slightly deformed, without definite evidence of a crater. The remainder of the duodenal loop showed no evidence of a pressure defect. The liver appeared slightly enlarged, and the spleen normal. At six hours the barium was in the proximal colon. There were a few calcified nodes in the midportion of the abdomen.

The patient had a poor appetite, but with supplementary intravenous feedings he was maintained on a high-carbohydrate, high-protein, high-vitamin and low-fat diet. He was given an ampule of Hykinone each week. After three weeks his stool became somewhat darker and contained a small amount of bile. The van den Bergh reaction dropped to 9.0 mg. per 100 cc. direct, and 12.4 mg. indirect. The alkaline phosphatase fell to 6.4 units, and the test for urobilinogen in the urine was positive in dilutions up to 1:100.

After four weeks in the hospital the patient was discharged to his home under close observation and with a carefully selected diet. The temperature, pulse and respirations had remained normal, but he had lost 5 pounds and his icterus had not noticeably diminished.

Second admission (nineteen days later). In the interim he had become stronger; he walked about a mile each day but had lost 3 more pounds. His chief complaint during this time was heartburn, which usually came on several hours after meals. There was no nausea, and he was never wakened from sleep. Three days before admission he vomited for the first time, shortly after drinking a glassful of water. The vomitus contained only the fluid that he had recently drunk. On the following evening he again vomited. He spoke of vague, nonradiating discomfort in the epigastrium.

globulin ratio such as she exhibited there must have been little cirrhosis. Severe cirrhosis should give quite marked ascites, because most of the osmotic pressure in the blood is produced by albumin rather than by globulin. With the evidence in the history suggesting a high portal pressure I think one should make a diagnosis of a mild degree of some form of cirrhosis.

One ends up with the question whether she had a tumor. On the basis of mild cirrhosis she could have had multiple liver-cell carcinomas or hepatomas, accompanied by so-called "carcinomatous cirrhosis." That is a perfectly good diagnosis and would explain the fever, because most patients with carcinoma of the liver have a fever, usually from necrosis in the center of the tumor. Such tumors may be myelomatous.

I can make one definite diagnosis, saying that this patient died of severe liver damage, cholemia, in spite of a large liver. I believe that she had a mild degree of cirrhosis. The other diagnosis lies between those that I have mentioned and cannot, I think, be stated with conviction, but I favor a diagnosis of multiple hepatomas.

DR. PAUL C. ZAMECNIK: Our impression was that the patient had Laennec's cirrhosis to begin with, even though there was no evidence of alcohol ingestion. We also thought that she had a superimposed toxic hepatitis or subacute yellow atrophy.

DR. AUB: I did not discuss that possibility because I thought that the slight degree of jaundice on entrance was much against that diagnosis.

DR. ZAMECNIK: It is interesting that during hospitalization she was able to take little by mouth and was largely fed intravenously. As our efforts failed, we decided to try amino acids. Certain members of the staff suggested that in the face of a failing liver amino acids might be an additional burden. Our experience in giving amino acids for a day or two was that the patient's temperature rose and the jaundice deepened, so that we discontinued this therapy, believing that it did her no good.

DR. JONES: I should like to comment on one remark that Dr. Aub made relative to amyloid disease. I do not believe that I have ever seen a case of amyloid disease with hepatic failure and this degree of jaundice. If it occurs, I am not familiar with it. It would not have occurred to me as a possibility. I should think that one would have to include metastatic disease, and I wonder whether metastatic lesions of a cancer of the pancreas ought to be considered.

CLINICAL DIAGNOSIS

Portal cirrhosis, with superimposed toxic hepatitis.

DR. AUB'S DIAGNOSES

Cholemia, due to liver cell destruction.
Cirrhosis of liver, mild.
Multiple liver-cell carcinoma.

ANATOMICAL DIAGNOSES

Acute hepatitis.
Portal cirrhosis?
Bile nephrosis.
Ascites.
Splenomegaly.
Pulmonary tuberculosis, old.
Tuberculous ulcer of ileum.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The liver weighed slightly under 1500 gm. and was extremely tough. One could not put one's finger through the parenchyma, even with the fingernail, indicating the presence of a large amount of connective tissue. It was yellow to greenish brown, with scattered areas of fibrosis. Although the liver was fibrotic, there was no granularity of the surface. One could not make out individual nodules of regeneration on the surface, such as are found in portal cirrhosis. There were also a large number of yellow-orange areas that we believed were foci of necrosis.

Microscopical examination showed few remaining normal liver cells. Most cells were large, swollen and necrotic. Many near the areas of degeneration had four or five nuclei in them, a finding indicating active regeneration or hyperplasia of the liver cells. These multinucleated cells were observed in many of the cases of epidemic jaundice recently reported by Lucké.* In many of the portal areas that could be identified there were lymphocytic and polymorphonuclear infiltration and definite fibrosis. There was in this case, therefore, a severe, acute hepatitis that might be likened to that in cases of epidemic jaundice and that may have been due to a virus or a toxin of some sort. This patient's illness was of ten weeks' duration and I do not believe that so much fibrosis could have been produced in that time. I suppose one has to assume, as Dr. Aub did, that there was an underlying disease that had existed for years, probably a mild cirrhosis. I have recently shown these slides to Lieutenant Colonel Tracy B. Mallory, who believes that this amount of fibrosis can be produced in as short a period as ten weeks. If that is so, we do not have to assume an underlying cirrhosis. The toughness of the gross specimen, however, is in keeping with an old process, which lessened the chances of recovery.

The kidneys were large, weighing 700 gm., and showed a bile nephrosis. The peritoneal cavity contained 1500 cc. of yellowish fluid. The spleen was about twice the normal size, weighing 350 gm.

The lesion in the right apex of the lung proved to be old tuberculosis. The cause for the blood in the stools was a tuberculous ulcer, 1 cm. in diameter, in the terminal ileum.

DR. JONES: More than once there has been objection to the term "hepatic failure" as the im-

*Lucké, B. Pathology of fatal epidemic hepatitis. *Am. J. Path.* 20: 471-593, 1944.

vading and destroying the anatomic relations in that region without giving a big palpable mass. But against that again is the absence of a long story of gall-bladder disease, because gallstones nearly always precede cholecystic carcinoma by twenty-five years or more.

As we go on in the story we find that the patient did begin to have epigastric pain and to vomit. It is also important to notice that the duodenal loop was not widened, because if we grant that there was a tumor well down in the ductal system it would not be surprising to find some abnormality by x-ray in that region. There is some flattening in the upper end of the duodenal loop, and I do not know whether to take that as evidence of an extrinsic mass. I assume that Dr. Schulz does not feel that way about it, and furthermore no mass was palpable. The stools were guaiac negative on many occasions, which is suggestive evidence at least that the patient did not have a tumor low in the ductal system, because the papilla of Vater tumor often gives a guaiac-positive stool when it ulcerates, even if it is only a tiny ulceration at the duodenal entrance of the duct. So, although his pain was minimal, I think the facts that the degree of obstruction fluctuated, that he had no palpable gall bladder and that he later had some epigastric discomfort and vomiting are in favor of obstruction due to stone. He had some weight loss, it is true; but I think we can and do see that in prolonged common-duct obstruction from any cause.

DR. CHESTER M. JONES: I saw this man in consultation. In taking the history I got the story of an abrupt onset of gastrointestinal symptoms, followed about a week later by jaundice, anorexia and nausea. He was clear in telling the story to me, and he gave an excellent story of infectious hepatitis. The thing that was difficult for me to understand at the time was that he had had jaundice for many weeks without the slightest enlargement of the spleen, either then or subsequently. That to my mind is always a disturbing finding, because serious infection of the liver is frequently associated with moderate splenic enlargement. Even though one cannot feel the spleen it usually can be percussed or demonstrated by x-ray. The x-ray films gave no suggestion of enlargement of the spleen. When one cannot demonstrate that finding, the diagnosis of infectious hepatitis always should be treated with a good deal of reservation.

DR. MOORE: How about the normal temperature?

DR. JONES: These patients usually have normal temperatures when jaundice sets in. Only a small proportion of them run a fever.

Our reasoning was similar to that of Dr. Moore, and we believed that the patient's disease was not running true to form, although for at least several weeks he really improved—the jaundice diminished, there was more bile in the stools, and it looked as if he were on the mend. Because he did not get

beyond that point we thought that we had no right to postpone operation any longer. We decided on exploration. The family was told that he might have either carcinoma or gallstones.

CLINICAL DIAGNOSIS

Choledocholithiasis?

Carcinoma of bile duct or pancreas?

DR. MOORE'S DIAGNOSIS

Choledocholithiasis.

ANATOMICAL DIAGNOSIS

Adenoacanthoma of pancreas.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: I am sorry that Dr. Arthur W. Allen is not here to describe the operation. At exploration he found a greatly distended gall bladder filled with bile. There were no stones in the gall bladder, and he could not feel any in the common duct. He did feel a large hard mass in the head of the pancreas, which was not definitely neoplastic or inflammatory. On the chance that it was a tumor, a cholecystostomy and jejunostomy were performed in preparation for a pancreatoduodenal resection to be done later. A biopsy was not taken because the lesion was too deep within the pancreas.

About three weeks later Dr. Allen resected the head of the pancreas and duodenum. At that time he noticed that the liver, which had been quite swollen and large at the first operation, had shrunk somewhat and that the mass in the pancreas seemed to be much larger than formerly; in fact, he was sure that the mass was a cancer. We did a frozen section and made a diagnosis of carcinoma. Unfortunately the tumor had spread into the body of the pancreas and was quite adherent to the portal vein, hepatic artery and superior mesenteric vein. Resection was carried through the body of the pancreas, but it was thought that all the tumor had not been removed. The carcinoma proved to be an adenoacanthoma, that is, an adenocarcinoma in which some of the epithelial cells had undergone squamous-cell change.

The patient did fairly well for a while but died four months following the operation. At autopsy we found that the tumor had extended down to the tail of the pancreas and that there were metastases in the liver, which were not present at the time of operation, and also in the lungs.

The patient died of cholemia and bronchopneumonia. He was extremely jaundiced. The tumor had invaded around the anastomosis, with ulcerations into the jejunum.

DR. MOORE: Had anyone ever felt a big distended gall bladder?

DR. JONES: We tried again and again, but no one ever felt it.

Physical examination showed no significant change. His icterus, nutritional status and sense of well-being were essentially the same. The liver was five fingerbreadths below the costal margin, and the spleen was not felt.

The urine gave a + test for albumin and a ++++ test for bile; the sediment contained an occasional white cell. The hemoglobin (photoelectric method), which had been 14.3 gm. at the time of discharge, was 12.8 gm. The white-cell count and differential were normal. The stool was clay-colored and guaiac negative and contained no bile. The prothrombin time was normal, but a cephalin-flocculation test was ++++ in twenty-four hours. The alkaline phosphatase was 7.8 units per 100 cc., and the van den Bergh reaction 9.28 mg. direct and 13.2 mg. indirect. The urobilinogen in the urine was positive in a dilution of 1:40.

A week after admission the alkaline phosphatase was 9.6 units per 100 cc. and the cephalin flocculation was negative. His diet was supplemented by intravenous feedings, and he received three transfusions. During one transfusion he had a chill and the temperature spiked to 101°F., otherwise the temperature, pulse and respiration remained normal. A laparotomy was performed on the twelfth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS D. MOORE: This case seems to me to contain elements suggesting various pathologic lesions. If one reads through most of the case one would say that the jaundice was painless, but then this must be qualified because later the patient did have some discomfort, characterized as epigastric pain. The jaundice was fluctuating. So it was fluctuating, obstructive, "almost painless" jaundice.

May we see the x-ray films? The main thing that I should like to find out from Dr. Schulz is whether this man did have an ulcer, or whether it was gall-bladder disease that the patient or his physician thought was an ulcer.

DR. MILFORD D. SCHULZ: I think that he probably had an ulcer. The duodenal bulb is flat and slightly irregular. I do not believe there is anything shown by the films beyond what has been stated in the protocol.

DR. MOORE: He has no opaque gall stones, a little duodenal deformity but nothing striking and no widening of the duodenal loop, which is important.

Was the jaundice primarily obstructive, not being due to intrahepatic disease or excessive hemolysis? I think that it probably was. The direct to indirect ratio of the van den Bergh reaction was about 75 per cent, which favors such a diagnosis: this interpretation is not infallible, but in this hospital over a period of time it has been fairly reliable. The highest direct to indirect ratio was the first one obtained. Later, the patient apparently developed liver damage, as evidenced by the positive cephalin-

flocculation test and also by a change in the ratio of the direct to indirect bilirubin in the direction characteristic of parenchymatous liver disease. The alkaline phosphatase was elevated on several occasions, which is in favor of obstructive jaundice. There was little urobilinogen in the urine when the patient was first admitted. Later it was high, and during the second admission it was about halfway between. To get urobilinogen in the urine there must be urobilinogen in the feces. This patient had urobilinogen in the urine at a time when he had a bile-free stool. That finding is inconsistent, but the amounts present do not support the idea that it was a hemolytic process, nor do the red-cell counts recorded in the protocol.

Can we dismiss an acute hepatitis? I think we can. The patient did not have fever. His liver enlarged slowly. When first seen, the liver was not large or tender, which I think is unusual for acute hepatitis, and he had clay-colored stools right from the start, even antedating the jaundice. He had a negative cephalin-flocculation test on the first admission, suggesting that early in the disease the liver cells were not working under too great a burden. Just before operation, the cephalin-flocculation test changed from positive to negative in a short time. I do not know enough about the test to be sure that that is suggestive of a change in status. I should rather believe that it was a laboratory phenomenon.

Then there are portal cirrhosis of the liver and one of its precursors to be considered. Against these are the facts that he had not developed ascites, that the serum was normal and that he had no esophageal varices.

So, narrowing ourselves down to obstructive phenomena of one sort or another, we have tumor on the one hand and stones on the other. Tumor usually produces a story of increasing jaundice that does not fluctuate. This man had definite fluctuation of bile in the stools and of his jaundice, suggesting that the obstruction let up for a while. That is in favor of a stone. In favor of tumor, however, is the relatively rapid onset in a man of fifty-five, with apparently little previous history of disease of any sort unless the ulcer story was really gall-bladder disease.

One other fact that I think is important is that he did not have a palpable gall bladder. If the obstructive jaundice had been due to neoplasm involving the biliary tree from the junction of the cystic and common ducts downward we should expect him to have developed a big, soft, nontender, palpable gall bladder. The fact that he did not have that in the presence of jaundice, which was apparently obstructive, suggests that it was due to stone and that the reason the gall bladder did not enlarge was that it was involved in old chronic cholecystitis. One might argue the other way, and say that he had carcinoma of the gall bladder, which is capable of in-

pected the human serums used in the preparation of the vaccines. Their suspicion was strengthened by the fact that all the icterogenic lots contained serum from donors who had previously suffered from catarrhal jaundice. It was thought that there was evidence to suggest that a fairly large proportion of normal persons act as carriers of the icterogenic agent, which they assumed to be a virus. They made numerous attempts to isolate the causative agent by inoculation of various experimental animals with the incriminated vaccines or with blood, tissues or excreta from jaundice patients. Their studies gave only negative or, at most, suggestive results.

A thorough pathological study based on 125 fatal cases of hepatitis that occurred in the United States Army during 1942 and made by Lieutenant Colonel Balduin Lucké,⁴ of the Army Medical Museum, has recently been published. Many photographs of the gross and microscopical findings in the liver are shown, some of them in color. The findings were essentially those of yellow atrophy of the liver. The mechanism of the jaundice was considered to be obstruction of the lobular canaliculi. Cerebral lesions, consisting of an acute nonspecific degeneration of ganglion cells and a mild meningoencephalitis, were found in 5 per cent of the cases and were believed to be due to a loss of the detoxifying functions of the liver. The exact nature of either lesion, however, is not known.

In another paper, Lucké⁵ presents the pathological findings in 14 patients who recovered from typical hepatitis during the epidemic and subsequently died or were operated on. In 6 of the cases death resulted from traumatic accidents, and 6 of the other deaths were due to unrelated diseases. In the 2 remaining cases a fragment of liver was removed in the course of an operation. The tissues were obtained from one to fourteen months after clinical recovery from the jaundice. In those who died from intercurrent diseases during convalescence or within a month after clinical recovery, the liver lobules were mostly reconstituted but there was still some evidence of the previous damage. In those examined more than one month after recovery, the liver parenchyma was completely restored without significant scarring and with only traces of the previous damage found in the portal areas; no evidence

of permanent hepatic damage was found. It is well to mention, however, that these cases did not include any in which symptoms were prolonged for many months, as has been noted in some of the cases of post-inoculation jaundice. It is possible that in such cases considerable pathologic changes may persist.

Additional investigations concerning the etiology of these types of jaundice have also been recently reported. Neefe and his coworkers⁶ succeeded in producing hepatitis in each one of 9 volunteers. In some of the subjects there were definite symptoms accompanied by jaundice, whereas in others there was demonstrable hepatitis by laboratory tests although clinical jaundice did not appear. In 5 of these subjects pooled mumps convalescent plasma was used; 4 of them developed hepatitis with jaundice, and the fifth showed laboratory evidence of mild hepatitis without jaundice. Two more received intravenous injections of plasma from one of the previous group twenty-five days after inoculation, and both developed mild hepatitis without jaundice; the donor of the plasma developed jaundice eighty-seven days after the plasma was obtained. Two more volunteers were given subcutaneous inoculations of a lot of yellow-fever vaccine known to be icterogenic, and both developed hepatitis, one with and the other without jaundice. One of the volunteers was reinoculated with the same material after recovery but remained free of disease during one hundred and forty days of observation. The onset of the disease in 6 of these 9 cases occurred twelve to thirty-five days after inoculation, which is a considerably shorter incubation period than that in most of the cases of post-vaccination or other types of homologous serum jaundice. There were 2 cases of jaundice that may have resulted from contact with one of the volunteers.

Some of the earlier studies of Findlay and his colleagues, particularly those concerned with the transmission of post-inoculation jaundice by means of intranasal inoculation, were referred to in a previous editorial.² More recently these workers⁷ have reviewed the clinical findings in 689 cases of jaundice that occurred in the British Army. They have also presented immunologic and epidemiologic

INFECTIOUS HEPATITIS

CASES of epidemic jaundice and of homologous serum jaundice continue to attract a great deal of attention, large numbers still being encountered both in military practice and in the civilian population. Although deaths are relatively few, the disease is of considerable importance. Even in mild cases there is usually an acute illness that lasts about three or more weeks, and convalescence may be quite prolonged before there is a complete return to normal. Among American troops, particularly in cases that followed inoculation with yellow-fever vaccines containing the icterogenic agent, serious disabling sequelae of various sorts have been encountered. Interest in this subject therefore is

great; intensive investigations have recently been made, and many are still in progress. Attention has already been called in these columns to some of the significant work that has contributed to an understanding of such conditions.^{1, 2} A few of the more recent contributions have shed further light on this perplexing problem.

One of these studies is contained in a report to the Surgeon General of the United States Army by a special group of workers who investigated the cases of jaundice among Army personnel in the western region of the United States and their relation to vaccination against yellow fever.³ Cases occurred in this area throughout 1942, but the main outbreak began in March and continued through July, with two peaks during that period. There had been a few small outbreaks of jaundice among civilians in California before the cases occurred in the Army, but the civilian cases could not have given rise to the widespread epidemics in the military personnel. It was more difficult, however, to determine whether some of the later cases in the Army might not have resulted from the earlier outbreaks.

In agreement with the results of many other workers, the jaundice in the Army personnel was traced to vaccination against yellow fever and particularly to a number of lots of vaccine, all of which contained the same human serum. The jaundice began in most cases from thirteen to sixteen weeks after the vaccination. Cases among unvaccinated individuals were scattered throughout the year, and in that respect they resembled the cases that occurred in men who were vaccinated with nonicterogenic lots of yellow-fever vaccine. The occurrence of such cases extended over a period of seventy-eight weeks after vaccination. The case fatality rate was 3 per 1000 among the patients with hepatitis who received the icterogenic lots of vaccine. It is of interest that, as a matter of chance, no icterogenic lots of vaccine had been used in foreign countries and in the Navy at the time of these investigations.

From their own studies these workers were not able to determine which of the various materials used in the preparation of yellow-fever vaccine actually contained the agent responsible for the outbreak of the post-vaccination jaundice. On the basis of the findings of others, however, they sus-

feces from both spontaneous and post-inoculation cases. The incubation period varied from twenty to eighty-four days, averaging thirty-seven. One case of moderately severe jaundice appeared among the uninoculated personnel of that institution fifty-one days after the beginning of the experiment and thirty-one days after the first experimental case had developed. At another institution 3 of 5 volunteers developed hepatitis from fifty to seventy days after the intracutaneous inoculation of icterogenic serum. In another series of feeding experiments the incubation period was found to be twenty-eight days,¹² which is considerably shorter than that after the inoculation of icterogenic serums.

The results of various transmission experiments are reviewed by MacCallum and others.¹³ Transmission to pigs has been claimed by Danish workers, and the infection of chick embryos and canaries with materials from human cases has been reported by German investigators, but these results have not been confirmed. In man the disease has been produced by serum, duodenal juice, urine and feces from cases of infectious hepatitis and by serum and nasal washings from cases of homologous serum jaundice. It is also claimed that the jaundice resulting from arsenotherapy may result from traces of serum left in the syringe from previous injections of other patients who harbored the infectious agent. The latter possibility is rendered plausible by the experience of Bradley et al.,¹⁴ who observed an outbreak of homologous serum jaundice involving 57 per cent of persons injected with a particular batch of pooled human serum that was being used in a study of allergic reactions. Jaundice resulted from doses varying from 0.1 to 1200 cc. Neither the incubation period, which varied from forty-five to one hundred and four days, nor the severity of the jaundice was related to the size of the dose.

All these observations are of considerable interest, but many important problems still remain unsolved. It is to be expected that current investigations will shed further light on the etiologic agent and on many of the clinical features of this disease. In the meantime it is obvious that one is dealing with a serious infection caused by a fairly sturdy agent, which is transmissible through inoculation, as well as through natural channels, and

which may persist for considerable periods in the patient. The most obvious implication is that blood banks should refuse to accept as donors persons who have had an attack of infective hepatitis within a few months — possibly within a year. To obtain more information concerning the occurrence and spread of this important disease it is also imperative that it be made reportable. Such facts could then be applied to the control and prevention of the disease. In this connection, the possible value of gamma globulin in the prevention and modification of the disease is now under investigation.

DEATHS

CHESBRO — Lt. Comdr. Wallace L. Chesbro, formerly of Springfield, was killed on April 28 when the hospital ship, *U. S. S. Comfort*, was attacked by a Japanese suicide pilot off the coast of Okinawa. He was in his thirty-third year.

Dr. Chesbro received his degree from Tufts College Medical School in 1938. He was a fellow of the American Medical Association.

His widow, his daughter, his mother and two brothers survive.

HAVILAND — Walter C. Haviland, M.D., of Mansfield Depot, Connecticut, died May 14. He was in his sixty-fourth year.

Dr. Haviland received his degree from Baltimore Medical College shortly before he moved to Worcester in 1904. He became superintendent of the Herbert Hall Hospital in 1912, and on May 10, 1932, was appointed to the Worcester Board of Health. In 1934 he left Worcester to take a position at

observations purporting to show that post-vaccination jaundice, that is, homologous serum jaundice and infectious hepatitis or catarrhal jaundice, are caused by the same or closely related agents. This conclusion is based on three types of evidence. In the first place, they present case histories that suggest the spread of post-vaccination jaundice to contacts who had not been inoculated. Secondly, they ascertained the incidence of infectious hepatitis earlier in life among a sample of British officers and enlisted men and deduced from their findings that a previous attack of infectious hepatitis gave some, although not absolute, protection against post-inoculation jaundice. Finally, in complement-fixation tests with an antigen prepared from the liver of a patient who died of post-inoculation jaundice they obtained positive results with convalescent serums from patients with post-inoculation jaundice and also from patients with infectious hepatitis who had not been vaccinated. The complement-fixation test was not specific, however, giving positive results with serums from cases of arsenical hepatitis and yellow fever. The antigen responsible for the complement-fixation was not considered to be the agent responsible for the jaundice, since they obtained no positive takes following its inoculation. They also point out that hepatitis can occur without jaundice since positive complement-fixation tests were obtained in certain persons who gave no history of jaundice. They carried out additional transmission experiments, which, however, were mostly unsuccessful.

From a study of the answers to questionnaires among British officers and enlisted men these investigators obtained a history of catarrhal jaundice in 6.3 per cent of the 2614 men who replied. Only 4 men, or 2.6 per cent, of those with positive histories had a second attack, the period intervening ranging from one and a half to fifteen years. Among the 689 cases of hepatitis that they analyzed, relapses occurred in 14, or about 2 per cent, which is an incidence quite similar to that of those with a second attack of catarrhal jaundice.

A case reported by Neefe et al.⁸ is of interest with respect to the relation of the two types of jaundice. Their case was one of a severe and prolonged hepatocellular jaundice following the injection of pooled

mumps convalescent serum. This serum was given because of symptoms suggesting pancreatitis that developed in the course of an attack of mumps acquired by the patient from one of his children. The patient gave a history of having had a characteristic attack of catarrhal jaundice nine years previously. In this connection may be mentioned Hayman and Read's⁹ report of an outbreak of 405 cases of jaundice following yellow-fever vaccination observed in an Army hospital between April and September, 1942. Among these cases were 7 in which a history was obtained of "catarrhal jaundice" occurring six months to twenty years previously. One patient stated that he had received yellow-fever vaccine in October, 1939, before going to South America for an oil company and that he developed jaundice in January, 1940, together with a number of other employees of the company. These authors subsequently observed another group of 100 cases of jaundice among troops returning from the combat zone who had had yellow-fever vaccine from twelve to eighteen months previously. Evidence of a short incubation period, suggesting that these were cases of epidemic jaundice or infectious hepatitis, was obtained from 2 cases in nurses. One of them had taken special care of a fatal case nineteen days before she developed jaundice, whereas the other had been "out" with an officer two days before he developed jaundice and became jaundiced after twenty-eight days.

Oliphant¹⁰ attacked the problem more directly by inoculating icterogenic serum subcutaneously into persons convalescent from attacks of jaundice. He observed that recovery from homologous serum jaundice resulted in immunity to reinoculation with serum from acute cases of infectious hepatitis or with icterogenic yellow-fever vaccine. This immunity persisted for at least twelve to eighteen months. On the other hand, pooled serum obtained from one to three months after recovery from homologous serum jaundice, when mixed with icterogenic yellow-fever vaccine, failed to protect 1 of 10 persons who were inoculated with the mixture.

Havens and his co-workers¹¹ succeeded in transmitting hepatitis to 5 of 9 human volunteers in one institution by feeding specimens of serum, urine or

LYMPHOSARCOMA OF THE BOWEL IN CHILDHOOD*

GEORGE D. CUTLER, M.D.,† RICHARD B. STARK, M.D.,‡ AND H. WILLIAM SCOTT, JR., M.D.§

BOSTON

PRIMARY neoplasms of the large or small intestine are extremely rare in childhood as compared with those in adult life. Except for true adenomatous polyps, most intestinal tumors encountered in early life are sarcomatous. Lymphosarcoma is one of the more frequent types of this group, and it is the purpose of this paper to describe our experience with this tumor in children under twelve years of age, as well as a case of reticulum-cell sarcoma.

PATHOLOGY

Lymphosarcoma was separated from the general group of lymphoma in 1893 by Kundrat,¹ who described it as a highly malignant tumor of lymphoid tissue having a fairly uniform cell type. The tumor may arise in the lymph nodes, spleen, tonsils and the lymph follicles of the gastrointestinal tract, and apparently in many organs not usually thought of as containing significant amounts of lymphoid tissue. Extensive studies including reviews of the literature on this subject were reported in 1919 by Graves,² in 1932 by Ullman and Abeshouse,³ in 1940 by Sugarbaker and Craver⁴ and in 1942 by Stout.⁵

The controversial subject of the classification and inter-relations of the various types of lymphoma exceeds the scope of this paper. In this regard reference may be made to the work of Gall and Mallory,⁶ Jackson,⁷ Warren and Picena⁸ and Krumbhaar.⁹ The close relation between the various manifestations of neoplasia of the lymphocyte and its precursors seems to be quite well established. The confusion in the terminology applied to these tumors is widely known. Gall and Mallory⁶ were unable to predict from histologic examination of lymph nodes involved by so-called "lymphocytoma," "lymphoblastoma" or "lymphosarcoma" whether there were accompanying leukemic blood changes.

Certain pathologists apparently believe that the diseases designated by the terms "lymphatic leukemia," "aleukemic lymphatic leukemia," "lymphoblastoma," "lymphocytoma," "reticulum-cell sarcoma" and "lymphosarcoma" are variants of the same fundamental neoplasm.

Regardless of the inter-relation of these conditions, a malignant tumor of the lymphoid tissue may certainly appear as an original focus in the intestinal tract, and may remain temporarily local but ultimately invade and metastasize in a manner closely resembling that of carcinoma. The term "lymphosarcoma" may conveniently be applied to this neoplasm, despite certain theoretical objections.

The tumor arises in the lymphoid follicles of the submucosal layer of the bowel and infiltrates the remaining layers, although tending to remain intramural, and to extend through mucosa and serosa only as a relatively late change. Longitudinal and circumferential subserosal extension may cause diffuse thickening and dilatation of a segment of bowel, giving rise to the so-called "garden hose" appearance. The absence of a well-developed fibrous stroma as in carcinoma accounts for the rarity of the "napkin-ring" constriction of the bowel so frequent in the latter. Yellowish-white, subserosal plaquelike tumors, frequently umbilicated and frequently multiple (Fig. 1), represent a relatively early stage of the process. Since the mucosa is not primarily involved, large fungating masses completely enveloping the bowel may develop before intestinal obstruction is caused (Fig. 5). For the same reason, ulceration due to ischemic necrosis of the mucosa is a late result, in direct contrast to its early appearance in carcinoma. On palpation the lymphosarcomatous mass is softer, more friable and more rubbery than the hard mass of carcinoma.

Elaborate cytologic classifications of the subtypes of lymphoma have been developed by several pathologists.⁶⁻⁸ For practical purposes two general groups are recognized — lymphosarcoma and reticulum-cell sarcoma. In the first group the type cell is the lymphocyte or lymphoblast. Both groups are characterized microscopically by destruction of normal

MISCELLANY

NOTE

A new medical society, the New Hampshire Roentgen-Ray Society, was founded a few months ago. The aims of the society are to maintain and improve the standards of x-ray service in that state. Dr. Fred S. Eveleth of Concord was elected president, and Dr. Richard C. Batt, of Berlin, secretary.

CORRESPONDENCE

RH FACTOR

To the Editor: The editorial "The Rh Blood Factor" in the April 19 issue of the *Journal* is timely and brings attention to a subject to which physicians as a whole are giving scant regard. Strangely enough, even in Boston, where the Blood Grouping Laboratory directed by Dr. Louis K. Diamond has been most active, most physicians view this subject as being of no practical importance. The editorial, however,

in its attempt to emphasize the practical importance of this subject has possibly conveyed a wrong impression, which I believe was not intended.

In one paragraph the editorial reads, "The practical importance of the Rh factor concerns Rh- women and their Rh+ offsprings." May I disagree that the practical importance of this factor is in pregnancy alone, which is implied in the above quotation. The practical importance of the Rh factor concerns all Rh- people, whether it be man or woman.

To quote further from the editorial: "The inferences are obvious. Rh- persons should not receive repeated transfusions from Rh+ donors." The foregoing statement leads to an erroneous conclusion because of the word "repeated." It implies that one transfusion of Rh+ blood to an Rh- person is of no consequence. Again, the editorial would be much more accurate if it were written, "Rh- persons should not receive any whole-blood transfusions from Rh+ donors." For instance, a young girl long before she enters the stage of puberty may have to receive a whole-blood transfusion for one reason or another. If she is Rh- and is transfused with Rh+ blood and then years later is married to an Rh+ man and becomes pregnant, her first pregnancy may be seriously affected by the transfusion given years before. In other words, such a transfusion sets a stage that years later may seriously affect her and her offspring's health and viability. On the other hand, if an Rh- man or boy, for one reason or another, is given a transfusion of Rh+ blood, that individual may be sensitized for the remainder of his life. At a much later date he may be involved in a serious accident or may have to undergo a major operation in a hospital, either of which may demand an immediate whole-blood transfusion. If in this emergency procedure he is again given Rh+ blood, — and he has an 87 per cent chance of this being so, — he is likely to suffer a transfusion reaction, which may kill him or at best will add insult to injury. Therefore, it is important in every case that an Rh- man, woman or child does not receive Rh+ blood.

I realize that the editorial later explains the phrases and words quoted above, but my point is that most people, if they peruse the editorial page, read the first sentence of a paragraph or at least remember only that part of it and may not read the subsequent sentences and paragraphs.

I believe that calling attention to these statements about whole-blood transfusions will impress your readers to the extent of encouraging changes in their methods and ideas of testing blood prior to transfusion.

NOTICES

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, June 7, at 7:15 p.m. in the classroom of the nurses' residence. Mr. Lester W. Dearborn will speak on the subject "Some Psychological Aspects of Frigidity." Dr. Lucile Lord-Heinstein will be chairman.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JUNE 7

FRIDAY, JUNE 8

*9:00-10:00 a.m. Medical clinic. Isolation Amphitheater, Children's Hospital.

10:50 a.m. Postgraduate clinic in dermatology and syphilology. Amphitheater, Mallory Building, Boston City Hospital.

12:00 m.-1:00 p.m. Clinicopathological conference (Boston Floating Hospital). Joseph H. Pratt Diagnostic Hospital.

SATURDAY, JUNE 9

*10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham Hospital.

(Notices continued on page xix)

Postoperatively, the patient did fairly well for a short period. After the pathologic diagnosis of lymphosarcoma had been made, it was decided not to do a second-stage resection of the chronic intussusception as planned but to give roentgen-ray therapy alone. Because of delayed wound healing only 600 r of x-ray radiation was given, following which the patient was discharged home on the 35th day, to return for heavy roentgen therapy when the wound was well healed. Because of parental difficulties, however, he did not return for admission but died at home 1 month after discharge. Repeated blood examinations showed no evidence of leukemia.

Microscopical study of an omental biopsy showed diffuse infiltration of omental fat by closely packed lymphocytic cells in no orderly arrangement. There were numerous mitoses. Diagnosis: lymphosarcoma.

CASE 2. E. C. (CH103886), a 7-year-old boy, entered the hospital in December, 1933, because of an abdominal mass noted 2 days previously. He had been well until 3 weeks before admission, when he became anorexic, listless and easily fatigued and complained of vague abdominal pains. The bowels were constipated. There was no vomiting. Two days before entry the family doctor was consulted, who sent the patient to the hospital because of a large mass in the right side of the abdomen.

Physical examination on entry showed a well-developed and well-nourished boy with a protuberant, distended ab-

domen. The stools had been normal. The past history was noncontributory.

Physical examination on admission showed a well-developed and well-nourished baby crying as if with pain. The abdomen was slightly distended, but without tenderness, spasm or a palpable mass. The liver edge and the tip of the spleen were just palpable. The rest of the examination was essentially negative. The urine showed a ++ test for albumin but was otherwise negative. The red-cell count was 4,200,000 and the white-cell count 6000, with 71 per cent neutrophils, 22 per cent lymphocytes, 5 per cent monocytes, and 2 per cent eosinophils. The platelets were normal.

During the first 12 hours on the ward the patient refused feedings and vomited three times. He then began to develop intermittent episodes of abdominal pain with doubling of the knees on the abdomen. Fluoroscopy with a barium swallow revealed dilated loops of small bowel and fluid levels. A diagnosis of intussusception was made and laparotomy was performed. An enteric intussusception of the ileoileal type was present in the distal ileum. This was easily reduced, and the congested bowel quickly regained normal color. The cause of the intussusception was identified as two plaque-like, yellowish, intramural tumors of the intussusceptum measuring 2.5 by 1.5 cm. in diameter, respectively. These were situated on the antimesenteric border of the ileum 3 or 4 cm. apart. This segment of ileum was consequently resected (Fig. 1) and a lateral anastomosis was constructed.

FIGURE 1. Photograph of a Surgically Excised Segment of Ileum Containing Two Intramural Lymphosarcomas That Had Caused Acute Intussusception (Case 3).

domen. There was an enormous hard, nontender mass filling most of the right side of the abdomen, extending from the midline to the midaxillary line and from the costal border into the pelvis. Its lower limit was easily felt by rectum. Aside from additional signs of abdominal fluid the remainder of the examination was essentially normal. Urinalysis was negative. The red-cell count was 4,080,000 and the white-cell count 11,400, with 70 per cent neutrophils and a normal smear. Roentgenograms of the chest showed no metastases.

Laparotomy was carried out with a preoperative diagnosis of abdominal tumor. Opening of the abdomen revealed a grapefruit-sized, whitish-yellow tumor of the cecum and ascending colon. This was diffusely infiltrating and enveloped the large bowel, extending posteriorly to the abdominal wall and medially to the omentum. Several adjacent loops of small bowel were adherent to the mass. The mesenteric lymph nodes were enlarged, rubbery and hard. There was no hope of successful resection. A biopsy of the tumor was performed, and the abdomen was closed.

Postoperatively, the patient had a rapid downhill course. Although he did not become obstructed, he quickly developed marked cachexia. Delayed wound healing prevented early roentgen-ray therapy, and death occurred from terminal pneumonia on the 16th postoperative day. The peripheral blood showed no evidence of lymphatic leukemia.

Microscopical examination of the biopsy specimen showed closely packed masses of lymphoblasts with numerous mitotic figures. Diagnosis: lymphosarcoma.

CASE 3. F. R. (CH264439), a 4-month-old boy was admitted on July 29, 1942, with a 7-day history of irritability and refusal of feedings. In the 24 hours before entry he had

Postoperatively the patient had a stormy course for 5 days, and then passed stools satisfactorily and remained afebrile. Repeated blood smears showed no evidence of lymphatic leukemia. No roentgen-ray therapy was given. The patient was discharged home in apparently good condition on the 18th day. He quickly became listless, irritable, anorexic and pale and developed a petechial rash over the extremities. He was readmitted to the Medical Service 10 days after discharge with a picture of advanced acute lymphoblastic leukemia. The liver and spleen were enlarged as were the cervical lymph nodes. The red-cell count was 2,520,000 and the hemoglobin 6.5 gm. The white-cell count was 76,000, with 4 per cent neutrophils, 3 per cent eosinophils, 4 per cent monocytes, 15 per cent mature lymphocytes and 74 per cent lymphoblasts. No platelets were seen on the smear. Therapy was omitted at the parents' request, and the infant died at home 5 days after the second hospital entry.

Microscopical examination of the intramural tumors of the excised ileum showed diffuse infiltration of bowel wall with masses of cells resembling lymphocytes and less numerous lymphoblasts. Mitoses were frequent. Diagnosis: lymphosarcoma.

CASE 4. J. B. (CH273465), a 26-month-old boy, was admitted on June 5, 1943, because of bloody stools of 25 days' duration. The past history was irrelevant. Except for diminished appetite and failure to gain during the month prior to admission there were no symptoms. Examination by the family physician had revealed a mass in the rectum. Proctoscopy and biopsy had been carried out in another hospital, followed by referral to this hospital with a diagnosis of malignant tumor of the rectum.

nodal architecture, capsular invasion, numerous mitoses and predominance of one of the above cell types.

In our 5 cases of lymphoma arising primarily in the bowel, 2 were of the lymphocytic variety, 2 were lymphoblastic, and 1 was of the reticulum-cell group.

CLINICAL ASPECTS

In a recent ten-year study of histologically verified malignant tumors at the Children's Hospital, Farber¹⁰ found 75 (21 per cent) belonging to the leukemia-lymphoma group. Of these 47 were classified as acute leukemia, 14 as Hodgkin's disease and 14 as lymphosarcoma. Five of these patients had primary tumors of the bowel with symptoms and signs that led to operative intervention. Data of these cases are summarized in Table 1. The youngest

was found to have one of the ileoileal type whose leading point was an intramural lymphosarcoma. Two older patients (Cases 1 and 5) had increasing constipation for four and three months, respectively, leading to fecal impaction. One of these patients developed acute intestinal obstruction a few days after hospitalization and by barium enema was found to have an ileocolic intussusception (Fig. 4) associated with a large tumor of the terminal ileum. The other patient proved to have a chronic colocolic intussusception resulting from lymphosarcoma of the cecum and ascending colon. The presenting complaint in another patient (Case 2) was an essentially asymptomatic irregular abdominal mass filling the right lower quadrant of the abdomen. In the last patient (Case 4), bloody stools attracted attention to a lemon-sized intramural reticulum-cell sarcoma of the rectum (Fig. 2).

TABLE 1. *Summary of Data from Five Children with Lymphosarcoma of Bowel.*

CASE No.	AGE Yr.	SEX	CLINICAL PICTURE	SITE OF TUMOR	OPERATION	X-RAY THERAPY	TERMINAL LEUKEMIA	COURSE
1	6 4/12	M	Fecal impaction and chronic intussusception	Ascending colon	Ileotransverse colostomy (biopsy)	600 r	?	Died
2	7	M	Abdominal mass	Ascending colon	Laparotomy (biopsy)	None	No	Died
3	4/12	M	Acute intussusception	Terminal ileum	Reduction and resection, with anastomosis	None	Yes	Died
4	2 1/12	M	Melena and rectal mass	Rectum	Abdominoperineal resection	3000 r	No	No recurrence; well for 15 mo.
5	6 6/12	M	Fecal impaction and acute intussusception	Terminal ileum	Mikulicz resection	1350 r	Yes	Died

patient was four months of age and the oldest seven. All were boys. This is in keeping with the male predominance reported in the literature.

The general incidence of lymphosarcoma of the bowel in children may be further illustrated by reports from other clinics. Cave¹¹ in 1932 found only 1 case in a child among 15 patients observed during a twenty-one-year period at Roosevelt Hospital. McSwain and Beal,¹² reporting 20 cases of lymphosarcoma of the gastrointestinal tract treated at New York Hospital during the last nine years, encountered this tumor in 2 children. Donovan¹³ states that only 1 child with enteric lymphosarcoma has been observed in the last fifteen years at the Babies Hospital in New York City.

Ullman and Abeshouse³ believe that there is no absolutely characteristic clinical picture of this disease. Symptoms may have an insidious onset or may present themselves as an acute abdominal catastrophe. Obviously, the manifestations of disease are more or less dependent on the location of the tumor and the degree of intestinal obstruction it causes. The youngest patient in this series, a four-month-old baby (Case 3), had the classic symptoms of acute intussusception and at operation

The peripheral blood showed no detectable abnormality in any of these 5 patients at the time of admission. Terminally, however, 2 of them developed the blood picture of lymphoblastic leukemia.

CASE REPORTS

CASE 1. W. T. (CH149544), a 6-year-old boy, was admitted in June, 1931, because of intermittent abdominal cramps of 3 months' duration. Four months before entry, appendectomy had been carried out at another hospital for alleged acute appendicitis. Irritability, fatigue and anorexia but no vomiting accompanied the pain. There was increasing constipation, and 10 days before entry a mass was noted in the epigastrium.

Physical examination on admission showed a well-developed and well-nourished boy in no acute distress. In the right upper quadrant of the abdomen there was a rounded, firm, nontender mass 7 cm. in diameter. Hard fecal lumps were palpable in the sigmoid and rectum. The remainder of the examination disclosed nothing remarkable. The urine, blood and stools were normal. After evacuation of the impacted feces by enemas, fluoroscopy of the colon showed a filling defect in the transverse colon suggesting intussusception. A diagnosis of chronic intussusception was made. Laparotomy revealed an irreducible intussusception of the ileocolic type that had passed just beyond the hepatic flexure. There were numerous large rubbery, yellow nodules in the omentum, which was adherent to the ileum and had been drawn into the intussusciptions. The mesenteric nodes were large and firm. Biopsy was taken of the omental nodules, and a short-circuiting lateral anastomosis between proximal ileum and transverse colon was carried out.

FIGURE 4. Roentgenogram of a Barium Enema in a Patient (Case 5) with Lymphosarcoma of the Ileum.

An ileocolic intussusception was partially reduced by the radioligant, with a residual filling defect in the cecum.

masses. The liver and spleen were not enlarged. The rectum contained concretelike fecal material. No other ab-

8 per cent lymphocytes and 5 per cent monocytes. No immature cells were noted, and the platelets appeared normal.

Cleansing enemas were given and copious fecal masses were evacuated, but there persisted a hard, grapefruit-sized mass in the lower midabdomen that could not be reached on rectal examination. On the 5th day signs of acute intestinal obstruction developed. A harium enema revealed displacement of the sigmoid to the left by a large, soft-tissue mass in the lower abdomen. In addition, there was an intussusception reaching the hepatic flexure; this was partially reduced by the roentgenologist (Fig. 4).

Laparotomy was immediately carried out and revealed a grapefruit-sized, hard, rubbery, yellowish-white tumor. The terminal ileum ran directly through the mass, which was situated 25 cm from the ileocecal junction. The omentum was densely adherent to the anterior surface of the tumor, and the latter extended across to the sigmoid, which it had invaded. Four or five yellow plaque-like tumors measuring 4 to 6 cm. in diameter were present in the proximal ileum, jejunum and root of the mesentery. The terminal 15 to 20 cm. of the ileum was edematous and reddened, suggesting a spontaneously reduced intussusception. The large tumor of the ileum was freed from its attachments to the omentum and sigmoid, and a Mikulicz resection of the terminal ileum bearing the tumor was carried out (Fig. 5).

Postoperatively the patient went steadily downhill, rapidly developing malignant cachexia. Recurrent intestinal obstruction necessitated Miller-Abbott suction and a second laparotomy with lysis of adhesions. One thousand three hundred and fifty r of roentgen-ray therapy was given. During the 4th week lymphoblasts appeared in the blood smears. The spleen became enlarged, and the whole lower abdomen became filled with masses of tumor. There was a terminal leukopenia with diminished platelets and a rise in lymphoblasts to 16 per cent. The patient died on the 39th postoperative day.

The surgically excised tumor of ileum showed on microscopical examination masses of rapidly growing lymphoblasts exhibiting numerous mitoses (Fig. 6). Autopsy showed severe emaciation and purpura hemorrhages in the skin and viscera, with massive extensions of tumor to the mesenteric and aortic nodes, several loops of the ileum and the sigmoid and bladder. Metastatic nodules were present in the kidneys,

FIGURE 5. Photograph of a Resected Lymphosarcoma of Ileum That Had Extended to the Sigmoid and Root of the Mesentery (Case 5).

normalities were noted. Urinalysis was negative. The red-cell count was 3,800,000 and the hemoglobin 60 per cent. The white-cell count was 11,900, with 87 per cent neutrophils,

diaphragm, liver, lungs, testes and spleen. The bone marrow was heavily infiltrated. Diagnosis: lymphosarcoma, with generalized metastases.

Physical examination on admission showed a pale, thin boy with a hard, smooth, lemon-sized tumor on the posterior rectal wall, extending to the brim of the pelvis. There were no other significant findings. Routine blood and urine examinations were normal. Roentgenograms of the skull, chest and skeletal system showed no evident metastases.

into the lumen, except over a 2-cm. ulcerated area near the center of the mass (Fig. 2). Microscopical examination revealed a tumor consisting of large polygonal cells with abundant purplish cytoplasm and clear vesicular nuclei. Phagocytosis was prominent. Tumor cells were found in the blood vessels and lymphatics and diffusely infiltrated the entire rectal

FIGURE 2. Photograph of a Resected Reticulum-Cell Sarcoma of the Rectum (Case 4).

Consequently, a one-stage combined abdominoperineal resection of the rectum and lower sigmoid containing the neoplasm was carried out. The tumor lay in the wall of the rectosigmoid and was removed intact. Several large nodes in the mesosigmoid were excised. Postoperatively, the patient did well except for a troublesome urinary infection. He was given a

wall, but did not extend through the serosa (Fig. 3). Reticulum fibers were demonstrated by Foot's stain. Diagnosis: reticulum-cell sarcoma.

CASE 5. G. H. (CH283174), a 6½-year-old boy, was admitted in May, 1944, with fecal impaction and a story of

FIGURE 3. Photomicrograph of a Reticulum-Cell Sarcoma of the Rectum (Case 4). Note the tumor cells in the lymphatic vessel.

total of 3000 r of roentgen-ray therapy to the abdominal drainage area and was discharged home on the 60th day. He has remained in good health and has shown no evidence of recurrence of tumor.

The excised rectum and lower sigmoid contained a hard, spherical, yellowish intramural tumor measuring 7 by 4.6 by 4 cm. The rectal mucosa covered the tumor, which bulged

progressive constipation following appendectomy at another hospital 4 months before entry. There had been no bowel movement in the 7 days prior to admission, and for 2 days the patient had had crampy epigastric pain. There had been no vomiting, anorexia, weight loss or melena.

Physical examination showed a thin boy with a protuberant, distended abdomen filled with hard, nontender movable

SHOCK IN ACUTE INFECTIONS

MAJOR H. D. WARREN, M.C., A.U.S., CAPTAIN V. G. BALBONI, M.C., A.U.S.,
CAPTAIN F. T. ROGLIANO, M.C., A.U.S., AND CAPTAIN A. FEDER, M.C., A.U.S.

THE recognition and treatment of shock have received much attention in the last few years, especially since the beginning of the war. Emphasis has been focused largely on the shock that occurs following surgical emergencies, such as injuries, hemorrhage and burns, and little attention has been directed toward shock in the course of acute infections. Since the occurrence of shock in association with infections is not infrequent, it is the purpose of this paper to stress the importance of the recognition of this syndrome and its vigorous treatment in combination with equally vigorous specific treatment of the infection.

Shock, regardless of its cause, is the result of a disparity between the circulating blood volume and the size of the vascular system. This may occur as a result of a loss of fluid from the circulation or an uncompensated increase in the size of the vascular bed. The latter factor is of most significance in the present study, although undoubtedly dehydration does play a part. Clinically this syndrome is manifested in the typical case by apathy, a cold, clammy skin, shallow respirations, a thready, rapid pulse and low blood pressure.¹⁻³ It has been the intent of recent surgical studies to point out the need for earlier diagnosis and thus earlier treatment of shock in order that the irreversible state toward which this condition tends to progress may be prevented.^{1,4} In acute overwhelming infections, however, it is often impossible to anticipate the development of secondary shock, which frequently occurs precipitously. The peripheral vascular dilatation so often seen in acute infections is not to be confused with shock. The former is characterized by a flushed, warm skin, a bounding pulse, digital pulses and murmurs over the great vessels and is due to arteriolar dilatation, which is the customary response of the body to fever.⁵

The recognition of shock of the so-called "secondary type," or what may better be termed "cold shock," during the course of acute infection is not new. The weak heart sounds of a failing circulation in acute febrile illnesses were described in 1831 by Laennec,⁶ but were erroneously attributed by him to heart failure. This concept of heart failure persisted in the medical literature, and it remained for Janeway⁷ to show that the vascular collapse seen in the course of severe infections was due not to heart failure but to failure of the peripheral circulation with pooling of the blood in the capillaries. In his paper, he stressed vasomotor failure as the cause of death at the height of such infectious diseases as pneumonia, typhoid fever and septic fevers and referred to the experimental work of Romberg, Pässler et al.⁸ The latter authors as

early as 1899 had produced vascular collapse in rabbits by the intravenous injections of various bacteria, and had suggested the term "toxic shock" for the apparently similar vascular collapse occurring in acute infections. In 1930, Atchley,⁹ in an exceedingly informative paper again brought out the importance of shock in medical conditions and stressed its early recognition and treatment, and in 1934, he and Loeb¹⁰ reported studies along similar lines. The appearance of shock due to hemolytic streptococcus infections of postoperative wounds was emphasized by Stewart.¹¹ In all of Stewart's cases the state of shock was recognized and specific antishock therapy was instituted. The infection producing the shock, however, was not immediately recognized, and all the patients died in spite of adequate shock therapy in the absence of vigorous antibacterial therapy.

The following cases are typical of the therapeutic problems presented by three serious infections not infrequent in Army medical practice. We do not believe that these cases are comparable to those of Ebert and Stead,¹² whose patients were in the older age group and thus more prone to degenerative changes of the cardiovascular system.

CASE 1. A 37-year-old man was admitted to the hospital with a history of cough for several days and chilliness on the day preceding admission. Examination revealed nasal congestion and moderate pharyngeal injection. The white-cell count was 4000, with 58 per cent polymorphonuclear leukocytes and 42 per cent lymphocytes. The urine was free of albumin and sediment. Its specific gravity was 1.020. The oral temperature was 99.4°F. The course was benign until the afternoon of the 3rd hospital day, when the temperature rose to 103°F. At that time the patient's face was flushed and he vomited and had mild diarrhea. The vomiting continued, and at about 7:00 p.m. he developed a typical scarlet-fever rash.

The patient's general condition rapidly deteriorated. At 6:00 a.m. of the 4th day the rectal temperature was 105.4°F., the pulse 140, and the respirations 40 to 50 (Fig. 1). The white-cell count was 11,850, with 80 per cent polymorphonuclear leukocytes. Shortly he lapsed into a state of profound cold shock, the rectal temperature fell to 100°F., the extremities became cold and clammy, the pulse threadlike and barely perceptible and the lips cyanotic. The systolic blood pressure was 58; the diastolic pressure could not be determined. There was marked air hunger, and the patient had severe hiccuping.

Energetic treatment was promptly begun. One hundred cubic centimeters of pooled human convalescent scarlet-fever serum was administered intravenously. The patient was placed in an oxygen tent, and an infusion of 1000 cubic centimeters of 5 per cent glucose in normal saline solution followed by 1000 cc. of plasma was administered during the first 24 hours. At the outset of the rather sudden collapse, he had been given caffeine. The hematocrit index prior to the giving of the plasma was 56 per cent and blood nonprotein nitrogen was 58 mg. per 100 cc. Intravenous fluids were continued, and the pulse gradually improved in quality and slowed so that it fell below 100 in 48 hours. The respirations returned to normal 24 hours after treatment of the scarlet fever and shock was instituted.

At 7:00 p.m. on the 4th day, the blood pressure began to rise and reached 70/54 at that time. On the following day it

DISCUSSION

Preoperative recognition of lymphosarcoma of the intestinal tract in childhood offers many difficulties. In adults, bowel lesions of this type are usually confused with carcinoma until histologic examination clarifies the issue. The extraordinary rarity of carcinoma of the bowel in children is of considerable aid in differential diagnosis, and in all probability the practical consideration that a neoplasm of the intestinal tract in an infant or child is

SUMMARY

Four cases of lymphosarcoma and 1 case of reticulum-cell sarcoma of the bowel treated at the Children's Hospital during the last fifteen years are reported.

The pathologic and clinical aspects are discussed. Radical surgical extirpation followed by roentgen-ray therapy seems to be the most logical treatment.

The mortality in this series was 80 per cent. Two patients developed terminal lymphatic leukemia.

FIGURE 6. Photomicrograph of a Lymphosarcoma of the Ileum (Case 5).
Note the large lymphoblasts with numerous mitoses.

lymphosarcoma until proved otherwise is justifiable. The frequency of intussusception seems worthy of comment. This occurred in 3 of these 5 patients.

In our opinion a combination of radical surgical extirpation of the involved bowel and mesentery followed by heavy roentgen-ray therapy to the abdominal and mediastinal drainage areas offers the patient the optimal chance of survival, if, indeed, any such chance may be called optimal in this highly fatal disease. The mortality in this series was 80 per cent. The sole surviving patient has had no evidence of recurrence during the fifteen months since the abdominoperineal resection of the rectal tumor.

SHOCK IN ACUTE INFECTIONS

MAJOR H. D. WARREN, M.C., A.U.S., CAPTAIN V. G. BALBONI, M.C., A.U.S.,
CAPTAIN F. T. ROGLIANO, M.C., A.U.S., AND CAPTAIN A. FEDER, M.C., A.U.S.

THE recognition and treatment of shock have received much attention in the last few years, especially since the beginning of the war. Emphasis has been focused largely on the shock that occurs following surgical emergencies, such as injuries, hemorrhage and burns, and little attention has been directed toward shock in the course of acute infections. Since the occurrence of shock in association with infections is not infrequent, it is the purpose of this paper to stress the importance of the recognition of this syndrome and its vigorous treatment in combination with equally vigorous specific treatment of the infection.

Shock, regardless of its cause, is the result of a disparity between the circulating blood volume and the size of the vascular system. This may occur as a result of a loss of fluid from the circulation or an uncompensated increase in the size of the vascular bed. The latter factor is of most significance in the present study, although undoubtedly dehydration does play a part. Clinically this syndrome is manifested in the typical case by apathy, a cold, clammy skin, shallow respirations, a thready, rapid pulse and low blood pressure.¹⁻³ It has been the intent of recent surgical studies to point out the need for earlier diagnosis and thus earlier treatment of shock in order that the irreversible state toward which this condition tends to progress may be prevented.^{1,4} In acute overwhelming infections, however, it is often impossible to anticipate the development of secondary shock, which frequently occurs precipitously. The peripheral vascular dilatation so often seen in acute infections is not to be confused with shock. The former is characterized by a flushed, warm skin, a bounding pulse, digital pulses and murmurs over the great vessels and is due to arteriolar dilatation, which is the customary response of the body to fever.⁵

The recognition of shock of the so-called "secondary type," or what may better be termed "cold shock," during the course of acute infection is not new. The weak heart sounds of a failing circulation in acute febrile illnesses were described in 1831 by Laennec,⁶ but were erroneously attributed by him to heart failure. This concept of heart failure persisted in the medical literature, and it remained for Janeway⁷ to show that the vascular collapse seen in the course of severe infections was due not to heart failure but to failure of the peripheral circulation with pooling of the blood in the capillaries. In his paper, he stressed vasomotor failure as the cause of death at the height of such infectious diseases as pneumonia, typhoid fever and septic fevers and referred to the experimental work of Rombert, Pässler et al.⁸ The latter authors as

early as 1899 had produced vascular collapse in rabbits by the intravenous injections of various bacteria, and had suggested the term "toxic shock" for the apparently similar vascular collapse occurring in acute infections. In 1930, Atchley,⁹ in an exceedingly informative paper again brought out the importance of shock in medical conditions and stressed its early recognition and treatment, and in 1934, he and Loeb¹⁰ reported studies along similar lines. The appearance of shock due to hemolytic streptococcus infections of postoperative wounds was emphasized by Stewart.¹¹ In all of Stewart's cases the state of shock was recognized and specific antishock therapy was instituted. The infection producing the shock, however, was not immediately recognized, and all the patients died in spite of adequate shock therapy in the absence of vigorous antibacterial therapy.

The following cases are typical of the therapeutic problems presented by three serious infections not infrequent in Army medical practice. We do not believe that these cases are comparable to those of Ebert and Stead,¹² whose patients were in the older age group and thus more prone to degenerative changes of the cardiovascular system.

CASE 1. A 37-year-old man was admitted to the hospital with a history of cough for several days and chilliness on the day preceding admission. Examination revealed nasal congestion and moderate pharyngeal injection. The white-cell count was 4000, with 58 per cent polymorphonuclear leukocytes and 42 per cent lymphocytes. The urine was free of albumin and sediment. Its specific gravity was 1.020. The oral temperature was 99.4°F. The course was benign until the afternoon of the 3rd hospital day, when the temperature rose to 103°F. At that time the patient's face was flushed and he vomited and had mild diarrhea. The vomiting continued, and at about 7:00 p.m. he developed a typical scarlet-fever rash.

The patient's general condition rapidly deteriorated. At 6:00 a.m. of the 4th day the rectal temperature was 105.4°F., the pulse 140, and the respirations 40 to 50 (Fig. 1). The white-cell count was 11,850, with 80 per cent polymorphonuclear leukocytes. Shortly he lapsed into a state of profound cold shock, the rectal temperature fell to 100°F., the extremities became cold and clammy, the pulse threadlike and barely perceptible and the lips cyanotic. The systolic blood pressure was 58; the diastolic pressure could not be determined. There was marked air hunger, and the patient had severe hiccoughing.

Energetic treatment was promptly begun. One hundred cubic centimeters of pooled human convalescent scarlet-fever serum was administered intravenously. The patient was placed in an oxygen tent, and an infusion of 1000 cubic centimeters of 5 per cent glucose in normal saline solution followed by 1000 cc. of plasma was administered during the first 24 hours. At the outset of the rather sudden collapse, he had been given caffeine. The hematocrit index prior to the giving of the plasma was 56 per cent and blood nonprotein nitrogen was 58 mg. per 100 cc. Intravenous fluids were continued, and the pulse gradually improved in quality and slowed so that it fell below 100 in 48 hours. The respirations returned to normal 24 hours after treatment of the scarlet fever and shock was instituted.

At 7:00 p.m. on the 4th day, the blood pressure began to rise and reached 70/54 at that time. On the following day it

was 90/68, and on the 6th day 110/80. Thereafter it remained within normal limits.

From the outset of the patient's acute collapse and for 72 hours thereafter he was anuric, and the blood nonprotein nitrogen rose to 130 mg. per 100 cc. Improvement in the renal function paralleled the rise in blood pressure, and the

commenced, breaking out over the entire trunk, extremities and face and even involving the mucous membranes of the mouth and pharynx. The pulse was imperceptible, and the systolic blood pressure was 65. Respirations were shallow at 40, and the rectal temperature was 101°F. The white-cell count was 24,000, with 95 per cent polymorphonuclear leukocytes. A diagnosis of septicemia with severe secondary shock was made, and blood cultures were taken that later grew Type 2a meningococci. The spinal fluid was clear, and no organisms could be cultured from it.

Antibacterial therapy was immediately instituted and consisted of 5 gm. of sodium sulfadiazine in 100 cc. of sterile water intravenously and 4 gm. of sulfadiazine by mouth, followed by 1 gm. of sulfadiazine orally every 4 hours. Sodium bicarbonate was administered orally — 3 gm. per gram of sulfadiazine. Concomitantly with the institution of chemotherapy, efforts were directed to combat the severe and apparently progressive shock that the patient manifested. Two thousand cc. of 5 per cent glucose in normal saline solution, 1000 cc. of 10 per cent glucose in distilled water and 500 cc. of plasma were administered daily for the first 3 days. In addition, the patient was urged to take water and fruit juices by mouth. Five milligrams of cortate was given intramuscularly every 4 hours, and the foot of the bed was elevated on shock blocks.

On this regimen a blood pressure of 60/40 to 80/50 was maintained for the first 2 days. One hundred and five cubic centimeters of urine was passed the first day. On the second day, however, a total of 1500 cc. of urine was passed, and from then on the urinary output remained satisfactory. The

FIGURE 1. Scarlet Fever (Case 1).

In this and the two subsequent figures, each vertical subdivision represents a four-hour period. The temperature recordings were oral, except in the darkly shaded "shock" areas, when they were rectal.

blood nonprotein nitrogen gradually dropped, becoming normal 6 days later. There was never any evidence of cardiac failure, and the patient was eventually discharged to duty.

CASE 2. A 37-year-old officer was admitted to the hospital complaining of generalized malaise, chilly sensations and a mildly sore throat. He had felt perfectly well until 2 hours prior to coming to the hospital, at which time he commenced to feel chilly and thought he was coming down with a "cold."

Physical examination showed an injected throat of moderate severity but was otherwise negative. The temperature was 102°F., the pulse 105, and the respirations 19. The white-cell count was 13,600, with 67 per cent polymorphonuclear leukocytes and 33 per cent lymphocytes. The urine was negative. A tentative diagnosis of pharyngitis was made and the patient was admitted to a respiratory ward.

Early the next day — 9 hours after admission — he experienced a severe chill and the temperature rose to 105°F. (Fig. 2). Physical examination was still essentially negative, although the patient's general appearance was quite toxic. Six hours later a profuse, blotchy, hemorrhagic skin rash

FIGURE 2. Meningococcemia (Case 2).

blood pressure rose to 100/60 on the afternoon of the 3rd day and over the next 3 days gradually returned to a normal level (120/80). Intravenous fluids were abandoned after the 3rd day. Chemotherapy was stopped on the 12th day, and convalescence was uneventful.

CASE 3. A 25-year-old soldier was admitted to the hospital because of a cough and moderate pain in the right chest of 4 days' duration. His previous health had been excellent. On admission he was moderately ill.

Physical examination revealed rales over the right lower lobe, and an x-ray film taken the day of admission showed an

was secondary to the acute infection. He was given 2000 cc. of 5 per cent glucose in normal saline solution and 500 cc. of plasma over the next 12 hours. Simultaneously with the above measures, he was placed in an oxygen tent and started on sulfadiazine therapy. Five grams of sodium sulfadiazine was given intravenously, followed by 1 gm. of sulfadiazine orally every 4 hours. Sodium bicarbonate was given orally, 3 gm. per gram of sulfadiazine.

The blood pressure gradually rose to 120/70 over the next 24 hours, and with its return to normal all signs of shock disappeared and the urinary output improved. Because the patient continued to run a febrile course, however, he was given 200,000 units of Type 3 antipneumococcus serum in addition to the sulfadiazine. The spiking fever persisted, and on the 8th day signs of fluid developed in the right chest. A right-sided thoracentesis revealed purulent fluid containing pneumococci. On the 20th day closed-tube drainage of the right chest was instituted, and from then on convalescence was uneventful.

Figures 1, 2 and 3, which record the temperature, pulse, respirations and blood pressure determined at four-hour intervals in each case, emphasize several points of similarity that are readily noted graphically and that may warn clinicians of impending events. There was an abrupt rise in temperature to a high level shortly preceding the overwhelming spread of the infection. This was followed by an equally abrupt fall in temperature, although the pulse and respirations did not correspondingly drop. Oliguria was present during the period of hypotension. Each patient had been examined prior to the onset of shock and clinically presented evidence of an essentially negative cardiovascular system and appeared to be in good fluid balance.

The mechanism producing the shock in all 3 cases is probably due to the sudden invasion of the vascular system by bacteria or bacterial toxins or both that paralyzes and dilates the capillary bed. A pooling of blood occurs in the dilated capillaries, with a concomitant reduction in the venous return to the heart and in the cardiac output. Romberg et al.⁸ demonstrated in 1899 that the injection of bacteria and bacterial products intravenously could produce vascular collapse, and other investigators^{10,13} have confirmed their findings.

The first case presented in this study was one of severely toxic scarlet fever. Presumably in this type of case one is dealing with a true bacterial exotoxin that is absorbed into the blood stream. By the intravenous administration of pooled convalescent scarlet-fever serum the temperature and some of the toxic manifestations were controlled. However, the tone of the vascular system did not return until the fourth day, and during that time intravenous fluid and plasma were necessary to maintain the blood pressure at a critical level. The disparity between the circulating blood volume and the size of the vascular bed was further aggravated by the loss of fluid through vomiting and diarrhea.

The second case was one of a fulminating meningococcemia, with a massive invasion of the blood stream by bacteria and bacterial products. As is

FIGURE 3. *Pneumococcus (Type 3) Pneumonia (Case 3).*

infiltration in the same area. The temperature was 102°F and the white-cell count 10,400, with 69 per cent polymorphonuclear leukocytes. The urine was normal. A diagnosis of primary atypical pneumonia was made, and the patient received symptomatic therapy.

During the first 4 hospital days his course was uneventful and he appeared to be recovering. On the 5th day the rectal temperature rose to 106.2°F. (Fig. 3) in 4 hours. The respirations became labored. The blood pressure dropped precipitously from 120/70 to 70/0 and later to 60/0, and shortly thereafter the rectal temperature decreased to 100°F. The skin was cold, and the pulse was imperceptible. The patient was extremely restless, and there was cyanosis of all the extremities.

Examination of the chest at that time revealed signs of frank consolidation at the right base, although the white-cell count was still only 12,000, with 74 per cent polymorphonuclear leukocytes. The sputum contained Type 3 pneumococci. Blood cultures were negative. It was believed that the patient had developed a severe bacterial pneumonia superimposed on the original infection and that the state of profound shock

well known, many of these patients die in severe shock before the infection can be controlled by chemotherapy. In this case again, it was possible by the use of intravenous fluid and plasma to maintain the circulating blood volume and blood pressure at a critical level until the infection could be controlled by sulfadiazine.

In the third case, one of Type 3 pneumococcus pneumonia, although blood cultures failed to demonstrate a septicemia it was thought that the severe state of peripheral vascular collapse was due to an invasion of the blood stream both by bacteria and by bacterial products. Here again, while the infection was being treated energetically with sulfadiazine and Type 3 anti-serum, the circulating blood volume was maintained by intravenous plasma and fluids.

The institution of specific measures to combat the infection is of primary importance, since they are directed at the cause of the shock state. It is our contention, however, that death in the early stages of acute fulminating infections may occur as a result of secondary shock; furthermore, if vigorous anti-shock therapy directed to maintain an adequate circulating blood volume is resorted to, as in the cases cited above, many patients may be maintained until specific serum or chemotherapy or both have been able to control the infection.

It is considered advisable to give warning that overly enthusiastic use of procedures designated to restore inadequate circulating blood volume in patients with certain types of acute pneumonia, particularly interstitial pneumonia, so frequently seen in young children, may result in an increase in exudation in the lungs and harm to the patient.

SUMMARY

Shock during the course of acute infection is discussed, and its importance as a preventable cause of death is stressed.

In the treatment of shock in acute infections, attention is called to the need for maintaining an adequate circulating blood volume by the use of intravenous plasma and fluids while the infection is being vigorously treated by appropriate chemotherapy or serotherapy. The use of oxygen in the face of anoxemia and other supportive measures are not to be neglected.

Three case reports that illustrate acute infections not infrequently seen in medical practice and that presented serious states of shock are given in detail, with their treatment.

MEDICAL PROGRESS

OPHTHALMOLOGY

EDWIN B. DUNPHY, M.D.*

BOSTON

THE following ophthalmologic subjects have been selected as being of general interest. Some of them are not new, but because of recently revived interest in them, they were thought to deserve review.

RELATION OF GERMAN MEASLES TO CONGENITAL CATARACTS

One of the most interesting recent developments in the field of ophthalmology has been the recognition of the fact that congenital cataracts can be caused by German measles occurring in the mother early in pregnancy. Gregg,¹ of Sydney, was the first to point out this relation, and in 1941 he reported a series of cases to the Ophthalmological Society of Australia. He stated that in the summer of 1940 there had been an epidemic of unusually severe rubella in southeastern Australia. The following year there occurred a great increase in the incidence of congenital cataracts among the newborn of Sydney and other neighboring cities. Gregg reported 78 cases of cataracts, 20 of which were seen by him and the remaining 58 by colleagues and reported to him. In all but 10 cases, a history of rubella during early pregnancy was obtained. The cataracts were bilateral in 62 cases and unilateral in 16. Microphthalmia was present in 10 of the unilateral cases.

According to Gregg, these cataracts were of a special type, being dense white with all layers of the lens involved. Most of the babies were small and ill nourished and presented definite feeding problems. Forty-four of them had congenital heart disease. Fifteen deaths were recorded. Autopsy in 3 cases revealed patency of the ductus arteriosus.

An interesting feature was the reported intolerance to atropine exhibited by all these infants. When 1 or 2 drops of a 0.5 per cent solution of this drug were used to dilate the pupils, considerable constitutional disturbance took place, consisting of flushing of the skin, pyrexia and disturbed digestion.

Gregg believed that there was more than a casual relation between the attack of rubella and the occurrence of the congenital cataracts. In 35 cases in which accurate records were available, the affected baby was the first child in 26 cases, the second child in 3, and the third, fourth, fifth, sixth, eighth and tenth child in the remaining. Other children in the families showed no signs of cataracts, nor did the parents.

Gregg raised the question whether the causative factor was really German measles because of the severe epidemic of sore throat that was sweeping the country concurrently with the rubella, most of the mothers having had tonsillitis at the time of their illness. He suggested that the rash diagnosed as German measles might have been a toxic erythema accompanying a streptococcal throat infection.

Naturally this report stimulated great interest throughout Australia, and under the direction of the National Health and Medical Research Council a group was appointed to determine the following points: whether the disease of the mothers was rubella or some illness simulating it, the period of pregnancy in which the disease produced congenital defects, the full extent of these defects and whether these defects could have been produced by other infectious diseases during pregnancy. This extensive investigation was conducted by Swan, Tostevin, More, Mayo and Black.² All the physicians in certain sections were circularized, and all pregnant women with exanthematous diseases were registered. All new cases of congenital cataracts in infants were investigated, and the history of each mother was carefully gone over for evidence of prenatal illness. The results of this study were published in 1943 and showed that of 61 infants examined, 36 had congenital defects. Forty-nine of the mothers had had rubella during pregnancy, 9 had had morbilli and 2 mumps; 4 denied knowledge of any disease. Of the 49 mothers with rubella, 31 gave birth to infants with congenital defects. Of these, 13 had cataracts, in 10 of whom they were bilateral, 1 had buphthalmos, 7 were deaf mutes, and 17 had cardiac anomalies. Some degree of microcephaly was apparent in all. All but 2 of the mothers of the infants with congenital defects had contracted rubella during the first three months of pregnancy.

It was the conclusion of the investigators that there was no valid evidence that the epidemic of 1940 was other than rubella and that the predominating organism in the concurrent epidemic of sore throat was *Haemophilus influenzae*. Furthermore, they stated that subsequently, when there was no epidemic of sore throat, congenital cataracts were found in the offspring of mothers who had had German measles.

In a subsequent communication, the same authors³ reported 12 additional cases of rubella occurring during early pregnancy, eleven of the infants showed congenital defects. These included 2 cases of cataracts, 5 of deaf mutism and 4 of heart disease,

*Clinical professor of ophthalmology, Harvard Medical School; chief of the Ophthalmological Service, Massachusetts Eye and Ear Infirmary

well known, many of these patients die in severe shock before the infection can be controlled by chemotherapy. In this case again, it was possible by the use of intravenous fluid and plasma to maintain the circulating blood volume and blood pressure at a critical level until the infection could be controlled by sulfadiazine.

In the third case, one of Type 3 pneumococcus pneumonia, although blood cultures failed to demonstrate a septicemia it was thought that the severe state of peripheral vascular collapse was due to an invasion of the blood stream both by bacteria and by bacterial products. Here again, while the infection was being treated energetically with sulfadiazine and Type 3 anti-serum, the circulating blood volume was maintained by intravenous plasma and fluids.

The institution of specific measures to combat the infection is of primary importance, since they are directed at the cause of the shock state. It is our contention, however, that death in the early stages of acute fulminating infections may occur as a result of secondary shock; furthermore, if vigorous anti-shock therapy directed to maintain an adequate circulating blood volume is resorted to, as in the cases cited above, many patients may be maintained until specific serum or chemotherapy or both have been able to control the infection.

It is considered advisable to give warning that overly enthusiastic use of procedures designated to restore inadequate circulating blood volume in patients with certain types of acute pneumonia, particularly interstitial pneumonia, so frequently seen in young children, may result in an increase in exudation in the lungs and harm to the patient.

SUMMARY

Shock during the course of acute infection is discussed, and its importance as a preventable cause of death is stressed.

In the treatment of shock in acute infections, attention is called to the need for maintaining an adequate circulating blood volume by the use of intravenous plasma and fluids while the infection is being vigorously treated by appropriate chemotherapy or serotherapy. The use of oxygen in the face of anoxemia and other supportive measures are not to be neglected.

Three case reports that illustrate acute infections not infrequently seen in medical practice and that presented serious states of shock are given in detail, with their treatment.

Post¹⁷ has collected the records of 57 cases of myopia in which the vision was definitely improved by one or another type of exercise. One of the most remarkable of these cases was that of a twenty-four-year-old man whose vision had become progressively worse through the years, it being 20/200 in each eye corrected to 20/20 with about -2.00 spheres and small cylinders. These tests had been made under a homatropine cycloplegia. Being rejected for military service, he took so-called "muscle exercises" for twenty-four lesson periods, at the end of which he was able to see 20/20 with each eye without glasses. Homatropine refraction then showed the same error as he had had before taking the exercises! In this case, care had been taken to prevent memorizing the test letters. The same ophthalmologist examined the patient on both occasions. Since his refractive error under the cycloplegia had not changed, his great improvement must have been due to learning how to use his visual powers to the utmost advantage by practice and repetition.

According to Lancaster, "seeing is only partly a matter of the image on the retina but is, in still larger part, a matter of cerebral synthesis in which memories play a principal role. By repetition one builds up a substratum of memories very useful for the interpretation of sensations and facilitates the syntheses which are the major part of seeing." Experience has shown that, although some patients are improved by these methods, the improvement is usually not lasting. Many patients state that they did not have time to keep up their exercises and eventually went back to wearing glasses. The dangers of the unsupervised use of these exercises in cases of detached retina and glaucoma have been pointed out by Duke-Elder.¹⁸

Men rejected for military service because of color blindness often apply for treatment to cure their defect. A number of optometrists have claimed that they are able to help these persons. The treatment consists in fixation of colored lights, the sorting of colored beads and the use of filters in viewing the test plates. By constant repetition the patients learn to interpret their sensations more efficiently, and undoubtedly a number of them have been able to pass the test. Subsequent reports from the Army and Navy¹⁹ indicate, however, that the improvement in such cases has not lasted, patients later on having fallen down badly in critical situations that required accurate color perception.

According to Bridgman and Hofstetter,²⁰ two optometrists at Ohio State University, the alleged improvement in color vision after this type of training is due to learning made possible after repeated testing. They illustrate this by the report of a color-blind subject who at his first examination scored only 15 out of 46 plates. He was merely told each time that he was wrong but was not told the correct answer. On the second, third, and fourth test-

ings, his scores were 27, 35 and 43 correct. These authors concluded that the color-filter treatment is not only ineffective in curing color blindness but is, in fact, dangerous, since it leads persons into the acceptance of responsibilities that they will be unable to fulfill.

It must be kept in mind that there are various degrees of color blindness and that in mild cases repeated testing leads to proficiency in correctly naming the test plates. When the scene is changed, however, such persons are still found to be "color weak." This is borne out by some recent unpublished work by Gallagher²¹ and his associates. Forty-five students were selected as being color weak from their responses to the American Optical Company pseudoisochromatic test plates²² and were given training on these plates until all could pass the test perfectly. They were then tested on the Ishihara plates,²³ which are quite similar, but only 6 of them made perfect responses on this test, which was unfamiliar to them. Several months later, 15 of them were retested on the American Optical Company plates and a sharp decrease in their ability again to name these plates correctly was noted. Even when these 45 students were at the peak of their proficiency in passing the American Optical Company test, they were unable to pass the color-desaturation test. In this test various saturations of red and green light are thrown on a screen in random order and the subject is asked to say whether the color is red or green. Gallagher and his associates conclude that there is no evidence that color training improves the ability of a color-weak subject to discriminate between colors except in the situation in which the training is given.

EFFECT OF FLUORESCENT LIGHTING ON EYES

The fluorescent lamp has been an important development in electric lighting. Since its introduction some years ago, however, there have been many complaints that it is fatiguing to the eyes. Physicians are often asked by their patients whether it is actually harmful. It may be helpful, therefore, to review the evidence on this question.

The fluorescent lamp is a mercury-vapor lamp giving off chiefly ultraviolet radiations within a tube. The inside of the tube is coated with certain substances that fluoresce under this radiation. No ultraviolet light reaches the eye, as is generally believed by the laity. The lamp has the advantage of producing three times as much light per watt as the regular incandescent lamps. Another advantage is the relatively low degree of radiant heat given off when high levels of illumination are used, daylight fluorescent lamps giving forth only one quarter as much heat as an incandescent lamp of equivalent light output.²⁴ Furthermore, the comparative low brightness per square inch of glass surface and the long form of the tubes make it possible for the

If these two series are combined, it is seen that of 61 mothers who had rubella during pregnancy, 42 gave birth to children with congenital defects and of these 15 had cataracts. In analyzing the data, the investigators concluded that if a woman contracts German measles during the first two months of pregnancy, the chances of a congenitally defective infant are practically certain. If the disease occurs during the third month, about half the infants will be affected.

During the past year several American reports have corroborated Gregg's original findings. Thus, Reese⁴ reports 3 cases of dense white cataracts and congenital heart defects in infants whose mothers had been treated for rubella during the first month of pregnancy. Rones⁵ reports 3 maternal cases of rubella and 1 of morbilli. In 2 of these cases the exanthema had occurred in the second month of pregnancy and the infants were born with bilateral cataracts; 1 of them had congenital heart disease. In the other 2 cases the disturbance took place in the third month and the infants were born with congenital glaucoma.

Erickson⁶ reports 9 cases of congenital cataracts in infants born of mothers who had had rubella during the first two and a half months of pregnancy. All but 2 of these showed heart defects in addition to the cataracts.

It is known that important developmental changes take place in ocular and cardiac tissues of the embryo during the first three months of pregnancy.⁷ It is also known that embryonic tissues are especially susceptible to virus infections. Goodpasture⁸ has pointed out the greater susceptibility of chick embryo, as compared with the hen, to a wide variety of infections inoculated in the chorioallantoic membrane. It is not improbable that the human embryo possesses the same increased susceptibility, so that infections such as German measles, which cause only slight or no damage to adult tissues, result in profound changes to embryonic cells.

With formation of the placenta at the end of the third month of pregnancy, there is apparently a reduction in the penetrability of the barrier between mother and fetus. This may in part explain the decreased incidence of congenital defects when the infections occur in the later months of pregnancy.

Little is known concerning the exact mechanism of cataract formation. Swan and his co-workers² suggest interference with the nutrition of the lens by action of the agent on the hyaloid artery. It seems more probable, however, that the lens is directly affected.

This whole subject brings up the question of whether abortion is justified if a woman contracts rubella during the first three months of pregnancy. Certainly it is desirable that girls be exposed to this disease before marriageable age. There are, of course, practical difficulties in this procedure.

EYE EXERCISES FOR IMPROVING VISION

The question of eye exercises to improve visual acuity is one that crops up perennially and has for years been the subject of bitter debate. The Bates method,⁹ originally brought forth in 1920, has recently been repopularized by Huxley's¹⁰ book *The Art of Seeing*.

Bates, a New York physician, claimed that accommodation was due not to an increase in the convexity of the lens, as is generally believed, but to a change in the shape of the eyeball brought about by the action of the superior and inferior oblique muscles. He believed that all refractive errors were due to the unbalanced pull of these muscles. The animal experiments on which he based this theory were open to certain criticisms. Also, his claim that the cure of all refractive errors lies in so-called "dynamic relaxation," which can be brought about by certain exercises, was not accepted by the medical profession. The method was employed by many cultists, and after enjoying several years of popularity with the public gradually fell into disrepute, only to have a renaissance in recent years when men were being rejected for military service because of eye defects. Although the majority of orthodox ophthalmologists¹¹⁻¹⁵ decry such antics as "palm-ing, swinging the eyes, sunning, thinking of black velvet and so forth" as pure nonsense, one must nevertheless admit that there are a certain number of people who, by these methods, do achieve improvement in their visual acuity without the aid of glasses. To the simple neurotic such a system may be expected to give aid and comfort. It is also understandable that it might benefit borderline cases of myopia, since many patients are not really myopic but, owing to excessive accommodation, have brought the focal point of the fixated object anterior to the retina, thus producing an artificial myopia. Learning to relax their accommodation, by whatever means employed, results in their being able to see normally without glasses. Lancaster,¹⁶ who has approached the subject with an unbiased mind, illustrates this point with the story of a young man who came to him asking whether there was any chance of his passing the 20/20 visual test. His vision with his weak myopic lenses was 20/15 but without them was only 20/30. He was given +1.00 spheres to wear constantly for three days. He then read 20/15 without glasses. This man was not a true myope; he had simply learned to relax his accommodation by wearing convex lenses for a while. The same results could probably have been obtained by the Bates exercises.

Even in true myopes, going without glasses for a few days and learning to relax often results in some visual improvement on the test chart. It is not that the refraction has changed essentially, but that the patient has learned to interpret blurred objects more or less correctly through practice. This point has been emphasized by Lancaster.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

CASE 31231

PRESENTATION OF CASE

A sixty-three-year-old business man was admitted to the hospital because of fever, dyspnea, inability to urinate and exacerbation of a chronic scrotal infection.

For several years he had had nocturia, frequency and hesitancy. These symptoms progressed, and two years before admission he had a transurethral prostatic resection in a community hospital. On the tenth postoperative day he developed a right epididymitis, which progressed to abscess formation and necessitated a right epididymo-orchectomy. Since that time he had had a draining sinus at the upper angle of the wound. The discharge was offensive and the sinus refractory to local treatment. The patient continued to work despite moderate frequency, a draining sinus and occasional bouts of left scrotal pain and swelling. Seven months before admission he experienced some nausea and abdominal discomfort. He went to another hospital where he was found to have anemia, with a red-cell count of approximately 1,000,000; the spleen was enlarged, extending to the level of the umbilicus. For several months he was treated for anemia. Six weeks before admission he was given three x-ray treatments to the spleen, which allegedly caused some decrease in size and was followed by a rise of the red-cell count. His appetite improved, and he gained weight. Since the operation two years before entry he had been taking 0.1 gm. of digitalis daily. Ten days before admission he experienced malaise and dyspnea and felt vaguely ill. A physician advised bed rest. Shortly after this the patient found that he could not urinate. After several catheterizations he developed pain in and swelling of the left scrotum. The temperature rose to 104°F., and after nine days on sulfadiazine therapy (6 gm. a day, with sodium bicarbonate) he became oliguric and was brought to the hospital. The dyspnea and moderately severe orthopnea, requiring two or three pillows, had continued. A cough that had been present and nonproductive for several years had, during the past few weeks, become productive of yellow, tenacious sputum, especially pronounced on change of position. He

*On leave of absence.

had had no chest pain, palpitation or swelling of the ankles.

Physical examination revealed a well-developed, well-nourished man with dry, hot and flushed skin. The throat was dry and red. The neck veins were distended and distinctly pulsating. The chest was emphysematous and had limited motion. There were rales in both bases posteriorly and in the axillary region. The diaphragm was low on both sides and showed limited motion. The heart was enlarged to just beyond the left midclavicular line. The sounds were distant. An inconstant apical gallop rhythm developed and persisted. No murmur or thrill was noted. The aortic second sound was greater than the pulmonic. The abdomen was flaccid; the liver was nontender and extended two fingerbreadths below the right costal margin. The spleen extended five or six fingerbreadths below the left costal margin and almost to the midline. There was distinct bilateral costovertebral tenderness, but that on the right side disappeared in a day. There was no fluid, and no other masses were felt. The right scrotum was empty and retracted. There was a small draining sinus at the upper angle of the orchectomy scar. The left testis was tender, and the left epididymis was enlarged, tender and hard, with an overlying warm, red skin. A slight purulent discharge came from the urethra. The penis was normal. Rectal examination revealed little prostatic tissue and no hemorrhoids. There were varicose veins of the legs and mild pitting edema of the lower extremities, sacrum and back. The legs were symmetrical, and the pulsations of the dorsalis pedis arteries were good.*

The temperature was 104°F., the pulse 120, and the respirations 50. The blood pressure was 110 systolic, 60 diastolic.

Examination of the blood showed a red-cell count of 2,900,000, with 9.7 gm. of hemoglobin. The red cells showed quite marked anisocytosis and poikilocytosis. The white-cell count was 6400, with 89 per cent neutrophils; there were 2 per cent band forms and 1 per cent myeloblasts. A voided urine specimen was cloudy, amber and acid in reaction. The specific gravity was 1.006. There was a ++ test for albumin, and the sediment contained 3 to 5 granular casts per high-power field, as well as numerous white cells and crystals resembling sulfadiazine; no red cells were seen. The sulfadiazine level of the blood was 2.9 mg. per 100 cc. The serum nonprotein nitrogen was 85 mg. per 100 cc., and the protein 5.8 gm. The albumin-globulin ratio was 1.2. The carbon dioxide and chloride were normal. A smear of the discharge from the scrotal sinus showed no tubercle bacilli, but the culture yielded a moderate number of colonies of *Staphylococcus albus* and a few of a beta-hemolytic streptococcus. The urine culture showed moderate growth of a beta-hemolytic streptococcus and a few colonies of an alpha-hemolytic streptococcus. A Congo red

fixtures to be hung at low levels with an even distribution of light.

Fluorescent lamps operate on alternating current, usually 60 cycles per second. With each change in the direction of the current there is a slight pause during which no current is flowing. This pause is almost infinitesimal, but during it the lamp becomes less bright. Under most circumstances this makes no difference. If, however, the eye is moving rapidly over a wide area, a series of successive images fall on different points of the retina and a series of separate sensations are observed, since each one persists after the next one begins. The same effect can be obtained if the eye is stationary but the object moves rapidly across the field. This flicker may give rise to disagreeable sensations under the above-mentioned conditions, but if only a small stationary area is being viewed, the successive images fall on the same position of the retina and a continuous or fused picture is produced.²⁵ This stroboscopic or flicker effect can be eliminated by combining tubes in pairs so that the maximum output of one coincides with the minimum output of the other. Indeed, most modern installations are of this type.

The whole question of fatigability under fluorescent light has been investigated by Luckiesh and Moss.²⁶ They base their conclusions on the results obtained by comparing visual performance under fluorescent light with equivalent illumination from tungsten-filament lamps. After testing a number of subjects they found no difference in visual acuity when either of these two types of illumination was used. The fluctuation in the light output of a daylight fluorescent lamp did not cause ocular fatigue as measured by the rate of blinking²⁷ during reading. This is not surprising since the flicker of the fluorescent lamp is well above the critical flicker frequency of the human eye and should not be bothersome if the eyes are fixed on a small area. The fixational pauses²⁸ that occur during reading were electrically recorded and were not found to be prolonged under fluorescent light.

From the above experiments Luckiesh and Moss concluded that there is no basis for the oft-heard criticism that fluorescent light fatigues the eyes. Although the criteria they used may be open to some criticism as not truly determining ocular fatigue, nevertheless no one has been able to bring

forth any valid evidence that fluorescent light in ordinary office use is either harmful or tiring. If care is taken in installing the fixtures to minimize glare and to provide an adequate and even distribution of light, this type of illumination should be just as satisfactory as any other type now in use.^{29, 30}

DR. WILLIAM DAMESHEK: When I first saw him the problem was not so much the urinary one that had been in the background but rather the enlarged spleen and anemia. The anemia was of the macrocytic variety, associated with a slightly elevated white-cell count and the presence in the peripheral blood of myelocytes and nucleated red cells. These findings in association with a large spleen make one think of myeloid metaplasia of the spleen, with a faulty liberation of myelocytes and nucleated red cells into the peripheral blood. I like to consider that myeloid metaplasia is not "agnogenic" or "idiopathic" as some observers believe but that it is secondary to some sort of more fundamental disorder of the bone marrow, which is often sclerotic, such as the condition reported by Dr. Chapman² some years ago.

X-ray studies of the bones, which were not done here apparently because the patient was too ill, showed the typical picture of osteosclerotic anemia, with irregular areas of osteoporosis and increased density of the pelvic bones and the femurs. Since a sternal puncture failed to bring up enough marrow material for diagnosis, we then did a sternal trephine bone-marrow biopsy, which showed sclerosis of the bone and bone marrow, but in addition hyperplasia of the white-cell elements, interpreted by a pathologist as leukemia. I did not think that this diagnosis was warranted and was inclined to consider the case as one of osteosclerotic anemia with myeloid metaplasia of the spleen. Later, because the patient was going downhill, we tried the effect of a few x-ray treatments over the spleen. The spleen actually (not "allegedly") went down in size and the patient's red-cell count went up. Theoretically, this should not occur in myeloid metaplasia of the spleen. In the background was the chronic urinary infection, which at the time I studied the patient was minimal. Regarding the matter of amyloid disease, I must admit I gave it no consideration.

DR. WYMAN RICHARDSON: I saw this patient and thought that the blood picture suggested pernicious anemia, complicated by a uremic state, although there was also some immaturity of the cells seen in the blood film. I thought that it might be the result of the complicating uremia. I also suggested that he be given liver extract, on the bare chance that he might respond. This was tried, but he had no response.

CLINICAL DIAGNOSES

Pernicious anemia?
Chronic sepsis.
Uremia.

DR. CHAPMAN'S DIAGNOSES

Chronic bacterial sepsis (scrotum and kidneys).
Amyloidosis of kidney and spleen.

ANATOMICAL DIAGNOSES

Splenitis, acute and chronic, with marked splenomegaly.
Epididymitis and orchitis, acute and chronic.
Pyelonephritis, acute and chronic.
Pulmonary emphysema and congestion.
Cardiac dilatation.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this man showed an enormous, moderately firm spleen; it weighed slightly over 1000 gm. In gross we obviously thought of myelogenous leukemia. In fact there were two small infarcts, which one often sees in myelogenous leukemia. The vertebral and sternal bone marrow on gross examination was red, and the marrow in the tibia and femur, which ordinarily is fatty, was pink, indicating hematopoietic hyperplasia. We were not impressed in the gross with the sclerotic character of the bone marrow.

The scrotum still contained a sinus tract, and there was an acute and chronic epididymitis. The epididymis was filled with pus, and the process had extended into the testis. Both kidneys were pale and slightly enlarged, the combined weight being 400 gm. Microscopically they showed an extreme pyelonephritis that undoubtedly was secondary to the scrotal abscesses, the orchitis and the epididymitis. The ureters were not distended but were moderately injected. There was no evidence of amyloid in the kidney or the spleen.

Microscopical examination of the spleen showed a picture that, had one not known about the history of the case, one would have called subacute bacterial endocarditis. There was edema, and widening of the Billroth cords. In the sinuses and throughout the pulp were plasma cells, lymphocytes, hemosiderin-laden phagocytes and polymorphonuclear cells. The appearance was that of long-standing chronic infection. Certainly it could not be called leukemia. That was borne out by the microscopical appearance of the bone marrow, which showed many mature polymorphonuclear and plasma cells, as well as cells of the red-cell series. There was some fibrosis, but this was slight and merely a secondary manifestation of long-standing hyperplasia of the bone marrow. I do not believe that one can call it an osteosclerotic type of anemia. It is the largest spleen that we have seen in chronic sepsis.

The only additional finding that we would have liked to demonstrate in this case is a bacterial endocarditis, but there was none. The lungs were emphysematous and congested, but we found nothing to explain the recent productive cough. The heart was dilated but not hypertrophied.

test showed 76 per cent of the dye remaining in the blood in one hour. The Hinton test was negative.

X-ray examination of the chest showed diffusely increased vascular markings throughout both lung fields, normal hilar shadows and a smooth diaphragm, with no evidence of fluid in the costophrenic sinus. The respiratory rate was rapid, and the diaphragmatic excursion quite limited. The heart was not grossly enlarged, and the cardiothoracic ratio was 13.9:31 cm. The aorta was somewhat tortuous, with some calcification of the arch. One electrocardiogram on the third day showed auricular fibrillation with almost ventricular rhythm at the rate of 90; there was slight left-axis deviation, with sagging ST₁ and ST₂ and low upright T₁ and T₂.

No sulfadiazine or salt was given, and the patient was fully digitalized at once. The oral fluid intake was about 2500 cc., and the output about 1750 cc., with a slight parallel rise in these values during the first week. By lysis, the temperature became normal on the fourth day, and the pulse and respiratory curves followed. These remained normal for three days and then began to rise again. The non-protein nitrogen rose to 135 mg. per 100 cc., and two days later, on the eighth hospital day, the patient expired.

DIFFERENTIAL DIAGNOSIS

DR. EARLE M. CHAPMAN: It seems evident that this man suffered from chronic bacterial infection, especially of the scrotum, from which area *Staph. albus* and beta-hemolytic streptococci were cultured. The urine was likewise contaminated.

The chronic nonproductive cough that he had had for years became productive of purulent sputum on change of position during his final illness, and then rales were discovered at the lung bases. These facts justify a clinical suspicion of bronchiectasis. Unfortunately the x-ray studies do not help us to establish such a diagnosis.

With this background of chronic sepsis we are next faced with explaining a man's death in renal failure — a rather unusual form of renal failure that was further complicated by the use of two potent and often toxic drugs — digitalis and sulfadiazine.

There seems little question that 54 gm. of sulfadiazine in nine days is excessive, and the cessation of urine flow toward the end of his illness favors a specific type of damage to the kidney. On hospital entry, however, only 2.9 mg. of the drug was found in the blood stream, and no red cells in the urine. These two facts do not support my first suspicion that his kidneys might have shown the granulomatous changes of sulfadiazine intoxication.

As for the digitalis, a person who has taken 0.1 gm. daily for two years, and has nausea and abdominal discomfort seven months before entry, and is then given more of the drug on hospital entry is

apt to become sick. The electrocardiographic changes, especially the sagging of the ST segments, are probable digitalis effects. How can the pathologist help us at autopsy in determining whether or not a person has been toxic from digitalis? I raised this question at the autopsy table recently and received little help.

The next thing to discuss is this man's death in renal failure. What type of kidneys should we expect to find? I am going to commit myself now to that unusual form called the "contracted amyloid kidney" — the kidney that in gross often has the appearance of a chronic glomerulonephritis. With this background of sepsis, allegedly nontuberculous, there might have been the condition favoring the release of protein complexes, with amyloid degeneration in the walls of the blood vessels in the kidneys and spleen.

I now wish to call your attention to the clinical features of renal amyloidosis in this man's record. The patient always had polyuria, — not influenced by transurethral resection, — and even toward the end he excreted a urine of low gravity and with the surprising daily volume of 1750 cc. He also had an anemia, chronic and resistant to treatment and yet not disabling; next, a normal-sized heart and a normal blood pressure — hypertension in renal amyloidosis is indeed rare; next there was a rather small amount of albumin in the urine, a low albumin-globulin ratio and, finally, a gradually rising serum nonprotein nitrogen.

Balanced against all this clinical evidence is one miserable laboratory test — the Congo red test. They tell us that it showed 76 per cent of the dye remaining in the blood in an hour. When Bennhold¹ described this test in 1923, he claimed that normally less than 30 per cent disappeared from the blood in an hour and that in amyloid disease 40 to 100 per cent leaves the blood in an hour. It has been found by others, however, that 40 to 60 per cent may remain in the blood in cases of amyloid disease and in other types of nephrosis, so that it is not always of practical value in determining the type of nephrosis. Bennhold did not differentiate the response in the gross lardaceous type from that in the small atrophic contracted type of amyloid disease, and it is for this reason that I am going to stick to my diagnosis in the face of a 24 per cent removal of Congo red from this patient's blood. If he turns out to have had small kidneys with rather quantitatively small amounts of amyloid, then the test could still be consistent with the clinical evidence.

DR. BENJAMIN CASTLEMAN: Do you want to comment about the size of the spleen?

DR. CHAPMAN: I assumed that it was part of the whole process, that is, that he had an amyloid spleen.

DR. CASTLEMAN: Dr. Dameshek, you saw this patient before he entered the hospital. Would you like to add anything?

fectious hepatitis. There had been far too much pain, and there had been a rather rapid development of extremely severe jaundice. The course of the disease was quite unlike what one would expect in that condition. I have already mentioned that I do not believe that this was a toxic acute yellow atrophy. We are told that the patient had gallstones removed many years before, which brings up the question, Did this patient have a complication of the previous cholelithiasis? Did a stone, for instance, in the common bile duct cause all the present jaundice? There is nothing in the history that is against that diagnosis or that rules it out. On the other hand, that certainly does not explain some of the present findings — the ascites and the gastrointestinal bleeding. Cirrhosis would not be expected to give this degree of jaundice and to terminate in such a short period, ten or fourteen days.

We now come to the likeliest diagnosis — some form of neoplasm. Certainly in a person with a previous history of cholelithiasis we have learned in recent years to think of carcinoma of the gall bladder or of the bile ducts as a not uncommon cause of death in a person with jaundice. The diagnosis of carcinoma of the gall bladder or bile ducts is sometimes difficult. One cannot always palpate the mass in the gall-bladder region. That was the diagnosis that I favored until I came to the story of bleeding from the upper gastrointestinal tract. I must say that I was disappointed to read about that tarry stool.

Could this have been one of the most frequent causes of jaundice in a person of this age, namely, carcinoma of the head of the pancreas? There is nothing in the entire picture that rules out that diagnosis, except, again, the gastrointestinal bleeding.

Could this have been a primary hepatoma or a diffuse carcinomatosis primary in the liver? It could have been, except for the bleeding in the upper gastrointestinal tract. There is nothing else against it. Even the fact that they did not feel a solitary liver mass does not rule out the diagnosis.

We must bear in mind that about a month before she developed jaundice she had a nonproductive cough, diagnosed as due to bronchitis. Possibly that was indicative of metastases to the lungs. So we must think of some type of neoplasm below the diaphragm, with early metastases to the lungs and later metastases elsewhere. On the basis of statistical frequency, carcinoma of the stomach is the likeliest diagnosis. Certainly it would account for most of the findings — metastases to the lymph nodes compressing the bile ducts, metastases to the liver, spreading to the peritoneum and part of the cause of the accumulation of the fluid in the abdomen, metastases to the lungs, and gastrointestinal bleeding.

As for the terminal episode, I do not know how we can tell whether she had a bronchopneumonia

or a terminal pulmonary embolus. We are told nothing about the physical findings at the time. I think that terminal bronchopneumonia is far more frequent in a case like this.

I should say then that this patient had carcinoma of the stomach with metastases to the lymph nodes, compressing the bile ducts, and metastases to the liver, peritoneum and lungs, arteriosclerotic heart disease, passive congestion of the kidneys and terminal bronchopneumonia.

A PHYSICIAN: Do you attach any significance to the elevated prothrombin time in connection with the tarry stool?

DR. JACOBSON: We have no evidence of a bleeding tendency in other parts of the body, but I should guess that bleeding sufficient to have changed the color of the stool from clay to tarry could hardly have been the result of a high prothrombin time.

A PHYSICIAN: What about the possibility of carcinoma of the ampulla of Vater?

DR. JACOBSON: In referring to carcinoma compressing the bile ducts I include the ampulla of Vater or some other place in the biliary tract.

A PHYSICIAN: Would that not explain the tarry stool?

DR. JACOBSON: It might by erosion into the gastrointestinal tract. It is a good possibility.

DR. CHESTER M. JONES: I saw this patient when she was first admitted. She was comatose practically all the time after admission and obviously a hopeless case. I thought at the time that she had malignant disease involving the liver and that it was primary or secondary. I could see no way of establishing a diagnosis.

The stool was a glove specimen, and it was pitch black. It would seem to me that Dr. Jacobson's comment was correct: namely, one would anticipate frank ulceration of the mucosa to underlie bleeding of that extent. On the other hand, with pronounced jaundice of this degree, one often obtains positive guaiac tests in the stools regardless of the underlying cause of the jaundice — whether it is intrahepatic or extrahepatic. This stool was actually tarry. I reasoned as Dr. Jacobson did — that there was ulceration. An ulcer in the presence of a clinical picture like this would make me suspect that there was a new growth that had ulcerated into the stomach or the duodenum. Carcinoma of the ampulla may invade the duodenum with subsequent erosion. I thought that the findings were consistent with spreading neoplastic disease.

The death, I believe, even as it is described here, is not at all suggestive of bronchopneumonia or anything else but complete failure of the liver. This woman had enough liver damage to prevent normal function. It is entirely comparable with the sort of picture seen in terminal acute yellow atrophy. We had an excellent example in a case discussed here a short time ago; the patient had carcinomatosis of the liver and a similar death.

CASE 31232

PRESENTATION OF CASE

A sixty-seven-year-old woman was admitted to the hospital because of jaundice and drowsiness.

Three or four months before admission she complained of severe pain that appeared to involve the entire epigastrium. A month later she developed a severe nonproductive cough, which was diagnosed as bronchitis. Ten days before admission she became jaundiced and began to suffer from generalized pruritus. The jaundice and pruritus were progressive, although the degree of jaundice seemed to fluctuate. During the few days prior to entry she became increasingly drowsy and unintelligible.

Many years before entry she had had gallstones removed, but the gall bladder was not taken out.

Physical examination revealed an obese, drowsy, deeply jaundiced woman. The skin showed excoriations from scratching. The breath was "mousy." The few remaining teeth were carious. A Grade 2 systolic murmur was heard over the entire precordium. The heart was enlarged, extending by percussion 14 cm. to the left of the midsternum. The abdomen was distended and showed a definite fluid wave with shifting dullness. The liver was palpable three fingerbreadths below the costal margin. There was slight tenderness in the right upper quadrant of the abdomen. A rectal examination was negative. The ankles showed moderate edema.

The temperature, pulse and respirations were normal. The blood pressure was 112 systolic, 60 diastolic.

Examination of the blood showed 15.3 gm. of hemoglobin and a white-cell count of 16,400, with 72 per cent neutrophils, 22 per cent lymphocytes and 6 per cent monocytes. The red cells and platelets were normal. The urine was dark amber, with a specific gravity of 1.018, and gave a +++ test for albumin and a ++++ test for bile. The sediment showed 15 red cells, 75 white cells and occasional granular casts per high-power field. A stool was black and tarry and gave a ++++ guaiac test. The serum nonprotein nitrogen was 50 mg. per 100 cc., the phosphorus 2.8 mg., the icteric index 180, the prothrombin time 44 seconds (normal, 18 to 20 seconds), and the alkaline phosphatase 6.0 Bodansky units. The fasting blood sugar was normal.

The temperature rose to 101.0°F., and the pulse to 100, and the respirations quite abruptly rose on the third day to 35. The patient received intravenous glucose and vitamins, in addition to a high-carbohydrate, low-fat diet given through a nasal tube. She also received a whole-blood transfusion. The stupor deepened, and she quietly expired on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. BERNARD JACOBSON: I should like to make a few comments on some of the findings. Three or

four months before admission the patient complained of severe pain. I assume that it was not one episode of severe pain but the beginning of recurrent pain of several months' duration. We are not told anything about her appetite or her general sense of well-being, but since she was apparently well nourished when she came in, I assume that she did not lose much weight. We are told that the degree of jaundice seemed to fluctuate, which is of some interest. By and large, severe cases of catarrhal jaundice are apt to have less fluctuation of the degree of jaundice than do those with stone in the common duct or carcinoma of the head of the pancreas.

The breath was "mousy." This of course is of some significance because a mousy odor is due to the presence of certain amines from the liver cells, and that usually signifies diffuse atrophy. But it is fair to say that, although it is suggestive of diffuse atrophy of the liver, it is not pathognomonic. We are told farther on that the liver was palpable three fingerbreadths below the costal margin. In an obese woman of this age that may not mean enlargement at all. It may mean a liver that has been pushed down one or two fingerbreadths and be a perfectly normal-sized liver for such a person.

We are not told anything about other masses in the right upper quadrant. Certainly one would be looking for masses other than the liver. I should be interested to know if there was a mass that corresponded to the size, shape and position of the gall bladder. On the other hand, the fact that none was noted in a woman with an obese abdomen may not be of any significance. A liver palpable three fingerbreadths below the costal margin is certainly against the diagnosis of acute yellow atrophy. The preceding history of the case—jaundice of ten days' duration and rapid progress to death on the fourteenth day—is consistent with the diagnosis of acute yellow atrophy, but the presence of a liver that did not shrink in size is definitely against such a diagnosis. We are told later that the patient had a hemoglobin of 15.3 gm. I rather suspect that this patient's hemoglobin was less; she may have been dehydrated at the time the initial blood count was taken. Nonetheless, that is an important finding, because it rules out for further consideration of such a rare diagnosis as congenital hemolytic jaundice.

Rather upsetting to me, with my preconceived opinion of what this case might have been, is the report that the stool was black and tarry. It seems to me that it would take a lot of blood to color a stool black, especially one that should have been rather light in color because of the absence of much bile pigment. It could not have been due to a recent hemorrhage. That is the first indication that there had been bleeding high in the gastrointestinal tract.

I believe that we can dismiss several of the common causes of jaundice in a person of this age. It certainly was not catarrhal jaundice or diffuse in-

INCREASING OPPORTUNITIES FOR WOMEN IN THE MEDICAL SERVICES

THE opening at Camp Edwards of a 6000-bed reconditioning hospital for wounded and sick veterans is a reminder that the healing of the wound is only a stage in the long process of treating the disabled. This sequence of events may be dramatically initiated with the administration of plasma; it is not finished until the highest possible degree of function is regained, a hopeful attitude toward life is restored, and a new skill, if necessary, is developed.

The amazingly high percentage of lives of wounded soldiers that are now being saved is a modern miracle of science, but it carries with it a great and

continuing responsibility—that of making as many as possible of these bodies useful to their tenants and to mankind, and of reducing to a minimum the permanent human wreckage that war always leaves in its wake.

Certain accessory medical services are largely instrumental in the attainment of such goals, and in these services, women are playing the leading parts. Bulletin 203 of the Women's Bureau, United States Department of Labor, describes the present situation as regards physical and occupational therapy, and the strides that these services have taken as a result of the war.

As the bulletin so aptly phrases it, physical therapy is a relatively new occupation in which an old art is plied—that of treating human ailments with heat, light, water, exercise and other physical means. Even greater progress in the development of this service for the future seems assured by the recent Baruch gift for research and specialized training for physicians in the field of physical medicine.

Physical therapists, more numerous than occupational therapists although still fewer than medical laboratory technicians, numbered before the war some 3100, of whom less than 50 were men. Sixteen approved institutions were then graduating about 150 women a year. Thirty-one institutions, including eight army hospitals, now maintain schools of physical therapy, and graduated over 700 technicians in 1944, representing a considerable increase, although a number still far short of the needs for military, veterans' and rehabilitation services.

The occupational therapist, as distinguished from the physical therapist,

... conducts programs for patients confined in hospitals and other institutions to provide them with directed activity and to assist in their rehabilitation; plans and organizes work projects for patients; supervises workers who teach and direct patients in assigned activities, ... studies patients' reactions while they are engaged in work situations, and writes reports describing their conditions.

Something under 2000 occupational therapists, registered and unregistered, were practicing by 1940; five approved schools were listed in 1941, a number that had grown to twenty-one in 1944. Ninety-nine per cent of occupational therapists are women.

All it implies is that the liver is profoundly damaged and that the patient finally dies of hepatic failure. If one had done blood chemistry determinations one would have found that terminally there was some superimposed renal failure.

CLINICAL DIAGNOSIS

Carcinoma of head of pancreas.

DR. JACOBSON'S DIAGNOSES

Carcinoma of stomach, with metastases to lymph nodes, compressing bile ducts, and to liver, peritoneum and lungs.

Bronchopneumonia, terminal.

Arteriosclerotic heart disease.

Passive congestion of kidneys.

ANATOMICAL DIAGNOSES

Hepatoma, with metastases to lungs, adrenal glands and vertebrae.

Jaundice.

Ascites.

Obstructive cirrhosis of liver.

Acute pancreatitis.

Cholelithiasis.

Dilatation of common bile duct.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy showed about half a liter of straw-colored fluid in the abdomen. There were no peritoneal implants. The liver was large, weighing 2350 gm. About 90 per cent of the parenchyma of the right lobe and 50 per cent of that of the left lobe were replaced by grayish-white nodules from 0.5 to 10 cm. in diameter. The intervening tissue was green. This gross appearance was consistent with a diffuse metastatic process. We looked carefully throughout the body for a primary source but were unable to find one. The stomach showed no erosions, and there were no gross erosions anywhere in the entire intestinal tract. I cannot explain the tarry stool except on the basis of jaundice. Small nodules, 2 or 3 mm. in diameter, were found in the adrenal glands and in the lungs, and most of the vertebral bone marrow was replaced by tumor. With this degree of bone-marrow metastasis it is surprising that the alkaline

phosphatase was not elevated and also that there was no anemia.

The liver parenchyma between the tumor nodules showed bile stasis and biliary obstructive cirrhosis. There were no enlarged lymph nodes compressing the extrahepatic bile ducts, but certainly the intrahepatic ducts were compressed and undoubtedly accounted for the jaundice; they may not, however, have accounted for the cirrhosis. The gall bladder did contain a stone, and the common bile duct was dilated, indicating that stones had been passing down for some time. In the head of the pancreas was an ill-defined 2-cm. area of acute inflammation, with foci of fat necrosis. This is further evidence that the stones had been going down the bile duct. I am just wondering whether some of the symptoms that this patient had, especially the pain, rather than being due to the hepatoma itself, might have been due to stone in the common duct that blocked the pancreatic duct and set off a pancreatitis that smoldered along.

DR. FRANCIS D. MOORE: How big was the stone in relation to the caliber of the cystic duct?

DR. CASTLEMAN: The stone measured about 0.5 cm. in diameter, and the duct measured up to 3 cm. in circumference. At some time, a stone could have become impacted in the ampulla at the entrance to the pancreatic duct, thus starting up an acute pancreatitis. I think that that is the best bet and that the jaundice was a combination of extrahepatic and intrahepatic bile-duct obstruction, although there was no stone in the common bile duct or pancreatic duct at the time of autopsy.

DR. JONES: It is rather surprising that with so much carcinomatous involvement she did not have a long period of jaundice.

DR. CASTLEMAN: Certainly more than half the liver was involved.

DR. JONES: It is also interesting that there was a striking family history of carcinoma. Various members of the family had died of carcinoma.

DR. MILFORD D. SCHULZ: Was the spleen normal?

DR. CASTLEMAN: It was small.

DR. SCHULZ: And the esophageal veins?

DR. CASTLEMAN: They were not enlarged. There was not much portal obstruction. The tumor had invaded the hepatic veins throughout the liver, which accounts for the metastases to the lungs.

countries. It is hoped, moreover, that after the war Great Britain will see fit to set up a medical library association on the lines similar to the associations so well established in America.

Medical bibliography is greatly indebted to Morton for his splendid publication, but in a field that is continually advancing one can only hope that his book will be considered as a steppingstone toward future publications along the same lines. Indeed, Morton himself expresses a similar opinion when he hopes that his book "may be considered worthy to serve as a starting point for something better, to the construction of which both the specialized knowledge of the medical historians and the bibliographical skill of the librarians can at some future date be devoted."

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

ANSHIN—Marcus M. Anshin, M.D., of Lynn, died May 21. He was in his fifty-third year.

Dr. Anshin received his degree from Loyola University School of Medicine, Chicago, in 1919 and did postgraduate work in Vienna and Berlin. He was a fellow of the American Medical Association.

His widow, a daughter and a sister survive.

FRASIER—Joseph A. Frasier, M.D., of New Bedford, died May 20. He was in his seventieth year.

Dr. Frasier received his degree from Columbia University College of Physicians and Surgeons in 1896.

His widow, a son and two sisters survive.

HURLBUT—Lt. Robert S. Hurlbut (MC), U.S.N.R., formerly of Cambridge and Marblehead, was killed in action March 26 when the destroyer *Halligan* was sunk off Okinawa. He was in his thirty-fourth year.

Dr. Hurlbut received his degree from Harvard Medical School in 1938 and was permanent secretary of his class. He was called to active duty in July, 1942, after serving two years as a surgical house officer at the Massachusetts General Hospital. Following service at the Chelsea Naval Hospital at the Office of Medical Officer Procurement, First Naval District, and as physician at the Harvard Naval Dispensary, he began sea duty on the *Halligan* in September, 1943. He saw service in the Atlantic and in North Africa, and was in invasion actions for more than a year in the Pacific.

His mother, his widow and four children survive.

LEVIN—Harry M. Levin, M.D., of Malden, a surgeon in the United States Public Health Service Reserve, was killed on January 29 when the ship he was on was torpedoed at Guadalcanal.

Dr. Levin had been on active duty with the United States Coast Guard since February, 1943. He was first assigned to stations on the West Coast and since September, 1944, had been on sea duty in the South Pacific.

His widow and three children survive.

CORRESPONDENCE

POSTWAR POSITIONS FOR ANESTHESIOLOGISTS

To the Editor: The Hospital Section of the Postwar Planning Committee of the New England Society of Anesthesiology would like to hear from physicians who are interested in the peacetime practice of anesthesiology in New England. This information will be made available to persons interested in obtaining the services of an anesthesiologist in private, group or hospital practice in New England. It is thought that the collection and dissemination of this information may facilitate the proper relocation of anesthesiologists now in the service when they return to civilian practice.

The following information is desired from those who are interested: age, medical school, year of graduation, internship (year and hospital), training in anesthesiology (in detail, giving length and type of training and chief of service), activity and specialty after completion of training, military experience in anesthesia, publications, membership in medical societies, present address and permanent address.

This information should be sent to me as chairman of the committee. The other members are Drs. Jacob H. Fine and Sidney C. Wiggin.

BOOK REVIEWS

Ourselfs Unborn: An embryologist's essay on man. By George W. Corner, M.D. 8°, cloth, 188 pp., with 18 illustrations. New Haven, Connecticut: Yale University Press, 1944. \$3.00.

Here is a book that everyone who is interested in life itself will want to read and to own. It is a scholarly, practical and intensely interesting account of the biography of the first few weeks of life. The distinguished author, who is director of the Department of Embryology, Carnegie Institution, Washington, D. C., and professor of embryology at Johns Hopkins University School of Medicine, presents his subject matter in a pleasant and facile style; here and there he infuses his discussion with provocative quotations from the history of embryology, philosophy, poetry and religion. Yale University was indeed fortunate in choosing Dr. Corner to give the Terry Lectures, which constitute this book. In presenting an account of the natural history of the human embryo, he shows how science can contribute to the broadening and purification of religion itself.

The first lecture considers the topic "The Embryo as Germ and as Archive," and the author concludes this lecture with the following paragraph: "Thus to the seeing eye the human embryo from egg to birth is an archive in which is written the evidence of its descent as an animal, a vertebrate, an amniote, a mammal, a primate; and it is an organic germ, in which the gift of life is intrinsically bound up with the necessity of growth and of ineluctable change. This is not only preparation for life; it is life itself." The second lecture is titled "Prenatal Fate and Foreordination." The author presents the problem of embryonic defect and death in the human species and makes it clear that in man, as in other animals, genetic and constitutional factors are operative in some cases, and disturbances of the maternal environment in others, in the production of prenatal damage and loss. The embryologist sees the human egg as endowed with a general property of organic creatures, and he would never have conceived the idea that an immaterial self-conscious existence is entrusted to the uncertain custody of the human egg. The author declares his conviction that the spirit of man—all that makes him more than a beast and carries him onward with hope and sacrifice—comes not as a high-born tenant from afar but as a latent potentiality of the body. It is true to a

Although the care of war casualties has, of course, opened up unlimited opportunities for these medical services employing women, they need have no fear of facing any serious postwar depression. The country will need these relatively new professional groups so long as it continues to expect a high grade of medical practice and hospital care.

MEDICAL BIBLIOGRAPHY

MUCH of modern medicine stems from Sir William Osler, and in the later years of his life, one of his principal interests was medical history and medical bibliography. He stimulated the late Fielding H. Garrison, of the Army Medical Library, to make out a list of the most important contributions to the literature of medicine and its ancillary sciences, to show the significance of individual writings in the history and development of the medical sciences. This list¹ first appeared in 1912, and since it was considered by Garrison "as a convenient scaffolding for a book," he later wrote his famous *An Introduction to the History of Medicine*,² a standard work invaluable to all students of the subject. When Garrison moved to Baltimore to become librarian of the Welch Medical Library, he expanded the list and republished it in 1933 under the title "Revised Students' Check-List of Texts Illustrating the History of Medicine, with References for Collateral Reading."³ In the last ten years, a further revision with additions and annotations was undertaken by Mr. Leslie T. Morton, the librarian of St. Thomas's Hospital Medical School in London. This important and outstanding reference work has now been published.⁴

Garrison's revised check-list contained 4186 entries; Morton has retained 3826 and has added 1680 new bibliographical notes. Some of the additions are to the important contributions made between 1933 and 1943, but many of the other sections have been expanded, with the idea of showing the significance of the entries more clearly. In addition, Morton has provided an author and subject index. The majority of references have been verified, and many minor corrections have been made. In a few instances, owing to the war, it was not possible for Morton to see the original publication, but he

has fortunately had the help and advice of friends in checking references that were not available to him in London or in other British library centers.

The list as published by Morton is extraordinarily complete and accurate. Its bibliographical matters, such as the spelling of names, the dates of birth and death of the author, the exact names of secondary contributors and the title and notes on the contents of each paper, sometimes not clear from the title, are features of this work for which only a trained librarian with a bibliographical instinct could be responsible.

The matter of how much to say about each contribution is something most difficult to decide, particularly in relation to a publication of recent date. No one, for instance, would question the propriety of putting in the paper by Lawrence O'Shaughnessy in 1936 on an experimental method of providing a collateral circulation for the heart as an outstanding contribution to medical advancement. That O'Shaughnessy, as stated by Morton, was killed in Flanders in May, 1940, while serving with the R.A.M.C., although important biographically, is of slighter value from the point of view of bibliography. The same might be applied to the note regarding John Locke's "Essay" stating that it occupied him off and on for twenty years. When Morton writes, however, that a book published in 1575 in Spanish, which is difficult to obtain, was translated and issued in 1696 in English, or that a publication of 1690 was reprinted in 1910, he is indeed giving important information and something that every student of medical history will welcome. The matter of inclusion or notation, however, is largely a question of individual preference. Even if an international commission of medical historians should meet, there would, no doubt, be many instances of disagreement.

Morton's list is of such importance that it would seem worth while to go beyond an individual compiler and to suggest further revision under the auspices of a combined British and American medical historical commission. Such an endeavor might well be the concern of the Medical Library Association in America and the National Medical Library in Washington, along with a nucleus of medical librarians in Great Britain and possibly in other

this belief in the adaptation of nature to man and further to indicate its purpose. The author has marshaled his facts rather well and has drawn them from the fields of the solar system and of the chemistry of the atmosphere and the ocean, as well as from the fields of evolution and the physiologic adjustment in animals including man.

Emphasis is laid on the points that there is directive purpose lack of everything and that this purpose is being carried out by a supreme being whom we call God. The high quality of science has always been to find a fact, and although science disclaims any desire to search for God, it is nevertheless true that men of the stamp of Copernicus, Darwin and others had deeply religious feelings. This book gives some support to the idea that only deeply religious people of our largely material age are the earnest men of science. It is perhaps in this sense that the book will make a strong appeal to general readers. The reviewer believes that the author offers reasonable testimony in the way of facts for his thesis that man does not stand alone — a keen challenge to Julian Huxley's book *Man Stands Alone*.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Endocrinology: A brief review for physicians. 12°, paper, 169 pp. Circular No. 177. *Heart Disease: An elementary reference for physicians.* 12°, paper, 63 pp. Circular No. 176. Published by the Department of Public Health, State of Illinois, Roland R. Cross, M.D., director.

These two elementary manuals on common disorders are published as part of the postgraduate medical education program of the Department of Health of Illinois. The department has felt the need of bringing advances in diagnosis and therapy to practitioners and consequently has adopted the plan of preparing brief summaries in various fields of medicine for distribution to all physicians in Illinois. It is hoped that through this service the busy doctor can keep himself up to date with a minimum of effort and without taking any time away from his practice.

Organic Chemistry. By Louis F. Fieser and Mary Fieser. 8°, cloth, 1091 pp. Boston: D. C. Heath and Company, 1944. \$8.00.

This new textbook has been made useful to physicians by the inclusion of a number of chapters dealing with significant applications of organic chemistry to the biologic and medical sciences. The presentation is in a readable narrative style, with an extensive body of factual data included in the form of comprehensive tables and citations under formulas. It is an up-to-date comprehensive authoritative text in its field.

The Sick African: A clinical study. By M. Gelfand, M.B., Ch.B., M.R.C.P., D.M.R., Government Medical Service, Southern Rhodesia, medical officer, Salisbury Native Hospital, physician to the War Emergency Hospital, government pathologist, Pasteur Institute and Public Health Laboratory, Salisbury. With a foreword by Colonel A. P. Martin, O.B.E., M.D., D.P.H., D.T.M. and H., director of medical services, chief health officer and medical director of Southern Rhodesia. 8°, cloth, 373 pp., with 123 illustrations. Cape Town, South Africa: Post Graduate Press, in association with Stewart Printing Co., Ltd., 1944. 25 shillings.

This clinical manual has been written for the members of the medical profession who practice among the African natives. It is hoped that it will also be of assistance to missionaries and native medical orderlies. The descriptions of diseases have not been gone into in great detail, but an endeavor has been made to stress the salient features of the diseases so that the physician will be able to recognize them without difficulty. Many of the clinical manifestations of disease in the native differ from those of the same diseases in the European, and these differences have been discussed in the light of medical men who have practiced among the natives. The civilization and the outlook of the native in no way resemble

those of the European. This fact must be taken into account, for it involves an entirely different angle of approach in investigation and treatment. There are also practical difficulties that should be considered, such as the long distances to be covered, the lack of facilities and the insufficiency of funds available for medical purposes. Much of the detail of helminthology, protozoology and parasitology has been purposely omitted. The author has endeavored to show how best to treat the patient in the most practical and simple way, without losing sight of the difficulties of native practice. Each disease has been discussed in a separate chapter without regard to classification. Colonel Martin in his foreword characterizes the manual as an outstanding work that should meet the needs of all workers in the African field of tropical medicine.

Physiology in Health and Disease. By Carl J. Wiggers, M.D., D.Sc., professor of physiology and director of the Physiology Department, Western Reserve University School of Medicine, Cleveland. Fourth edition. 8°, cloth, 1174 pp., with 246 illustrations. Philadelphia: Lea and Febiger, 1944. \$10.00.

The fourth edition of this standard textbook, first published in 1934, has been thoroughly revised and brought up to date in accordance with developments resulting from the war. To keep the book within a reasonable size and to include a great amount of new material, many topics and sections have been rearranged, rephrased and condensed or printed in small type. Many portions have been greatly enlarged, and several new chapters have been included. Approximately one third of the text has been completely rewritten; over a thousand new references to pertinent literature have been added, and the number of illustrations has been increased. Particular attention is called to new or expanded portions dealing with war physiology, for example, discussions of nerve regeneration, eye fatigue, color appreciation, somatic and visceral pain, headache, blood and plasma depletion, principles of transfusion, blood substitutes, blood volume, hemorrhage and shock, abnormalities of blood coagulation, artificial respiration, pulmonary edema, dietary deficiencies, undernutrition and starvation, muscular exercise, physical fitness and fatigue, water deprivation, acclimatization and aviation physiology, with particular emphasis on the effects of pressure changes, anoxia, acceleration and the role of proprioceptor, vestibular and ocular reflexes in flying. Altitude-sickness, airsickness and seasickness are likewise discussed.

Dr. Colwell's Daily Log for Physicians: A brief, simple, accurate financial record for the physician's desk. 8°, cloth. Champaign, Illinois: Colwell Publishing Company. \$1.00-\$5.00.

This standard account book, especially designed for physicians, should meet the needs of most practitioners. It constitutes a complete system of financial records, with the exception of the ledger. Any form of ledger may be used in conjunction with the *Daily Log*. The space provided accommodates an average practice for a calendar year. For physicians with large practices, however, an edition is issued in two volumes, providing double the space for each day.

Theory of Occupational Therapy. By Norah A. Haworth, M.A. (Cantab.), M.R.C.S., L.R.C.P., D.P.M., assistant medical officer, London Passenger Transport Board; and E. Mary Macdonald, principal, Dorset House School of Occupational Therapy, Barnsley Hall Emergency Hospital, Bromsgrove. With a foreword by Sir Robert Stanton Woods, M.D., F.R.C.P., consultant adviser in physical medicine, Ministry of Health, and physician in charge of the Department of Physical Medicine, London Hospital. Second edition. 8°, cloth, 148 pp., with 68 illustrations. London: Baillière, Tindall and Cox, 1944. \$2.50.

In the preparation of this second edition of a manual intended for students and nurses, the text has been thoroughly revised. A considerable amount of new material has been added, especially in the chapter on occupational therapy in a general hospital and also in that on the treatment of cardiac cases and arthritis. The first four chapters discuss the treatment of mental disorders, orthopedic and surgical cases, cardiac diseases and tuberculosis. The remaining chapters deal with equipment, records, finance and training. A bibliography of seven pages is appended to the text.

certain extent that the fate of the embryo is foreordained. The third lecture deals with the subject "The Generality and the Particularity of Man." The author indicates that the embryologists could hardly fail to support the most orthodox Darwinian-Huxleyan doctrine of the descent of man from an ape-like ancestor, in close relation with the gorilla and the chimpanzee. Readers will be interested in the concept of man's nature as a "Diagram of the Ladder," a point of view closely interwoven with the older thought of Christianity and the concept of the "Diagram of the Fan," which expressed the findings of evolutionary biology.

The reviewer strongly urges every educated person to read this book and thereby add to his intellectual stature.

The Analysis and Interpretation of Symptoms. Edited by Cyril M. MacBryde, M.D. 8°, cloth, 301 pp., illustrated. Philadelphia: J. B. Lippincott Company, 1944. \$9.00.

The striking feature about modern medicine is its increasing emphasis on the physiologic processes, and the trend is toward dynamics rather than static description. Physiologic principles are emphasized not only in the treatment and prevention of disease but also in its diagnosis as well. No longer is it stressed that such and such signs spell a certain medical syndrome, but rather one attempts to understand the changes in a particular case that deviate from the normal. With this view in mind, one can evaluate this book, which is a symposium by a group of prominent specialists, who analyze a small group of frequent symptoms and signs. The discussions are logically and well presented, and the conclusions in many of the papers are often summarized in one or two sentences. As in any book, there are statements with which one can take issue.

As a whole this book will prove valuable to those who would keep abreast of modern medicine, with its physiologic trends and its chemical analyses, which are great aids in diagnosis and tend to supplant that nebulous quality — the clinical sense — which will always have its place in medicine.

The Pathogenesis of Tuberculosis. By Arnold R. Rich, M.D. 4°, cloth, 1008 pp., with 89 illustrations, 20 tables and 4 charts. Springfield, Illinois: Charles C Thomas, 1944. \$10.50.

This monumental book is the culmination of the many fruitful years of labor that Dr. Rich has devoted to the pathology of tuberculosis. In the preface, the author states that the purpose of the book is to present the basic factors and principles that influence the occurrence of tuberculous infection and determine its progression or arrest. In his own words, the object has been "to determine the influence of each of those factors upon the pathogenesis of the disease and to correlate into a unified whole the basic interdependent, but at present often isolated, facts that have been given to us by bacteriology, immunology, pathology, clinical observation, experimental investigation, epidemiology and genetics."

In the twenty-one chapters, the writer does just that, and after reading through this book one stands both in awe and in amazement at the thoroughness with which this has been accomplished. He draws not only on his own rich experience but also on the vast amount of literature for the purpose of bringing the reader up to date on the best thoughts and opinions in the diversified fields of pathology and immunology in tuberculosis.

The reader will be well rewarded by referring to the chapters on the bacteriology of the tubercle bacillus, with a full discussion of its chemical constituents and the variations in its forms and virulence, as well as its modes of infection. The greater part of the book deals with pathogenicity versus immunology, and the problems of epidemiology and of individual, native and tissue resistance are thoroughly discussed. No clinician can afford to miss the scholarly dissertations on the mechanism of hypersensitivity and on desensitization and its relation to the characteristics of tuberculous lesions and symptoms.

Despite the formidable and intricate discussions, the style is smooth and the subject matter is presented in a clear and orderly manner. The short summaries at the end of each chapter are extremely helpful. The illustrations are adequate and are beautifully reproduced. As a reference book on the pathogenesis of tuberculosis, the reader will find it complete, concise and authoritative. The clinician, pathologist, bacteriologist and public-health worker should find the book useful and also stimulating.

Technic of Electrotherapy and Its Physical and Physiological Basis. By Stafford L. Osborne, M.S., Ph.D., and Harold J. Holmquest, B.S., B.S. (M.E.). 8°, cloth, 780 pp., with 240 illustrations and 72 tables. Springfield, Illinois: Charles C Thomas, 1944. \$7.50.

The authors of this book were evidently under the impression that medicine is both a science and an art and that electrotherapy, being a branch of medicine, should be treated with regard to these two forms of culture. Accordingly they do not confine themselves to mere statement of facts but present a scheme of laboratory tests to prove the authenticity of their claims for almost every method of treatment. The system of laboratory experimentation that is outlined in this book has all the earmarks of scientific precision and artistic form.

Although the authors state in the preface, "This text . . . is not to replace the clinical textbooks now available," the reviewer believes that it compares favorably with any one of them. The fact that it constantly stresses the rationale for choosing a certain physical measure in a given case, based on a familiarity with the underlying electrophysics and electrophysiology, tends rather to add than to detract from its clinical value.

Another praiseworthy feature of this work is the arrangement of its subject matter in a manner that will suit two classes of readers — the busy general practitioner and the specialist or teacher in this field. The former may have neither the time nor the desire to trace each case to its fundamentals in physics, chemistry, mathematics and mechanics. For him the essentials are stated with simplicity. On the other hand, the man who takes more than a lukewarm attitude to the subject will find a plentiful supply of data, references, curves, tables, charts, cuts and diagrams to illustrate, clarify and prove the soundness of the statements that are made by the authors. By way of illustration the book contains a table of logarithms and one of trigonometric functions of an angle. These do not concern the average reader of an electrotherapeutic text and are never found in one. On the surface they may seem to be out of place, but in reality they are part and parcel of those portions of the book that were written for the more profound students of electrotherapy.

On the whole this book is quite different from the usual textbooks on the subject, almost a stranger in their midst, but paraphrasing Shakespeare, one might say: "As a stranger bid it welcome."

Functional Disorders of the Foot: Their diagnosis and treatment. By Frank D. Dickson, M.D., and Rex L. Diveley, M.D. Second edition. 8°, cloth, 352 pp., with 202 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$5.00.

In this book the authors have described clearly and concisely the common disabilities of the foot. There is a decided improvement in this second edition both in the arrangement of the material and in the subjects that are considered. The book is excellently illustrated with line drawings and photographs. It is well written, and the suggestions for treatment are in accord with recognized orthopedic practice.

A book of this sort is timely and should help greatly in arousing interest in a large number of disabilities that are now frequently neglected. The classification of functional disabilities is probably too simple for extensive use. One would like to see more emphasis placed on the muscular faults of the foot, which are so commonly encountered in both children's and adult's clinics. The bibliography at the end of the book has not been revised to include many of the newer contributions in medical literature. But these are minor faults. The book can be recommended unreservedly as the most practical treatise on disabilities of the feet in the English language.

Man Does Not Stand Alone. By A. Cressy Morrison. 12°, cloth, 107 pp. New York: Fleming H. Revell Company, 1944. \$1.25.

Through the centuries from Galen, Cicero, Paley and others, detailed arguments have been set forth to show the remarkable adaptation of man to nature. Since the beginning of the twentieth century there have been equal efforts to show the adaptation of nature to man. The present book, written by a scientist, purports to bring to the attention of thinking people the f

PSEUDODOXIA PEDIATRICA*

HARRY BAKWIN, M.D.†

NEW YORK CITY

ALMOST three hundred years ago, Sir Thomas Browne wrote a treatise comprising seven books entitled *Pseudodoxia Epidemica or Enquiries into very many received Tenents and commonly Presumed Truths*. In this work he analyzed numerous fallacies generally accepted as truths in his day and demonstrated their absurdity.

The superstitions and magic rites that prevailed in the seventeenth century have been largely forgotten. But in the present scientific era, as well, theories and practices persist in medicine even though their falsity is patent or has been demonstrated. It is my purpose in this paper to inquire into some of the current pediatric errors and to analyze the reasons why they persist.

Notable progress in child care has been made since the turn of the century, and the results are strikingly registered in the greatly reduced morbidity and mortality rates for infants and children. Advances in medicine are made not only by the discovery of new principles, new information and new technics but as well by the discarding of false teachings and practices. One recalls how only a few years ago babies' mouths were meticulously cleansed, presumably to remove germs, and how the symmetrical ulcers of the palate, still occasionally seen, resulted. Even more recent was the discovery that mineral oil dropped into the nose, almost a routine procedure among well-cared-for babies a few years ago, may lead to pneumonia. One may mention here also vigorous removal of the vernix caseosa as an etiologic factor in impetigo of the newborn.

That early operative interference in empyema and osteomyelitis is contraindicated has been well established. Unfortunate was the patient of thirty years ago whose attending physician was alert and conscientious and recognized empyema early in its development. It is now known that over-rigid feeding schedules fostered parental overanxiety and frequently led to anorexia in young children.

These are practices that have come to be recognized as erroneous and that have been, in the main, abandoned. But there remain many others, equally erroneous and harmful, that continue in everyday use.

TONSILLECTOMY

Prominent among these unwise practices is indiscriminate tonsillectomy. This subject will not be discussed in detail, since it has already been thoroughly examined by Kaiser,¹ Brennemann,² Graeme Mitchell³ and others.⁴ Attention may be called to the facts that mortality from the operation is by no means negligible, about 80 persons dying each year in the United States as a result of the anesthesia administered for this operation (Table 1).

TABLE 1. *The Number of Deaths in the United States Associated with Anesthesia*

YEAR	TOTAL No. OF DEATHS	No. OF DEATHS ACCOMPANYING TONSILLECTOMY AND ADENOIDECTOMY
1922	513	87
1923	474	80
1924	598	75
1925	677	116
1926	654	108
1927	695	112
1928	569	89
1929	690	100
1930	702	91
1931	678	86

and an equal number in England, where chloroform is widely used⁵; that the morbidity from pneumonia, lung abscess, hemorrhage and sepsis is considerable; that the etiologic relation of tonsillectomy to bulbar poliomyelitis is well established⁶⁻¹¹; and that the operation may be an exciting factor in the anxiety neurosis of children.¹²

A convincing demonstration of the absurdity of indiscriminate tonsillectomy was given ten years ago by the American Child Health Association.¹³ It surveyed a group of 1000 children, eleven years of age, from the public schools of New York City and found that 61 per cent of these had had their tonsils removed (Fig. 1). The remaining 39 per cent were subjected to examination by a group of phy-

Modern Clinical Syphilology: Diagnosis, treatment and case study. By John H. Stokes, M.D., professor of dermatology and syphilology, School of Medicine and Graduate School of Medicine, University of Pennsylvania, director, Institute for the Control of Syphilis, University of Pennsylvania, and member, Commission on Syphilis and Cognate Diseases, League of Nations Health Organization; Herman Beerman, M.D., Sc.D. (med.), assistant professor of dermatology and syphilology, School of Medicine and Graduate School of Medicine, University of Pennsylvania, assistant director, Institute for the Control of Syphilis, University of Pennsylvania, dermatologist, Philadelphia General Hospital, and dermatologist and syphilologist, Pennsylvania Hospital; and Norman R. Ingraham, Jr., M.D., assistant professor of dermatology and syphilology, School of Medicine, University of Pennsylvania, associate director, Institute for the Control of Syphilis, University of Pennsylvania, chief, Division of Venereal Disease Control, Philadelphia Department of Public Health, and chief, Syphilis Clinic, Philadelphia General Hospital. Third edition. 8° cloth, 1332 pp., with 911 illustrations. Philadelphia: W. B. Saunders Company, 1944. \$10.00.

The first edition of this outstanding work was published in 1926, and the second in 1934. Ten years having elapsed, it was considered advisable, even under wartime conditions, to bring out this third edition. Approximately 65 per cent of the text has been rewritten. The penicillin chapter and the account of syphilis in public health and military medicine are new. The chapter on prenatal, now largely congenital, syphilis, has been expanded and rewritten. The progress of serologic diagnosis has been reflected in extended space devoted to the biologic false-positive reaction. Every important technic of treating syphilis receives full detail and practical discussion. The attempt to write for the student, the practitioner and the specialist simultaneously really telescopes three books into one. In order to keep down the size of the book much use of small type has been found necessary. Likewise it has been found impossible to incorporate full bibliographic references. The book is highly recommended to all those who come in contact with syphilis in their daily work and for all medical libraries.

Soldier to Civilian: Problems of readjustment. By George K. Pratt, M.D., psychiatric examiner, United States Armed Forces, Induction Center, New Haven, Connecticut. With a foreword by George S. Stevenson, M.D., medical director, National Committee for Mental Hygiene. 8°, cloth, 233 pp. New York: Whittlesey House, 1944. \$2.50.

The author is a practicing psychiatrist with military experience and service on the staff of the Mental Hygiene Committee. He has made a careful study of the problems of the serviceman's readjustment. This manual has been written for the lay person who will be faced with these problems when the serviceman is discharged from the military service. In simple language, sensible advice and concrete suggestions are given on how to handle such problems as family life, marital relations, community position and occupational adjustment. Particular attention is directed to the man who returns with a physical or psychiatric handicap. An appendix contains the first outline formulated by the newly created National Committee for Service to Veterans, entitled "Community Service for Veterans: A guide to planning and coordination."

Clinical Practice in Infectious Diseases: For students, practitioners and medical officers. By E. H. R. Harries, M.D. (Lond.), F.R.C.P., D.P.H., medical superintendent, North-Eastern Hospital (London County Council), and Milroy Lecturer, Royal College of Physicians; and M. Mitman, M.D. (Lond.), M.R.C.P., D.P.H., D.M.R.E., medical superintendent, River Hospitals. With a foreword by W. Allen Daley, M.D. (Lond.), F.R.C.P., D.P.H., medical officer of health, London County Council. Second edition. 8°, cloth, 570 pp., with 52 illustrations and 26 tables. Edinburgh, Scotland: E. and S. Livingstone, 1944. \$6.00.

The text in this second edition of a work primarily intended for students and first published in 1940 has been thoroughly revised and much new material incorporated throughout the book. The size of the book has been increased by over a hundred pages, and selected references to medical literature lacking in the first edition have been appended to each chapter. This manual has considerable value for ready reference, although it is based on English practice.

NOTICES

ANNOUNCEMENTS

Dr. Isadore Green announces the removal of his office from 636 Beacon Street to 483 Beacon Street, Boston.

Dr. Miriam S. Udin announces the removal of her office from 636 Beacon Street to 483 Beacon Street, Boston.

BOSTON DISPENSARY

A clinical staff meeting of the Boston Dispensary will be held at the Pratt Hospital Auditorium on Monday, June 11, at 12:30 p.m. Dr. Chester S. Kcefer will speak on the subject "Use of Penicillin." Luncheon will be served at 12 noon.

NEW ENGLAND PEDIATRIC SOCIETY

There will be a meeting of the New England Pediatric Society on Wednesday, June 13.

PROGRAM

- 12:00-1:00 p.m. Clinicopathological conference, Children's Hospital.
- 2:00-3:30 p.m. Clinic, Children's Hospital. Dr. Richard M. Smith and associates.
- 4:00-5:30 p.m. Clinic, Children's Center, 244 Townsend Street, Roxbury. Dr. Marian Putnam and associates.
- 6:30 p.m. Refreshments, Longwood Towers.
- 7:30 p.m. Dinner, Longwood Towers.
- 8:00 p.m. Behavior Problems in Childhood. Dr. Harry Bakwin, associate professor of pediatrics, New York University, New York City.

Members of the medical profession and students are cordially invited to attend the 8:00 p.m. meeting.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JUNE 14

FRIDAY, JUNE 15

- *9:00-10:00 a.m. Medical clinic. Isolation Amphitheater, Children's Hospital.
- 10:50 a.m. Hemangioma. Dr. G. Schwartz. (Postgraduate clinic in dermatology and syphilology.) Amphitheater, Mallory Building, Boston City Hospital.
- *12:00 m. Grand rounds. Children's Medical Service, Ether Dome, Massachusetts General Hospital.

SATURDAY, JUNE 16

- *10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, JUNE 18

- *12:00 m.-1:00 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY, JUNE 19

- *9:00-10:00 a.m. Medical clinic. Infants' Hospital.
- *12:15-1:15 p.m. Clinicoroentgenological conference. Peter Bent Brigham Hospital.

WEDNESDAY, JUNE 20

- *12:00 m. Clinicopathological conference. Children's Hospital.
- *12:00 m.-1:00 p.m. Clinicopathological conference, Cambridge Hospital.

*Open to the medical profession.

mastoid disease also fell (from 1.38 per cent of all admissions to 0.56 per cent). Especially striking was the reduction of purulent otitis media after myringotomy (from 15.6 per cent admissions in the early period to 4.7 per cent later), but even after spontaneous rupture the number of cases diminished

FIGURE 2. *The Incidence of Purulent Otitis Media in Percentage of Admissions. (Bakwin and Jacobziner¹⁴ — reprinted by permission of the publisher.)*

(from 7.6 to 4.5 per cent). This study showed beyond reasonable doubt that it is possible to induce purulent otitis media through excessive manipulation in the ear canal. It is little wonder, then, that there are many who consider the use of the direct otoscope a curse rather than a blessing.

DELIVERIES OF BABIES IN HOSPITALS

During recent years there has been a rapid increase in the percentage of hospital deliveries in America. In New York City, for example, 97.3 per cent of all births took place in hospitals during 1943, in comparison with 61.9 per cent in 1929, an increase of over 50 per cent in less than fifteen years.* The popularity of hospital deliveries has extended to all parts of the country and to rural as well as urban communities.

The hospital obviously offers certain advantages for mother, baby and obstetrician. The arrangements are presumably better, although the occurrence of epidemic diarrhea in some of the best hospitals and its absence from some of the more modest ones should make one cautious about drawing conclusions regarding the value of hospital equipment. Certainly better facilities are at hand for treating emergencies. Furthermore, the modern home — at any rate in many large cities — is often too small to permit the privacy desirable for delivery. For the obstetrician the hospital is a much easier place than the home in which to work.

There are, however, no data indicating that indiscriminate hospitalization for delivery has had a favorable influence on either maternal or neonatal mortality (Fig. 3). Between 1929 and 1933, the percentage of infants born in hospitals in New York

City rose from 61.9 to 78.2 per cent. During the same period the maternal mortality increased from 5.4 to 6.4 per cent and the neonatal mortality showed a slight fall. Since 1933 there has been a steady steep decline in maternal mortality, the rate falling from 6.4 per 1000 live births in 1933 to 2.2 in 1941. During these same years the rate of increase in hospitalization decreased. Whereas the percentage of hospital deliveries rose by 3.2 each year from 1929 to 1933, the annual percentage increase between 1933 and 1941 was only 1.9. The drop in neonatal mortality continued at a slightly accelerated rate.

Of interest in this connection is the experience of the Frontier Nursing Service of Kentucky, organized by Mrs. Mary Breckinridge in 1925. The results of their experience with the first 4000 deliveries are summarized in Table 2.¹⁵ The large majority

FIGURE 3. *The Percentage of Deliveries in Hospitals, the Neonatal Mortality (under one year) and the Maternal Mortality for New York City (1929-1943).*

(92.7 per cent) of deliveries were done in the homes, which were extremely poor ones, and by midwives. The maternal mortality was only 0.75 per 1000 births, as compared with 5.6 for the white population of the United States at the same time and 5.2 for the white population of Kentucky. Operative

*These data were kindly supplied by T. J. Duffield, Registrar of Records, New York City.

sicians, who selected 45 per cent of these for tonsillectomy and rejected the rest. The rejected children were re-examined by another group of physicians, who recommended for tonsillectomy 46 per cent of those remaining after the first examination. When the rejected children were examined a third time, a similar percentage was selected for tonsillectomy, so that after three examinations only sixty-five children remained who had not been recommended for tonsillectomy. These subjects were not further examined because the supply of examining physicians ran out. The study showed that there was no correlation whatsoever between the estimate of one physician and that of another regarding the advisability of tonsillectomy, and the authors therefore concluded that the chance of

mate—this means an annual load of sixty-five thousand tonsillectomies, or two hundred each working day. To the cost of medical and hospital care must be added the money spent by social agencies and school nurses in following up children referred for operation. Tonsillectomy is a factor increasing the cost of medical care. Money spent for this operation could be better employed for more useful health measures.

MYRINGOTOMY

Until the introduction of the sulfonamide drugs it was not unusual for the large majority of infants in a hospital ward to have purulent otitis media during the winter months. The high incidence of myringotomy was by no means limited to hospitals.

FIGURE 1. *The Theoretical Survival of Tonsils after Medical Examination.*

a child's being recommended for operation depended principally on the physician rather than on the child's health status.

If anyone suspects that financial considerations influenced the judgment of the physicians, the study showed this not to be the case. For of the children who took to a free clinic their school medical examination slips calling attention to their tonsils, practically all were operated on, whereas of those who went to private physicians only a small proportion were operated on.

The American Child Health Association report emphasized that tonsillectomy, as currently practiced, represents in the main a useless expenditure of time, effort and money. Furthermore, the focusing of interest and effort on this operation leads to neglect of defects that are in need of correction. It was found that, even in groups of children who had severe dental caries and visual handicaps for which practically nothing had been done, about 60 per cent had had their tonsils removed.

The annual cost of the operation must be great. If half the children in New York City have their tonsils removed—an extremely conservative esti-

mate—in home practice, too, the eardrums were and still are all too freely incised.

The attitude toward otitis media has changed somewhat since the introduction of the sulfonamide drugs. Interest has diminished to a considerable extent and tension and anxiety have lessened. The great diminution in the incidence of purulent otitis media is generally attributed to the new drugs, but this conclusion is not entirely justified, certainly not in the case of infants. It was possible to show at Bellevue Hospital—before the use of the sulfonamide drugs—that the incidence of purulent otitis media in infants could be greatly reduced simply by limiting otoscopic examinations and by laying down stringent criteria for myringotomy.¹⁴

During the three-year period 1931–1933, 23.3 per cent of the infants under two years admitted to the Children's Medical Service at Bellevue Hospital developed a purulent discharge from the middle ear (Fig. 2). In the five-year period 1934–1938, after the campaign against indiscriminate myringotomy had begun, the incidence was only 8.9 per cent—that is, a little more than one third the previous rate. The proportion of infants operated on for

discriminate hospitalization increases the cost of medical care without benefiting anyone.

HOSPITAL CARE OF INFANTS AND YOUNG CHILDREN

For some years it has been recognized that the hospital is unsuited for the care of infants. It seems likely that the high mortality in institutions for the care of healthy infants was due to emotional deprivation.¹⁷ Although many hospitals supply play and other outlets for older children, few make any such provision for infants. Rigid segregation for this age group is still the rule in most of the best infant hospitals. Meticulous care is given to the dietary needs, including vitamin supplements, even when the infant is to remain in the hospital for only a few days, yet no attention is paid to the psychologic needs. Parents are carefully excluded, and the babies are handled by doctors and nurses as little as possible.

There is need for a fuller appreciation of the results of emotional deprivation in hospitalized infants. There should be a suitable program.

Runabouts, too, are in general poorly managed in hospitals from a psychologic viewpoint. Little or no time is spent by the nurses in training the child to eat by himself, to dress himself or to control his bowels and bladder. With these functions aside, the child receives little attention and affection unless he happens to become the ward favorite. Here too the nursing staff needs fuller understanding and an active program.

ERRORS OF PSYCHOLOGIC MANAGEMENT

Although pediatricians have shown an increasing interest in the psychologic care of the child, they still underestimate its importance or are unwilling to make the effort necessary to inform themselves about it. Consequently the field has been left largely to nonmedical groups whose viewpoint is necessarily limited by lack of understanding of the growing child as a whole. The child is caught between the sentimentality of lay groups and the indifference of the pediatricians.

There is a general impression among pediatricians that consideration of the psychologic attributes is time-consuming. This is true to some extent of the treatment of behavior disorders, but it is not true of the handling of the general run of children. It requires little time to explain to a mother the principles underlying child training and the proper techniques to be employed. It does not take long to explain to a mother how a crippled child should be managed psychologically and what the results of mismanagement may be. It requires no extra time for the experienced pediatrician to recognize over-anxiety, overprotection, overauthority and so forth in a parent, and it requires but a few minutes to discuss them.

Aside from the fact that positive contributions can be made in this way to the health and happiness of both parent and child, appreciation of the psychologic attributes adds interest and zest to the work of the pediatrician, whose time is so largely taken up with the care of well children and children with common colds.

Pediatrics of the recent past was dominated to a large extent by a mechanistic viewpoint toward child rearing, and little or no attention was paid to emotional and spiritual needs. In its extreme form this attitude was expressed by Watson¹⁸ (who is not a physician) in his book published in 1928. He wrote: "It is a serious question in my mind whether there should be individual homes for children — or even whether children should know their own parents. There are undoubtedly much more scientific ways of bringing up children which will probably mean finer and happier children." Although pediatricians never overtly endorsed these views, nevertheless many of the accepted practices, such as the rigid attitude toward dietary prescriptions and schedules and the discarding of the cradle and many other devices to please infants, implied tacit acceptance. A whole-ome change has taken place within recent years, and children are now looked on as having emotional and mental attributes as well as physical ones.

Praiseworthy as is this change, certain fallacious views have already gained wide acceptance, principally among child psychologists and educators. The reaction to the over-rigidity of the past has led to a policy of overindulgence. Too much discipline has been replaced by too little. The pendulum has swung from a puritanical negation of the lighter pleasures to hedonism. In an effort to prevent insecurity, which to many is the principal aim of child rearing, children are coddled. This is unfortunate, since discipline is necessary for proper training. There is need for a better balanced viewpoint.

CHEF OR DIETITIAN

It is unusual nowadays to see a new patient who is not receiving vitamin supplements, yet there is no definite clinical evidence that deficiency diseases are at all widespread among children or that any benefit can be derived from the general use of vitamins, except in the case of vitamins C and D in infancy. Aside from the fact that most of the preparations used are expensive and that their administration is an extra chore and means, to a certain extent, invalidizing the child, a major fallacy is implied in the modern attitude toward diet. It is that appetite cannot be trusted in the selection of a proper diet and that laboratory investigations have progressed to the stage where they can be trusted to make such a selection. Except for limited groups, where deficiency disease is prevalent, this is an un-

deliveries were rare. The stillbirth and neonatal death rates did not differ significantly from those of the country as a whole.

Hospitals are unsuited for the care of the newborn. Physicians and parents who would hesitate

TABLE 2. *Statistical Analysis of the First 4000 Deliveries by the Frontier Nursing Service*

Percentage of babies delivered in the home	92 70
Percentage of babies delivered in the hospital	7 30
Puerperal deaths per 1000 live births	0 76
Cesarean operations per 1000 births	0 18
Forceps deliveries per 1000 births	0 83
Neonatal deaths per 1000 live births	30 3*
Stillbirths per 1000 live births	30 20

*This figure is slightly below the rate for Kentucky during the same period

to permit an older infant in a hospital ward seem to have no qualms about having newborn babies there, even though obstetric nurseries are generally

failure of many mothers to breast-feed their babies. The pediatrician is generally called in several days after delivery, during which time no effort has been made to initiate breast feeding. Instead, a formula has been prescribed, and this, since it satisfies the appetite, discourages the baby from sucking the breast, thereby removing the stimulus for secretion of milk.

The system of bringing babies to their mothers only at fixed intervals and allowing them to remain for limited periods is hardly conducive to proper breast feeding, especially during the early days of life. At this time the feeding demands of the infant are irregular and frequent.¹⁶ Only later, during the third week of life, does a fairly regular demand rhythm become apparent. It is obviously impossible in a hospital to bring a baby to its mother whenever it cries, and this is one of the drawbacks consequent on hospital delivery. But even in hospitals more freedom could be given than is at present the custom. Since the appearance of epidemics of diarrhea

more crowded than is the usual infant ward. Fortunately the newborn is resistant to many of the common infections that beset the older infant. The immunity of the newborn is, however, limited, as is evidenced by the frequency with which diarrhea, pneumonia, sepsis and other infections occur among them. These conditions are rare in the home, and the baby kept there is obviously not exposed to nursery epidemics.

The number of deaths from diarrhea of the newborn is not inconsiderable (Table 3). During the ten-year period 1934-1943, 669 infants died of this condition in New York City.

A great drawback in the hospital is the separation of mother and baby. This is unnatural and unphysiologic. Certainly among mammals it is the rule that the young remain in close contact with the mother during early life, snuggling against her.

Whereas the hospital facilitates the work of the obstetrician, it hampers that of the pediatrician, especially in the handling of private patients. The obstetric hospital is in good part responsible for the

in the newborn, this artificial situation has been further intensified, and the nurse is now fortified by department-of-health regulations.

That the hospital is the proper place for the delivery of selected patients where difficulties are anticipated is apparent. But some modification of the present system of indiscriminate hospital delivery is indicated. Relegation of the baby to a nursery is by no means a universal practice. It is the custom in most European hospitals to keep the baby in a crib at the foot of the mother's bed. Having a newborn child in a ward with several other mothers and babies is far from an ideal arrangement, but it may be preferable to ours. There are several other alternatives — a return to home delivery except where there are special reasons for hospital delivery, smaller nurseries or a shorter stay of the mother and baby in the hospital.

The subject is a timely one. With the overcrowding in obstetric hospitals at the present time, it is extremely difficult to give a sick child the attention he requires. Aside from other considerations, in-

under ordinary circumstances it bears no predictable relation to the sugar level in the blood, and for clinical purposes the relation has no significance.

The present reliance on the hospital as the proper place for the delivery of babies is also based on rationalization. The hospital, with its up-to-date equipment and its trained personnel, seems far superior to the humble home and the midwife. So we continue to deliver babies in the hospitals in face of the high maternal mortality and the real risks to the baby.

Another reason why many mistaken practices persist is the indifference of the academic pediatrician to the details of everyday practice. Absorbed in the study of disease mechanisms and their management, he lacks interest in or fails to appreciate the importance of such false practices as indiscriminate tonsillectomy and myringotomy. On the shoulders of the academic pediatrician rests also the responsibility for failure to train the physician to practice properly in the home.

A prominent source of pseudodoxia pediatrica is the tendency to do too much. The physician, eager to justify his function, is rarely content to tell the parent of a child who comes for a health examination that the child has no defects that require correction. He finds flat feet, large tonsils, malocclusion, a heart murmur, a tight prepuce, rickets, undernutrition and poor posture. Most of these are normal variants, but the physician often leads the patient's parents to unnecessary trouble, expense and anxiety by his prescriptions.

The mistaken practices and attitudes that have been listed are not isolated phenomena. They are part and parcel of the practice of medicine today, resting on assumptions that permeate daily routines. They represent, so to speak, the dead wood of medicine, perhaps the necessary obverse of gains in medical experience. It seems almost as though the slow acquisition of knowledge were inevitably accompanied by error. Yet the progress of humane science

requires that the freight of error be lessened steadily if the vessel is to make surer and swifter progress. As Marcel Proust²¹ so wisely said:

For, medicine being a compendium of the successive and contradictory mistakes of medical practitioners, when we summon the wisest of them to our aid, the chances are that we may be relying on a scientific truth the error of which will be recognized in a few years' time. So that to believe in medicine would be the height of folly, if not to believe in it were not greater folly still, for from this mass of errors there have emerged in the course of time many truths.

warranted assumption. Hear what the poet Ogden Nash¹⁹ has to say about modern eating:

Our daily diet grows odder and odder —
It's a wise child that knows its fodder.

Within recent years another change in children's eating customs has been advocated. It has been proposed that children eat one or more meals a day at school. The purpose of this is to supply the child with at least one "well-balanced" meal a day. According to Miss Dorothy Thompson,²⁰ heretofore known as a writer on politics but apparently also an expert on children's eating, such a program, financed of course by the Government, would not only greatly improve the health of the children but would also be more economical than the present one.

The effects of these mistaken teachings are widespread and profound. The food one eats and the manner of eating it have been integral parts of the culture of the home. Around the dinner table the family assembles not only to eat but to discuss family problems, exchange ideas and also give thanks to an unknown giver for favors, small and large. Surely we have been endowed with the sensation of taste for some purpose. Eating should mean roasts, sauces, puddings, pies — not calories, vitamins, minerals. A bit of home cooking is what men travel far to enjoy. The dining table should mean lively discussion and conversation, light or profound. It should be a pleasure, not metabolic wrangling. As between chef and dietitian, I choose the chef without reservation.

* * *

There are numerous other erroneous practices. Such are the unnecessary treatment of physiologic bowing of the legs; the premature use of orthodontia; the diagnosis and treatment of rickets because the ribs flare or the legs are bowed or the head shape is unusual, although rickets is not the cause. Physicians continue to prescribe expensive sugars for babies, although their superiority over ordinary cane sugar has not been demonstrated. Vitamin D is prescribed during the summer months, when it is not necessary.

EDUCATION OF THE PEDIATRICIAN

A major error in pediatric education is the failure to prepare students properly for practice in the home. Whether or not by intention, the impression is given that the management of disease in the home requires elaborate and expensive procedures. The student, entering practice after leaving a university hospital, believes that proper management of a child with lobar pneumonia includes a blood-cell count, a throat culture, a chest roentgenogram, a urine examination, perhaps a blood culture, and determination of the sulfadiazine blood level. Since he is not able to have these done, he feels that he is doing slipshod

work and consequently lacks that self-confidence which is so important in his work. He acquires, instead, a feeling of inferiority that interferes with the sense of satisfaction to which he is entitled. The medical student and the intern should know that the various laboratory procedures are used in hospitals primarily for purposes of teaching and study, and that he is exposed to them in the hospital so that he may learn to dispense with them in the home except when there are specific indications.

The medical student, learning his medicine in the impersonal atmosphere of the hospital, fails to comprehend the importance of disease and death to the family group. To him a death is a statistic. He is not taught to understand, nor can he be expected to grasp unaided, the sorrow, the feelings of emptiness, frustration and defeat, the fear and even the terror that overcome the parents of a child, ever so young, who has died. If he is to serve his function properly he needs to comprehend these things, — now, perhaps more than ever, since with so many people lacking the consolation of formal religion he must, in addition to his other functions, often take on the work of the spiritual comforter.

A further error in teaching medical students is the failure to emphasize sufficiently the personal nature of disease. Not disease as an abstraction but people with disease is what needs to be stressed.

REASONS FOR ERRORS

Why do we continue to countenance practices that we recognize as false?

One of the most frequent reasons for error is the tendency to accept ideas because they seem reasonable even though they have not been checked by experimentation or proved in practice. About twenty-five years ago it was suggested that vitamin D therapy should be withheld in infants with tetany until calcium salts have been given for a day or two. The reason given was that, if vitamin D is administered immediately, calcium is withdrawn from the circulating fluids and deposited in the rachitic bones and the tetanic manifestations are thereby intensified. Although this idea was based on the flimsiest sort of evidence, — indeed, it was quickly found to be false, — it has nevertheless persisted and can be found in the principal American pediatric texts. It has remained because it is an attractive rationalization. This teaching is not only false; it is dangerous. The quickest and most effective way to bring a tetanic child out of the danger zone is by the prompt administration of a large dose of vitamin D.

Another false idea that has survived for some twenty years because it seems reasonable is that an estimation of the sugar in the spinal fluid is of little value without a simultaneous determination of the blood-sugar level. Although it is true that in diabetes mellitus and hypoglycemic shock, the sugar in the spinal fluid may be significantly altered,

simulate body temperature, at or slightly below which the ointments are used clinically. Three such jars were set up for each ointment. At intervals of six, twelve, twenty-four, forty-eight and ninety-six hours, a 1-cc. sample of the water at a point 1 cm. above the center of the watch crystal was withdrawn and assayed for sulfonamide content. The Bratton-Marshall method of assay was used, employing an accurately calibrated Klett photoelectric colorimeter.

Table 1 shows the constituents of the ten ointment bases. It should be noted that use was made of one series containing 5 per cent sulfathiazole and another containing 5 per cent sulfanilamide.

RESULTS

The results of these studies are summarized in the accompanying graphs (Fig. 1). Analysis of the

FIGURE 1. Average Yield of Sulfonamides from Oil-in-Water Emulsion and Aqueous Jelly Bases (upper) and from Greasy Bases (lower).

In each graph the upper curve represents the yield of sulfanilamide, and the lower curve that of sulfathiazole. Note that the ordinate scale for the upper graph is one tenth that of the lower graph.

data obtained revealed that the ten bases studied could be divided into two general groups, one comprising Bases 1, 3 and 10, which were found to

yield little sulfonamide to the overlying watery medium, and the other comprising the remaining seven bases, which were found to yield large quantities of sulfonamides to the water. Since the differences in the values for the amount of sulfonamide liberated from the bases within each group did not seem significant, the results at each time interval were averaged for convenience in plotting. Bases 1, 3 and 10, which released little sulfonamide to the fluid in contact with them, are the heavy, greasy type that other investigators^{1, 6} also found unsatisfactory as vehicles for applying sulfonamides locally. The amounts of sulfonamide released by these bases were so slight that, in plotting data for this group, the ordinate scale had to be made ten times larger than for the other group of bases so that the curves would be clearly visible. In contrast to the greasy bases, the oil-in-water emulsion bases and aqueous-jelly bases readily liberated large quantities of sulfonamides to the surrounding liquid. The results with the series of bases containing sulfanilamide in general paralleled those with the series containing sulfathiazole, but, as might be expected, the amounts of sulfonamide liberated ran higher for the sulfanilamide series than for the sulfathiazole series, and these differences were much greater for the bases of the oil-in-water emulsion and aqueous-jelly type than for the greasy bases.

DISCUSSION

Sulfonamides applied locally can be expected to be therapeutically effective only if an adequate concentration of the drugs is maintained in intimate contact with the cutaneous lesion or wound under treatment. When a base so locks the sulfonamides suspended in it that the quantities released to a surrounding aqueous medium are so slight as to be practically negligible, it is extremely doubtful that this requirement will be met. Accordingly, it seems logical to avoid the all-grease or cold-cream type of base for the external application of sulfonamides if optimum therapeutic efficacy is to be realized. Besides obstructing the release of sulfonamides suspended in them, greasy bases have other disadvantages.^{7, 8} First, they are not miscible with water or wound exudates. Secondly, it is difficult to bring about an adequate and uniform dispersion of insoluble drugs in bases of this type. Thirdly, their greasiness and stickiness are often objectionable to the patient. Finally, their removal is usually difficult and a frequent cause of pain.

The preparations, such as oil-in-water emulsions and aqueous jellies of the type made up with pectin or bentonite, that were found to liberate larger quantities of sulfonamides to an aqueous medium should, no doubt, be of greater value in local chemotherapy. One characteristic that these preparations have in common is miscibility with water. Hence, they serve to bring the medicaments they contain

AN EVALUATION OF SULFONAMIDE OINTMENT BASES*

RUTLEDGE W. HOWARD, M.D.†

BOSTON

THE proved value of the sulfonamides for systemic use has led to a widespread application of these drugs for the treatment of surface infections. Recent studies tend to show that the type of base used as a vehicle for sulfonamides is of great importance. In 1941, Pillsbury and his co-workers¹ showed clinically that sulfathiazole is not so effective in an all-grease base as in an oil-in-water emulsion or stearate vanishing-cream base. In 1942, Gurd, Ackman, Gerrie and Pritchard² likewise pointed out that an oil-in-water emulsion base for sulfonamides

ments with a petrolatum base liberate only an inconsequential number of sulfonamides.

The present study was undertaken to evaluate the sulfonamide ointments and creams now usually prescribed from the standpoint of how readily the sulfonamides they contain are released from the base. If the heavy grease or waxy bases so often used in sulfonamide preparations yield little active drug to the tissues being treated, the therapeutic value of such preparations may be expected to be less than desired. Therefore, in choosing a sulfonamide

is more desirable. Diffusion studies by Waud and Ramsay³ showed that fatty and paraffin bases do not readily yield sulfonamides. They also believe that water-containing bases make the sulfonamide content most readily available. Ackman and Wilson,^{4, 5} also in 1942, described an oil-in-water emulsion base for a sulfonamide that, according to their observations, not only ensures constant delivery of the sulfonamide from the emulsion to the wound area but also favors proper drainage. Recently, Cochran⁶ has shown that most sulfonamide oint-

preparation for topical application, a physician should consider whether it is likely to maintain the sulfonamide concentration in the tissues at an effective level. This study shows that great differences exist between ointment bases with reference to the amounts of sulfonamide liberated to an aqueous medium.

METHOD OF STUDY

The method used was as follows. Six grams of each ointment, one sample containing sulfanilamide and the other sulfathiazole, was placed in a glass watchglass so that the ointment presented a smooth, flat surface. Each watchglass was placed in a 6-ounce, covered glass jar containing 100 cc. of distilled water; the jar was then incubated at 37°C. to

MEDICAL PROGRESS

UNDESCENDED TESTICLE*

WILLIAM C. QUINBY, M.D.†

BOSTON

DISCUSSING the diagnosis and treatment of imperfect descent of the testicle Browne¹ relates an example of the advice given by various physicians to the parents of such a patient. They were told that an immediate operation must be performed if the child was not to be practically a eunuch; that they should wait for five years to see what happened; that the patient should be treated by hormone injections; that operation must on no account be done, since it was invariably unsuccessful; and that the testis was held up by a displaced vertebra that must be treated (this advice was given by an osteopath). On examination Browne found the patient normal.

Of course, such diverse forms of advice emphatically point to a wide lack of unanimity in the minds of practicing physicians, as well as in those of the lay public, regarding the significance of undescended testicle and the importance of its treatment before the onset of puberty. To judge from the indecision frequently found in the past histories of patients coming to a hospital for the relief of undescended testicle, it seems that during the six years that have elapsed since the above incident but small progress has been made toward a unanimous opinion regarding this problem. This is made especially evident in general surgical clinics by the fairly frequent cases of patients well past puberty coming for relief of undescended testicle, toward the correction of which nothing had yet been done because of earlier conflicting or vague medical advice. The statistics of Counsellor² well illustrate this fact. Of 224 patients studied by him the average age was 19.5 years. Only 20 per cent of these patients were in the first decade of life, and 43 per cent were in the second decade. The rest were even older. It is therefore apparent that the facts that the undescended testicle cannot develop normally because of its faulty position and that correction of this defect in development can be successfully undertaken only at or before puberty are still frequently overlooked. Undoubtedly the pediatrician and the special clinics for children are on the whole well aware of these facts; not so, however, the general family physician.

PHYSIOLOGY

The testis is well known to have two functions — that of producing spermatozoa necessary for fer-

tilization, and that of secreting a hormonal substance having an important role of action on the accessory reproductive organs, such as the prostate, the vas deferens and the seminal vesicles. The spermatogenetic function of the testis is not automatic but depends directly on the pituitary gland, the activity of which causes marked stimulation of the testicular cells. In the other direction spermatogenesis is impeded or inhibited by the absence of certain food vitamins, notably vitamin E, and is also unfavorably influenced by heat. It has long been known that the undescended testis (cryptorchid) fails to produce spermatozoa, and by ingenious experimental observations Moore³ has shown that this depends on the peculiar heat sensitivity of the mammalian generative tissue. The temperature within the abdomen is three to five degrees higher than that within the scrotum, which by virtue of its thin skin, abundant sweat glands and absence of subcutaneous fat acts as a thermoregulator for the testis. Interesting examples of such a mechanism are also furnished by rodents, in whom the testes remain continuously within the abdominal cavity till just before and during the period of rut, at which time they descend into the scrotum. These facts adequately explain the failure of the undescended testis of man to mature and to produce spermatozoa. The second attribute of the testis, that of producing a hormonal substance by the activity of its interstitial tissue (Leydig's cells), is also probably interfered with by the lack of development caused by nondescent of the gland, although in most cases it is not entirely abolished.

A further factor in the problem of nondescent of the testis is found in its relation to the subsequent formation of neoplasms. For several years the opinion has been widely held that the undescended testicle is more prone to the subsequent development of a malignant tumor than is a normal one, and this applies to testicles that have undergone orchiopexy as well as to those that have not been operated on. Statistics concerning this point were either lacking or vague until a recent article by Gilbert,⁴ who analyzed 5500 cases of testicular tumor in the literature. In these he found malignancy in 841 cases in which the testis was undescended, and in 63 of these the tumor involved a testicle that had previously been operated on. In 31 of the operated cases, the period between operation and the appearance of the tumor averaged twelve years. Gilbert points out that the 11 per cent incidence of malignant tumor in persons with

in suspension into close contact with the infected area under treatment; moreover, they can be easily washed off.

Under certain conditions it is desirable to use a preparation having a lubricating effect and in others one having a drying effect. An oil-in-water emulsion provides better lubrication than does a pectin or bentonite jelly, and possesses the additional important advantage that it prevents dressings from sticking. The aqueous jellies tend to dry out rapidly and may prove especially valuable on moist lesions, such as those of impetigo.

The superiority of an oil-in-water emulsion base over an all-grease base as a vehicle for sulfonamides is also demonstrated by the results of agar-plate tests carried out with *Staphylococcus aureus* as the test organism. Figure 2 shows a marked zone of inhibition surrounding a preparation consisting of 5 per cent sulfathiazole suspended in an oil-in-water emulsion base (Base 4). In Figure 3, which shows the results when the same sulfonamide suspended in a petrolatum base (Base 1) is tested, no zone of inhibition is visible. The only apparent explanation for these differences is that the oil-in-water

the all-grease base acts as a barrier, keeping the sulfonamides away from the organisms.

SUMMARY

Heavy grease and cold-cream bases yield little sulfonamide to an aqueous medium.

FIGURE 3. Lack of Zone of Inhibition with 5 Per Cent Sulfathiazole in a Petrolatum Base (Base 1).

FIGURE 2. The Zone of Inhibition Surrounding 5 Per Cent Sulfathiazole in an Oil-in-Water Emulsion Base (Base 4).

emulsion base readily releases its sulfonamides so that they can exert a bacteriostatic action on the bacteria in the surrounding agar medium, whereas

Oil-in-water emulsion, stearate vanishing-cream, bentonite and pectin-jelly bases yield high levels of sulfonamides to an aqueous medium.

It is apparent that, in prescribing sulfonamides for local use, careful consideration should be given to the choice of a vehicle for the drugs.

The temperature was 100°F., and the respirations were 35. The blood pressure was 150 systolic, 100 diastolic.

Examination of the blood showed a red-cell count of 4,750,000 and a white-cell count of 17,700, with 56 per cent neutrophils, 15 per cent lymphocytes, 17 per cent monocytes and 11 per cent eosinophils. Toxic leukocytic granules were prominent on the stained smear. The urine gave a green reaction with Benedict's solution but was otherwise negative. An electrocardiogram showed sinus tachycardia at a rate of 120, with a PR interval of 0.16 second. There was a normal axis, with deep S_1 and S_2 and a broad shallow S_3 ; QRS was 0.09 second; the T waves were upright, and the ST segments normal.

The patient was treated for congestive failure but soon became unresponsive. His breathing became more shallow, and he expired in respiratory failure approximately twenty hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS M. RACKEMANN: I should like to take the last part of this story first and point out that this man died in respiratory failure, which I assume means an increasing respiratory rate, with shallower breathing, and the heart still beating when the end came. That fact, with progressive asthma and the typical chest findings, indicates death from asthma, and I should expect that Dr. Castleman found lungs with pale grayish surfaces and the plugging of the small bronchi. What about the heart? Was there a cor pulmonale? The heart was enlarged, the veins were full, the liver was low, and he had edema of the ankles. He had been treated for congestive failure. On the other hand, the electrocardiogram showed a normal axis. Furthermore, the heart continued to beat; if therefore he did have cor pulmonale, he did not die of it. He could have had a chronic cor pulmonale, and I believe that the right ventricular wall was found dilated and the wall thickened. A diastolic thrill is described. In such cases one can feel with the hand rales of all sorts in the chest, and rales and thrills are easily confused.

This first x-ray film was taken five months before death. It is a lateral view and shows distortion of the spinal column. The lungs are clear, the peribronchial areas are clear, and the diaphragm is low. And that goes along with the idea that he had asthma. I am quite ready to say that he died of asthma, and that he presented the typical findings.

What kind of asthma did he have and what caused it? The onset at the age of twenty means, other things being equal, that it was due fundamentally to allergy. He had been treated with ragweed and mixed *Alternaria* extract. Good physicians would not treat him with these things unless there was clinical evidence that the asthma was worse in the fall of the year than in the ragweed

season. The precise dates are always important in the history of asthma. I should like to speculate and suggest that in this story I can supply the dates even though they are not given in the abstract. I should say that this man probably died in September or early October. This makes the onset one year previously also in September, and that fits the ragweed idea. Five months before entry, when he first came to the Out Patient Department, means April, and so the skin tests were done in May. Treatment was started in July, which is a little late perhaps for best results. I shall say that the asthma was of extrinsic origin and dependent on hypersensitivity to ragweed and molds and possibly to dogs as well.

There are other factors in this picture. From the x-ray films you can see that he had scoliosis, and that means two things to me. He was a long distance runner until a year before he came here. Therefore, he was either not much of a runner or the scoliosis was not too troublesome. I have read somewhere that scoliosis predisposes to tuberculosis, and the fact that he had scoliosis makes one wonder if he had the disease. Against it is this x-ray film of the chest, taken in April. I cannot see the apices. Can you rule out tuberculosis from this film, Dr. Schulz?

DR. SCHULZ: I do not believe that I can rule it out. I can say that there is no evidence of it. The apices are obscured by the deformity.

DR. RACKEMANN: I am going to rule it out anyway, and I am also going to rule out tumor. There is not much reason to think about tumor here.

The second point about scoliosis is that it makes asthma worse, perhaps because the cramping of the chest interferes with the compensatory hypertrophy or emphysema of the lungs. Dyspnea is increased by scoliosis.

There are a number of little bothersome things in the story. In the first place, on the day before death he developed frothy sputum. Asthmatics do not do that often. I do not believe that he died of acute heart failure.

Then, on the day of death he came to the Out Patient Department at 3 a.m. complaining of pain in the abdomen that woke him suddenly from sleep. That was very unusual so far as he was concerned; it was a new thing. Nothing is said about vomiting with the abdominal pain, and he had no fever when he was seen. He was given morphine, which I think would not have been given if it was thought that he had appendicitis. The picture does not sound like appendicitis. It is not like kidney stones. But I think it does sound like mesenteric thrombosis or at least a vascular episode. So please note that. He had a subconjunctival hemorrhage. That also connotes a vascular disturbance. He had some evidence of fluid in the chest and fluid in the abdomen. The numbness in the fingers and arms might have

CASE 31241

PRESENTATION OF CASE

A twenty-one-year-old man was admitted to the hospital because of dyspnea.

He had been a long distance runner and in good health until approximately one year before admission, when he began to have a severe cough, which was worse in the early morning and was productive of thick, nonodorous yellow sputum. He noticed wheezing in his chest and became dyspneic after climbing one flight of stairs. The wheezing progressed, and he became dyspneic at rest and when lying down. He was unable to sleep well but obtained no relief from the use of more than one pillow. For several months he had been treated for bronchitis. His cough and dyspnea progressed slowly. He had frequent night sweats and occasional flecks of blood in the sputum.

Five months before admission he came to the medical unit of the Out Patient Department, where loud musical rhonchi were heard throughout both lung fields. Occasional episodes of gallop rhythm and premature beats were heard. The blood pressure was 120 systolic, 98 diastolic. The temperature was normal, the pulse 114, and the respirations 24. An x-ray film of the chest showed marked dorsal scoliosis without evidence of bone pathology. The lungs were clear, and the heart appeared normal. A white-cell count was 17,000. A diagnosis of asthma was made. Four months before admission to the hospital, tests for all common allergens were negative. These tests were repeated two months later,

*On leave of absence.

at which time strongly positive reactions were obtained to ragweed and mixed *Alternaria* and weakly positive ones to dog hair and *Penicillium*. A program of desensitization against ragweed and *Alternaria* was begun, and the patient felt somewhat better for a week after each injection. One week before admission he developed marked swelling of the ankles, and on the day before entry his sputum became frothy. At 3 a.m. on the day of admission he was awakened by a sharp shooting pain in the low mid-abdomen, which was worse when he changed position. He came at once to the Emergency Ward and obtained prompt relief from morphine. During the morning he became hoarse. He experienced no chills, fever, cyanosis, palpitation or chest pain. His appetite had been poor during recent months.

He had had measles and whooping cough but no other illnesses. The scoliosis was first noticed at the age of eleven without a concomitant illness. His parents and two sisters were living and well.

Physical examination revealed a thin, markedly dyspneic and cyanotic man with a pronounced right dorsal, left cervical and left lumbar scoliosis, with rotation of the vertebral column and winging of the right scapula. The skin was cool and covered with perspiration. There was an area of subconjunctival hemorrhage in the left eye. The pupils were pinpoint and did not react (post-morphine effect). The voice was hoarse and feeble. The neck veins were slightly distended. The heart appeared enlarged to the left and to the right. The rate was 120 and regular, and there was no pulse deficit. A diastolic rumble and thrill were thought to be present over the apex, but auscultation was difficult. Expiration was greatly prolonged. The chest was filled with high-pitched musical rales and coarse crackles on inspiration, with rhonchi, groans and wheezes on expiration. Dullness at the bases and splashing noises on respiration suggested pleural effusion. The abdomen was slightly protuberant, with signs suggesting some fluid; it was tender in the right lower quadrant. The liver was felt four fingerbreadths below the costal margin; it was slightly tender. The spleen was not felt. There was marked edema of the ankles. The femoral pulsations were normal.

CLINICAL DIAGNOSES

Cor pulmonale, with congestive failure.
Bronchial asthma.

DR. RACKEMANN'S DIAGNOSES

Periarteritis nodosa.
Bronchial asthma, extrinsic.
Cor pulmonale, chronic.
Scoliosis.

ANATOMICAL DIAGNOSES

Periarteritis nodosa, involving especially the heart and lungs.
Bronchial asthma.
Cor pulmonale.
Bronchopneumonia.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy on this young man showed that he did not have fluid in the

all the gross characteristics of miliary tuberculosis, and for that reason we fixed everything in formalin to guard against spreading the bacilli. The heart weighed 280 gm. and was not hypertrophied. The right wall measured 5 mm., indicating definite hypertrophy. The myocardium was pinkish gray throughout, with many soft areas, and we thought that that also was a manifestation of this widespread tuberculous process. Microscopic sections, however, proved that it was not tuberculosis. The histologic preparations showed an unusual lesion.

Each one of the nodules observed grossly in the heart and lungs proved to be a zone of inflammatory and granulomatous reaction in the center of which was a partially destroyed artery (Figs. 1 and 2). The lesions varied considerably, some being very acute and others in their subacute or healing stages. Practically every involved vessel showed partial to complete necrosis of its wall and infiltration with neutrophils, eosinophils, plasma cells and lymphocytes, not only of the wall of the vessel but of a wide zone be-

FIGURE 2. Photomicrograph of a Vascular Lesion in the Heart.

chest or in the abdomen. The lungs were covered with small nodules, and scattered throughout both lungs within the parenchyma were similar nodules 4 to 5 mm. in diameter. There were no bronchial plugs to suggest that he died in an asthmatic paroxysm, although I am reasonably sure that he had had asthma. In the pericardium there was about 350 cc. of brownish, somewhat turbid fluid, with a granular exudate over the epicardium. A few small grayish-white nodules were also found over the peritoneum, liver and kidneys. Certainly he had

yond the adventitia. Many of the vessels were thrombosed and in these, especially within the lumen along the destroyed intima, was an extensive granulomatous reaction with numerous foreign-body giant cells. In the heart muscle there was an extensive eosinophilic infiltration not in direct relation to vessels, which possibly represents early infarction resulting from some of the thrombosed arteries. The granulomatous reaction was so prominent that for some time we were considering this case as one of an obscure infection; the almost con-

been due to vascular lesions of the nervous system. All these things put together compel one to consider periarteritis nodosa, in spite of the fact that all the evidence for this diagnosis occurred in the last twenty-four hours. There is one more point — he had a leukocytosis, first noted five months before he died, and again at the end. That one count five months previously was out of place. Why should he have had a count of 17,000 five months before death? The figure is perfectly compatible with periarteritis nodosa, and the 11 per cent eosinophilia also fits in with the idea, although in the fatal cases of periarteritis nodosa observed in this hospital the percentage of eosinophils was much higher. In the

sema and plugs in the bronchi; possibly there were areas of old tuberculosis, and perhaps there was fluid in the pleural and peritoneal cavities, which does not go with the asthma but goes with the periarteritis. Secondly, I believe that he had chronic cor pulmonale that was not fatal, and finally that he had periarteritis nodosa that was probably of five months' duration and that was diagnosable only in the last twenty-four hours. I believe we shall find lesions in the heart and on the pleural surface of the lungs, and I shall throw in the kidneys, even though he did not have red cells in the urine.

DR. J. H. MEANS: I wonder if this man really had fluid in the chest and whether he had a pneumo-

FIGURE 1. Photomicrograph of a Vascular Lesion in the Lung.

eight cases of periarteritis nodosa which Dr. Greene and I* put together in 1939, all had a leukocytosis of 16,000 or over, and the eosinophils were at least 25 per cent.

From two hundred and twenty-nine references in the literature, however, Dr. Greene found only 19 cases that had asthma and periarteritis at the same time. Of the 19, only 12 had a high eosinophilia. In periarteritis nodosa without asthma, only 15 cases had an eosinophilia. Our patient here had only 11 per cent eosinophils in a white count of 17,000, but evidently that is enough for the diagnosis.

In conclusion, I shall say that this man had asthma, with typical pathology, including emphy-

sema and plugs in the bronchi; possibly there were areas of old tuberculosis, and perhaps there was fluid in the pleural and peritoneal cavities, which does not go with the asthma but goes with the periarteritis. Secondly, I believe that he had chronic cor pulmonale that was not fatal, and finally that he had periarteritis nodosa that was probably of five months' duration and that was diagnosable only in the last twenty-four hours. I believe we shall find lesions in the heart and on the pleural surface of the lungs, and I shall throw in the kidneys, even though he did not have red cells in the urine.

DR. RACKEMANN: I did not have good evidence, it was simply because of the splashing noise and the dullness at the bases.

DR. MEANS: If the splashing was due to effusion in the chest he must have had air in there also, and probably in his stomach.

DR. RACKEMANN: That is correct. I am not too fussy about the point. Whether or not he had fluid would not change my opinion. It is only one of several items.

DR. WYMAN RICHARDSON: I was wondering if the morphine had anything to do with his death.

DR. RACKEMANN: I should say that it had.

*Rackemann, F. M., and Greene, J. E. Periarteritis nodosa and asthma. *Tr. A. Am. Physicians* 54: 112-118, 1939

the bones of the pelvis there were scattered nodules of increased density. A gastrointestinal series with the patient in the horizontal position showed the esophagus to be normal. The mucosal folds of the stomach were greatly swollen (Fig. 2). An area of rigidity was seen just below the cardia on the lesser curvature for a length of 8 to 10 cm. On the spot films there seemed to be a shelf at the upper and lower edges of this lesion. A Graham test faintly outlined a normal-appearing gall bladder.

On the eighth day the patient spat up 10 cc. of

became more labored, and without a terminal episode, the patient expired on the twenty-second hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: The story is that of a relatively young man with an acute illness lasting four weeks.

Is it fair to look at the temperature chart? I was quite interested to know whether he had a high plateau type of fever or one that went up and down.

FIGURE 1. Roentgenogram of Chest Showing Extensive Density of an Unusual Pattern.

blood, which he stated came from his nose. A gastric analysis after histamine showed 9.9 units of free acid and 17.5 units of total acid. The sediment contained numerous polymorphonuclear leukocytes and was negative for tubercle bacilli. Repeated stool examinations showed +++ guaiac tests. The hemoglobin was unchanged. Successive differential counts showed the eosinophils to vary from 9 to 24 per cent.

The patient became progressively weaker and more dyspneic. During the third week the temperature rose slowly to 101°F., the pulse to 120, and the respirations to between 40 and 50. The urine and blood were unchanged. The peripheral lymph nodes were thought to be enlarged. Respiration

DR. BENJAMIN CASTLEMAN: You may see it. It is not striking.

DR. RICHARDSON: The fever apparently started off gently and really never did get particularly high. It was not a septic temperature.

First of all I want to run over some of the findings. The primary symptoms were pulmonary, and there was slight hemoptysis early in the disease. I think that this is worth emphasizing. He had night sweats. This is also worth emphasizing. The urine was essentially negative. It contained a few blood cells but no albumin. Several sputum examinations were done; but the story was that of an unproductive cough and there is nothing to suggest that what he was bringing up was really sputum. The alkaline

stant relation of a blood vessel to each lesion, however, justifies a diagnosis of periarteritis nodosa. Similar but less numerous lesions were found in most of the other organs, such as the gall bladder, adrenal glands, liver and kidneys.

It is interesting to speculate about the relation of the asthma and the periarteritis nodosa. We know that it is seen in people who have become allergic to an antigen of some sort. I do not know what could have happened while he had his asthma, but whatever it was it might have started him off on the road to periarteritis nodosa.

DR. CHESTER M. JONES: Had he had any chemotherapy, any sulfonamides?

DR. CASTLEMAN: Not so far as I know.

DR. RACKEMANN: Is it not fair to regard periarteritis nodosa as a pathological picture that occurs in the progress of this disease? When the so-called "toxic factor," whatever that is and however it is concerned with the allergy, reaches a certain point, it produces the peculiar lesions in the blood vessels that we call periarteritis nodosa. I do not believe that the word necessarily means a disease in itself. It is an episode in the course of disease.

CASE 31242

PRESENTATION OF CASE

A forty-three-year-old longshoreman was admitted to the hospital because of shortness of breath.

He was well until six weeks before entry, when he first began to note shortness of breath and weakness of the back and legs on climbing stairs and ladders. At about the same time he began to have a dry cough, especially after exertion. He was told that he had bronchitis and was treated with medicines, which afforded no relief. He had had slight hemoptysis on two occasions. Three weeks before admission he became sleepless and orthopneic, requiring three pillows. He had frequent night sweats. A week later he noted pain in his knees and thighs, but no swelling or redness. He also experienced a mild low substernal pain. The dyspnea and weakness had progressed to such a degree that, at the time of admission, he could not dress himself. During the six-week period of illness he had lost 15 pounds; he had had to quit his job two weeks after the onset of his illness.

At the age of four he had scarlet fever. He had not had rheumatic fever or any other severe illness. Four years before the present illness he had submitted to an Army physical examination and had been found to be in excellent health.

Physical examination revealed a slightly pale man with rapid, shallow labored breathing and limited chest expansion. The tongue was dry and red. There was no clubbing of fingers or toes. The neck veins were large but not pulsating. Fine moist rales were heard all over the chest, anteriorly and

posteriorly. No murmurs were heard. The heart was not enlarged. The aortic second sound was equal to the pulmonic. The abdomen showed some voluntary spasm, and the abdominal wall was "sore" from much coughing. Rectal examination revealed a normal prostate. Neurologic examination was negative.

The temperature was 99°F., the pulse 100 and regular, and the respirations 28. The blood pressure was 118 systolic, 75 diastolic.

Examination of the blood showed a red-cell count of 6,100,000, with 17.0 gm. of hemoglobin. The white-cell count was 9700, with 54 per cent neutrophils, 12 per cent lymphocytes, 27 per cent eosinophils, 6 per cent monocytes and 1 per cent basophils. The red cells and platelets appeared normal. The urine specific gravity was 1.030, and the pH 5.2. The sediment contained 3 red cells and 1 to 3 white cells per high-power field, with an occasional hyaline or granular cast. A stool was formed, dark and guaiac negative. Repeated smears of the sputum showed no tubercle bacilli. The serum nonprotein nitrogen was 37 mg. per 100 cc., the calcium 9.0 mg., the phosphorus 3.0 mg., and the cholesterol 205 mg. The protein was 4.98 gm. per 100 cc., with an albumin-globulin ratio of 1.8. The alkaline phosphatase was 16.6 units per 100 cc., and the acid phosphatase 3.3 units. A cephalin flocculation test was negative in forty-eight hours. The carbon dioxide and chloride levels were normal. The blood Hinton test was negative. An electrocardiogram on the first day showed a normal rhythm of 100, a PR interval of 0.17 second, and a flat and diphasic T₁, an inverted T₂, a deep S₂ and inverted T waves in CF₁, CF₂ and CF₃. At the same time an x-ray film of the chest showed extensive density of a rather unusual pattern in both upper lung fields and in the central portions of the left lower lung field (Fig. 1). The heart did not appear enlarged. The left diaphragm was slightly elevated, and there was mild scoliosis of the thoracic spine.

On the third day marked variation of pulse and heart rate and sounds were noted on expiration. The pulse slowed and weakened during inspiration. A diastolic gallop at the apex and an inconstant diastolic scratchy murmur over the pulmonic area were heard. The respiratory rate rose to 40 for twenty-four hours on the third day, then returned to the former rate of approximately 30. Sputum cultures for streptococci, pneumococci and fungi were negative. The venous pressure and the circulation time were normal. Repeated tuberculin and trichinella skin tests were negative. Re-examination of the chest fluoroscopically and additional films on the fourth day showed no appreciable change in the extensive increased density that involved both lung fields. Further x-ray studies one week after admission showed a normal intravenous pyelogram. A film of the abdomen showed no soft-tissue masses and a normal-sized liver and spleen. Throughout

tumor mass is seen, but there is ulceration of the mucosa along the rigid part of the stomach.

DR. RICHARDSON: I want to play down that lesion.

DR. SCHULZ: These swollen rugae are reminiscent of a case presented at this conference several years ago that proved to be merely gastritis with infiltration of the stomach wall.¹ Lymphoma of the stomach can also have this appearance.

DR. CHESTER M. JONES: Would you be willing to say that this was not an extraluminal gastric lesion, but that it was in the mucosa.

DR. SCHULZ: On the basis of these films I do not believe that one can tell.

DR. RICHARDSON: Now for the diagnosis. If one takes the eosinophilia seriously what does one have to consider? I am not going through all the possibilities, but some of them have to be considered seriously.

I do not know much about Loeffler's syndrome, but it has to do with a pneumonitis and a high eosinophilia. It is relatively acute and benign. I am not up on the literature, but in cases coming from the Mediterranean area I have seen mention of eosinophilia and chronic pneumonitis that lasted for a year or more. I do not believe that any of these cases had an acute fulminating process of this sort. I have seen one patient in this hospital who had an eosinophilia with lesions in the lung, a picture that suggested to me Hodgkin's disease. In the course of a year, however, all the lesions disappeared, as did the eosinophilia, and the patient made a spontaneous recovery. In the present case the disease seems to me to be too widespread and too quickly fatal to consider this group, and therefore I cross them out.

I think that one can make out a good case for periarteritis nodosa, whatever that may be. It is a clinical hodge-podge when one tries to make of it a clear-cut clinical picture. This case does not follow the pattern that one encounters in the asthmatic type. There is no peripheral neuritis, no mesenteric thrombosis, no renal symptoms, and only slight evidence of any actual coronary involvement. Furthermore, I do not believe that we see such a chest picture in the usual type of periarteritis nodosa. It seems to me that the course is too acute for a case of periarteritis nodosa, and in spite of the eosinophilia I am going to throw that diagnosis out. Also, bone lesions would be extremely rare with periarteritis nodosa.

Trichinosis can be fatal. When it is, I believe that it would cause a typhoid-like picture, which this patient did not show. There may be central-nervous-system involvement in fatal cases. Two skin tests were negative. If one is going to pay any attention to such tests it seems to me that they should have been positive in this case. I am going to rule it out.

Tumor seems to me the logical diagnosis in this

case. There is widespread disease involving bone, with lesions that Dr. Schulz says are consistent with metastatic tumor of the bone. There is a lesion in the stomach, and one can logically say that this patient had a tumor of the stomach with widespread metastases, or possibly primary tumor in the lung, with metastases elsewhere. Eosinophilia with tumor involving the lung is sometimes observed. I saw a case not so long ago with eosinophilia due to bone metastases from a pancreatic tumor, but if one is going to suggest tumor as a cause for eosinophilia there should be an accompanying anemia and changes in the blood characteristic of widespread bone-marrow involvement. This man had no anemia, in fact he had a polycythemia, probably due to a certain amount of dehydration and possibly accentuated by some anoxemia, although he is not described as being cyanotic. I do not get the feel from this case that it was a malignant tumor. It was rapidly fatal without any of the really good localizing signs or symptoms that one would expect with a rapidly fatal tumor. It is the kind of death that one might expect from acute leukemia. Nothing suggesting this was observed in the blood smear. Then we have the lymphoma group. It is rare to see a case as quickly fatal as this in any of the lymphomas, unless one includes acute leukemias, which I have already mentioned.

The whole picture to me is that of infection, and whereas I say that tumor is the logical diagnosis, I am going to throw that out also. It may be an infection that I know nothing about or that I have not thought of, in which case there is no use in talking any more. The only infection that I can think of that might produce such an acutely fatal illness is an acute miliary tuberculosis. Does miliary tuberculosis cause eosinophilia? I do not remember having observed it, although I have not seen many cases. That is one point against it. The tuberculin test was negative, but the tuberculin test is frequently negative in overwhelming infection by the tubercle bacillus. So we can allow that. The third point against it is this osteoblastic activity in the bone, which one would think ought to be osteolytic. I am not sure whether tubercles scattered throughout the bone marrow can "tickle up" the osteoblasts enough to lay down a little bone. I do not, however, feel satisfied with the diagnosis of tuberculosis.

The diagnosis of acute bacterial endocarditis ought to be entertained, but again there is no evidence of embolic phenomena, and the bone involvement does not seem to go with it. I am trying to make a soft bed for myself by saying that tumor is the logical diagnosis, but I am going to cross that out and say that this man had a fulminating infection, probably miliary tuberculosis.

DR. J. H. MEANS: Dr. Napier is here, and I have asked him to comment on the eosinophilia.

DR. L. EVERARD NAPIER: My remarks will not bear any relation to this case, but I have been in

phosphatase was elevated, and this suggests bone disease with osteoblastic activity. The murmur in the pulmonary area could possibly have been due to pericarditis, or to pleuritis from the overlying lung, or it may not have been significant at all. Tuberculin tests were negative. Repeated tests with trichinella antigen were also negative. There was pus in the gastric contents, an observation not frequently made, perhaps because it is not looked for. Perhaps we should see the x-ray films at this time.

DR. SCHULZ: Not quite like it, although somewhat approaching it. The findings in this film in association with the increasing dyspnea make one think about lymphatic spread of tumor, especially in view of the areas of increased density evident in the bones.

DR. RICHARDSON: Let us look at the bones.

DR. SCHULZ: There are many round areas of increased density in the pelvis that look like osteoblastic reaction to metastases. Similar bone lesions can be seen in lymphoma.

FIGURE 2 Roentgenogram of Stomach Showing the Swollen Rugal Folds

I am interested in the lesion in the stomach and the appearance of the chest, as well as some of the bone lesions.

DR. MILFORD D. SCHULZ: The films of the chest show extensive, symmetrically distributed mottled and stringy areas of increased density spreading into both lung fields. These go all the way out to the periphery of the lung fields and seem to be most prominent near the lung roots (Fig. 1). It ushers in as possibilities a whole group of lesions that includes lymphatic spread of tumor, fibrosis, miliary tuberculosis, sarcoid and others.

DR. RICHARDSON: You never see an x-ray of the chest like that with periarteritis nodosa, do you?

DR. RICHARDSON: Do you see areas of osteolytic activity?

DR. SCHULZ: I do not believe so. I think that they are osteoblastic.

DR. RICHARDSON: With widespread tuberculosis in the bone is there osteoblastic activity or is it mostly a destructive process?

DR. SCHULZ: I have never seen it look like this.

DR. RICHARDSON: This is, of course, a miliary process.

DR. SCHULZ: The fluoroscopist observed greatly swollen rugal folds. The films of the stomach show an area of rigidity along the lesser curvature, and this is quite constant on the spot films. No actual

Along this curvature we also found a slightly rigid area 2 to 3 cm. long that was only superficially ulcerated. The mucosal folds, however, were prominent (Fig. 4), and this prominence is undoubtedly

FIGURE 5. Photomicrograph Showing Nests of Carcinoma in Distended Lymphatics of the Lung and Pleura.

what was seen in the x-ray and led Dr. Jones to think of a lymphoma, because lymphoma does spread in submucosal tissues and elevates the mucosa. Of course, carcinoma can also spread in that way. These mucosal folds were high and could

not be depressed so that we knew there was something, almost certainly a neoplasm, beneath the mucosa. Microscopically all the lymphatic vessels in the pleura and lungs were plugged with nests of neoplastic cells, which proved to be those of an undifferentiated carcinoma (Fig. 5). The primary lesion was, of course, the rigid area in the stomach; it had extended throughout the submucosa to involve the serosal lymphatic vessels, the peripancratic lymph nodes and the peritoneum. The vertebral bone marrow was grossly involved, and it is surprising that the red-cell count was high. Two or three other counts were taken, and all were in the neighborhood of 5,000,000.

DR. RICHARDSON: If one had looked at the smear I suppose one might have found some evidence of red-cell activity.

DR. CASTLEMAN: This lung picture of lymphatic spread of metastases has been recently described by Dr. Mueller of the X-ray Department and by Dr. Sniffen of this laboratory.² About 70 per cent of all cases of lymphatic spread of cancer of the lungs come from the stomach: they usually occur in young persons, and the course is rapidly fatal.

DR. JONES: I think that it cannot be stressed too much that miliary lesions in the lungs may be due to many causes other than tuberculosis. One of the most frequent is metastatic malignancy.

the tropics, where we see a good deal of eosinophilia, much of which we cannot understand. We call it idiopathic eosinophilia. Frequently we find it running up to 60 or 70 per cent without any obvious

FIGURE 3. Photograph of the Pleural Surface of the Lung.

reason. Another aspect of eosinophilia in the tropics is the high eosinophilic count in the normal population, as compared with the figures one sees in the textbooks that are based on experience in temperate climates. We have taken counts of so-called "healthy people" in India and found an average eosinophilic count of 14 per cent. A good deal of this is attributed to parasitic infestation. That is not the whole story, however. When we exclude infestation we find an average eosinophilic count of 5 to 7 per cent. So the presence of eosinophilia would not excite me the same way that it does you here. The one thing you think of is trichinosis or trichiniasis, — it should really be called "trichineliasis" to be correct, — but we do not think of that in India because we scarcely ever see it. We have seen eosinophilia of the lung or eosinophilic pneumonitis, but it is essentially a benign disease.

DR. JONES: I saw this patient and thought that he probably had a lymphosarcoma originating in the stomach. The chest findings were perfectly consistent with such a diagnosis, and the x-ray film of the stomach showed a curious mucosal pattern, which was like that of several cases of lymphosarcoma of the stomach that I have seen. On the basis of this trabeculation of the gastric mucosa and the rest of the story, that is, the chest findings and the bone lesions, I thought that lymphosarcoma secondary to a primary focus in the stomach was the logical diagnosis.

CLINICAL DIAGNOSIS

Lymphosarcomatosis.

DR. RICHARDSON'S DIAGNOSIS

Miliary tuberculosis.

ANATOMICAL DIAGNOSES

Carcinoma of stomach with metastases to the regional lymph nodes, pleura, lung, pericardium, peritoneum and vertebrae.

Lymphatic spread of pulmonary metastases.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Both lungs were voluminous and filled the entire chest cavity. Scattered over both pleural surfaces was a yellow-white, lacelike network, which reminded me a bit of the lacteals in the intestines when they are ballooned with fat. This network was bright yellow in places and formed a pattern of the entire lymphatic system of the pleura (Fig. 3). It was very striking. This pleural process involved the entire pleura and extended on to the pericardium at the pleural reflection. This same lymphatic engorgement was seen throughout

FIGURE 4. Photograph of the Mucosal Surface of the Stomach.

the parenchyma of both lungs. We, of course, thought of metastatic carcinoma and focused our attention on the stomach. Along the lesser curvature we found enlarged lymph nodes adherent to the pancreas, but the pancreas itself looked normal.

knock-knees and condemn them to orthodontia, forcing them to wear bird cages in their mouths. We believe that, in order to earn our guinea, we should fix something, when often the best service we could perform would be to pocket the fee and leave the patient alone.

MEDICOLEGAL ABSTRACTS

THIS issue of the *Journal* contains the initial article of a new department, "Medicolegal Abstracts." These abstracts have been and will be prepared by members of the law firm, Palmer, Dodge, Chase and Davis, and it is hoped that a sufficient number will be available so that one can appear monthly.

Many decisions in various courts of law are of vital interest to members of the medical profession and although certain of these are not nationally applicable, being based on the statutes of a single state, they give an idea of the trend of legal thought in matters pertaining to medicine.

These abstracts will be divided into four main groups, each with various headings, as follows: regulation of practice by government (power of government, unauthorized practice, qualification to practice, unlawful operations and treatment, and regulation of professional conduct); relation of patient and physician (right to compensation, liability for malpractice, and authority to operate and to give treatments); testimony by physicians (privileged communications between patient and physician, and medical expert testimony); and institutions (medical societies, medical schools, medical journals, and hospitals).

OBITUARY

ABRAHAM RUDY

1895-1945

Abraham Rudy was born in Bialystok, Russia, on February 18, 1895. He studied at the University of Rouen, Moscow University and the University of Berlin, receiving the degree of M.D. from the last-named institution in 1923. In the same year he came to the United States and interned at the Beth Israel Hospital in Boston from 1924 to 1925. During the following year he assisted Dr. Frederick

M. Allen at the Institution for Metabolic Diseases. From 1926 to 1928 he was assistant in medicine at the Mount Sinai Hospital in New York City.

In 1928 he returned to the new Beth Israel Hospital in Boston, where he helped organize the Diabetic Clinic. As head of this clinic he devoted the next seventeen years to assiduous work and constant study. In his quiet, scholarly way he made important contributions to the understanding of the disease to whose alleviation he had devoted himself. He wrote on the role of heredity in diabetes, the carbohydrate metabolism of the skin, vitamin deficiencies in diabetics, diabetic retinitis and the neurologic manifestations of diabetes. He was the author of two books, *Practical Handbook for Diabetic Patients* and *Simplified Diabetic Manual*. His authority was recognized by the New York Diabetes Association, which invited him to write two of the fundamental concepts in *Treatment of Diabetes Mellitus and Its Complications*.

Abraham Rudy was instructor in medicine at Tufts College Medical School and associate in medicine at the Beth Israel Hospital. He was a member of the Massachusetts Medical Society, American Medical Association, Greater Boston Medical Society, Boston Society of Biologists, New England Heart Association, Society of Endocrinology and American Diabetes Association, as well as a fellow of the American College of Physicians.

Doctor Rudy's twenty-odd papers were the result of hard work, keen investigation, enthusiastic inquiry and painstaking clinical investigation. In his contacts with students, colleagues and patients he was invariably gentle, sympathetic and helpful. He had infinite patience. In the last two years of his life, with full knowledge of his fatal illness, he continued his daily work, influencing by precept and example all those who knew him. He was an inspiring physician.

S. S. and H. S.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

SHEEDY — John F. Sheedy, M.D., of Lawrence, died April 2. He was in his seventy-fourth year.

Dr. Sheedy received his degree from Baltimore University School of Medicine in 1898. He was a fellow of the American Medical Association.

WRIGHT — Rebekah Wright, M.D., of Brookline, died March 29. She was in her seventy-third year.

Dr. Wright received her degree from Northwestern University Woman's Medical School, Chicago, in 1896. For many years she was associated with the Massachusetts State Department for Mental Diseases as a consultant in hydrology. Since February 1, 1945, she had been consulting hydrologist at the Connecticut State Hospital, Middletown. She was a member of the American Medical Association, the American Psychiatric Association and the New England Society of Psychiatry.

NON NOCERE

THERE come times in the course of human activities when, if we are wise, we pause and look over the lay of the land; see in what direction we are heading, where our goal lies, and if we have been on the right road. It is too easy for us to drift with the crowd, to join an easy-going pilgrimage with no certain knowledge of its shrine and with no critical ideas how the march should be conducted. We are a little like the wartime Londoner who attached himself to the end of a long sidewalk queue and after a while was asked by a passing friend whither he was heading. "I don't know," was the reply, "but it must be pretty good, this queue is so long."

Dr. Harry Bakwin, in his paper "Pseudodoxia Pediatrica," presented before the American Pediatric Society last fall and published elsewhere in this issue of the *Journal*, points out certain false practices into which pediatrics has fallen but from some of which it has recovered.

Midwifery, perhaps even obstetrics rather than pediatrics, has been responsible for the wiping out of the mouths of newly born infants and for the harsh removal of the protective vernix caseosa—practices now largely abandoned. No longer are mineral oil nose drops employed, nor is cod-liver oil poured into the mouths of crying babies, in those circles where the sanctity of human life is still highly regarded. Even the rigid feeding schedule, symbol of Teutonic regimentation and source of parental anxiety and infantile anorexia, is being relaxed in those rarefied strata of society where it is recognized that infants can frequently contribute more to their own training than can their parents.

The indiscriminate tonsillectomy, according to Dr. Bakwin, — physicians, nurses and parents take notice, — may have its ill effects, and this anatomic sunderance, like the joining together in marriage, should not be entered into lightly. Myringotomy is a minor operation not to be performed without due regard to the fact that it is an operation, and it has been shown, even before the use of sulfonamide drugs, that the incidence of purulent otitis media can be sharply reduced by a reasonable abstinence in the use of direct otoscopy.

The lying-in hospital comes into Dr. Bakwin's purview. Convenient it certainly is for the obstetrician, but how safe is it for the infant, that by-product of obstetrics? There are risks to well babies lurking in crowded nurseries, not the least of which is the dreaded epidemic diarrhea of the newborn. In too many cases the pediatrician enters these temples of accouchement on sufferance only, and the obstetrician determines the alimentary career of the little visitor, come hell or high water.

We have, in fact, committed ourselves to a course of too much meddling in the physiologic affairs of our tots of destiny. We assail them with vitamins, regulate their feeding times and the methods of feeding them, correct their flat feet, unbend their

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Trichinosis. By Sylvester E. Gould, M.D., D.Sc., pathologist and director of laboratories, Eloise Hospital, Eloise, Michigan and assistant professor of pathology, Wayne University College of Medicine, Detroit. 8°, cloth, 356 pp., with 128 illustrations. Springfield, Illinois: Charles C Thomas, 1945. \$5.00.

The incidence of trichinosis in the United States has increased greatly in the past decade. Most of the cases studied after autopsy were not diagnosed during lifetime, revealing that the disease is not usually recognized except when it occurs in epidemic or severe form. The purpose of the volume is to bring the more important aspects of trichinosis to practitioners and possibly also to the attention of those producing and handling pork. An extensive bibliography of 32 pages concludes the work. The book is well printed on good paper and is illustrated sufficiently to bring out special points in the text.

A Method of Anatomy: Descriptive and deductive. By J. C. Boileau Grant, M.C., M.B., Ch.B., F.R.C.S. (Edin.), professor of anatomy, University of Toronto. Third edition. 4°, cloth, 822 pp., with 729 illustrations. Baltimore: Williams and Wilkins Company, 1944. \$6.00.

The text in this third edition of an authoritative anatomy has been revised, and many parts have been rewritten and rearranged. Fifty-five new illustrations have been added, and sixty-nine old illustrations have been redrawn and relabeled.

Hack's Chemical Dictionary. Completely revised and edited by Julius Grant, M.Sc., Ph.D., F.R.I.C. Third edition. 8°, cloth, 925 pp. Philadelphia: Blakiston Company, 1944. \$12.00.

Dr. Julius Grant is responsible for this new edition of an essential reference work. The dictionary has been completely revised and brought up to date in every respect, special care being taken to balance the treatment from the American and British points of view. The dictionary now contains over 57,000 definitions. It is recommended for all libraries and all persons having to do with chemistry.

Immuno-Catalysis. By M. G. Sevag, Ph.D., assistant professor of biochemistry in bacteriology, Department of Bacteriology, School of Medicine, University of Pennsylvania, Philadelphia. With a preface by Stuart Mudd, M.D., professor of bacteriology, School of Medicine, University of Pennsylvania, Philadelphia. 8°, cloth, 272 pp., with 19 tables. Springfield, Illinois: Charles C Thomas, 1945. \$4.50.

In the preparation of this monograph more than a thousand publications in English, French and German were consulted for material having a direct bearing on the subject matter. The author was unable to consult the literature in unusual languages, such as Russian, Chinese and so forth, although material pertinent to his subject may have been published in these languages. The work is divided into the following parts: antigens as bio-catalysts; antihody as a specific enzyme inhibitor; anti-enzyme immunity; immunity against bacterial enzymes; and the problem of antihody formation against respiratory enzymes. A bibliography of four hundred and eighty-two items is appended to the text.

Ventures in Science of a Country Surgeon. By Arthur E. Hertzler, M.D. 8°, cloth, 304 pp., with 85 illustrations. Halstead, Kansas: Arthur E. Hertzler, 1944. Free.

This collection of essays, principally in the field of surgery, epitomizes the experience of Dr. Hertzler over a period of fifty years in medical practice. Here will be found a summary of his original investigations on the anatomy and physiology of the peritoneum and on the healing of wounds. Two interesting chapters on the writing of books and the building of

a library should interest all librarians, as well as physicians who have literary inclinations. The chapter on visual education describes the author's methods in caring for microscopic slides, photographs and drawings.

A Bibliography of Aviation Medicine: Supplement. By Phebe M. Hoff, Ebbe C. Hoff, Ph.D., and John F. Fulton, M.D. Publication No. 9, Historical Library, Yale Medical Library. 4°, cloth, 109 pp. Washington, D.C.: Committee on Aviation Medicine, Division of Medical Sciences, National Research Council, acting for the Committee on Medical Research, Office of Scientific Research and Development, 1944. \$2.50.

This supplement brings up to date the literature of aviation medicine scattered throughout medical journals published during the past two years. A total of 2336 entries has been added to the original 5745 listed in the original bibliography. In the supplement more than two hundred additional journals have been added to the nine hundred cited in the original work. All the periodicals noted in the original or in the supplement have been brought together in one alphabet so that readers will not be obliged to refer back to the appendix of the original work. This book should be in all reference collections, as well as in the libraries of doctors interested in aviation medicine.

Pep, Pills and Politics: An odyssey of two cities. By Arthur W. Hopkins, M.D. 8°, cloth, 239 pp., with 23 illustrations. Brattleboro, Vermont: Vermont Printing Company, 1944. \$2.50.

This is an interesting autobiography of a country physician who became a power for good in his community. Dr. Hopkins writes interestingly of his childhood, his college and medical-school days at Dartmouth, his internship and the first years of practice. He concludes his narrative with stories about his later years of practice and his participation in town affairs.

Combustible Anesthetics in Hospital Operating Rooms. 8°, paper, 16 pp. Boston: National Fire Protection Association, International, 1944. 20 cents.

This advisory pamphlet embodies the report of the Conference Committee on Operating Room Hazards, which was officially adopted by the National Fire Protection Association in 1944. The first five sections contain the recommended safe practice for the use of combustible anesthetics in hospital operating rooms. The sixth and seventh sections contain recommendations concerning electrical wiring and equipment and on the reduction of electrostatic hazard. This pamphlet should be in the library of the superintendent's office of every hospital.

Surgery of the Hand. By Sterling Bunnell, M.D. 4°, cloth, 734 pp., with 597 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$12.00.

This new book was primarily designed to treat reconstruction but has been expanded to include other aspects of surgery that seemed necessary to complete the work. An effort has been made to keep the work concise and not to overburden it with historical references but merely to express the facts on a working basis. It is profusely illustrated and printed on good paper with a good type but is heavy, as is usual with books made of coated paper.

Essays in the History of Medicine: Presented to Professor Arturo Castiglioni on the occasion of his seventieth birthday, April 10, 1944. Edited by Henry E. Sigerist, with the assistance of Genevieve Miller. 4°, paper, 358 pp., with illustrations and frontispiece. Supplement No. 5 to the *Bulletin of the History of Medicine*. Baltimore: Johns Hopkins Press, 1944. \$5.50.

Dr. Castiglioni was honored by twenty-six of his associates and friends who collaborated in writing the essays contained in this memorial volume. The bibliographic chapters of Drs. Fulton, Galdston and Proskauer on Polydorus Vergilius, J. A. F. Ozanam and Hans Sachs, respectively, are of particular interest. Miss Genevieve Miller's paper on an early American marine medicine chest is a welcome contribution to the history of Colonial medicine. The volume is prefaced by an interesting dedicatory letter by Dr. Sigerist, followed by a bibliography of the books and articles written by Dr. Castiglioni, comprising one hundred and sixty-four items.

MEDICOLEGAL ABSTRACT

Power of Government: Licensing as chiropractors of persons not qualified to be physicians and surgeons.

The effect of a recent decision of the Texas Court of Criminal Appeals may be that a person is permitted to practice chiropractic in that state only if he has satisfied the educational and other requirements to qualify to practice medicine. The court held that the attempt in the Texas Chiropractic Act to license chiropractic as there defined as a separate science violated the State Constitution.

The Constitution provided:

The Legislature may pass laws describing the qualifications of practitioners of medicine in this State, and to punish persons for mal-practice, *but no preference shall ever be given by law to any schools of medicine* [emphasis supplied]

The act provided:

Chiropractic is defined to be the science of analysing and adjusting the articulations of the human spinal column, and its connecting tissues, without the use of drugs or surgery. Chiropractic shall in no sense be construed or defined as treatment or attempted treatment of patients by use of surgery or medicine.

The court treated chiropractic as defined in the act as a "school of medicine," within the meaning of the Constitution, and held that "the term 'schools of medicine,' as there used, means, and has reference to, the system, means, or method employed, or the schools of thought accepted, by the practitioner."

The court went on to point out how the act gave a preference to the chiropractic school of medicine. The court said that the educational qualifications required for the practice of medicine were decidedly more onerous than those required for the practice of chiropractic and that the subject embraced in the examination given applicants for chiropractic differed from those given applicants to practice medicine. The court further pointed out that the act took away from persons licensed to practice medicine the right to do so by the chiropractic system of the healing art and required that they must first qualify by satisfactorily passing the examination required under the Chiropractic Act.

The court argued that the Chiropractic Act gave a preference to a particular school of medicine, although the Optometry Act and the Dental Act, which were in many respects similar, did not give such a preference. The Optometry Act defined optometry as "the employment of objective or subjective means, without the use of drugs, for the purpose of ascertaining and measuring the powers of vision of the human eye, and fitting lenses or prisms to correct or remedy any defect or abnormal condition of vision." And the act provided, "Nothing herein shall be construed to permit optometrists to treat eyes for any defect whatsoever in any manner, nor to administer nor to prescribe any drug or physical treatment whatsoever, unless such optometrist is a regularly licensed physician or

surgeon under the laws of this state." The Courts said:

Thus the distinction between optometry and chiropractic is apparent. One relates to a particular organ of the body, without treating that organ for disease or disorder. Chiropractic relates to the whole of the body, and authorizes the treatment thereof for diseases or disorders.

Under the Dental Act the business of dentistry was to diagnose, treat, remove stains or concretions from teeth, treat, operate or prescribe, by any means or method, for any disease, pain, injury, deficiency, deformity or physical condition of the human teeth, alveolar process, gums or jaws. And the Court said:

Thus, in his particular field of endeavor, the dentist is restricted to a certain part of the human body. He is not authorized to treat the body generally for a disease or disorder. . . .

The Dental Act bears the same distinguishing features as does the Optometry Act.

The court's decision, being based on a violation of the Texas Constitution, may not have an important bearing in other states, for the court points out that many states are without a provision similar to that in the Texas Constitution that no preference shall ever be given by law to any schools of medicine. Nevertheless, the effect in Texas is to require for the qualification of chiropractors the same standards required for the qualification of physicians and surgeons. — (*Ex parte Halsted*, Texas, 182 S.W. [2d] 479 [1944].)

CORRESPONDENCE

SHELTERED WORKSHOP

To the Editor: Private physicians may send their patients with arrested tuberculosis who are able to do part-time work to the Sheltered Workshop, 35 Tyler Street, Boston. This shop is sponsored by the Boston Tuberculosis Association. All applicants are examined for admission by Dr. H. Louis Kramer on Mondays at the shop at 4 p.m.

Usually beginners are assigned two hours' work each day. The women are taught sewing, and the men carpentry, by well-educated and experienced teachers. Patients on the two-hour schedule arrive at the shop at 10 a.m. and are given a glass of milk and crackers. The patient then works until noon, when a substantial dinner is served. There is a rest hour from 1 to 2 p.m., after which the patients on a two-hour schedule go to their homes. The hours of work are increased by Dr. Kramer until finally the patient is doing a full day's work.

Guidance toward permanent placement in industry is given by the follow-up worker, who is employed by the Boston Tuberculosis Association. During the fifteen-year period in which the Sheltered Shop has been operating it has been found that 80 per cent of the patients who have received training in it have continued to remain well. The majority of these patients have been referred to the shop from board-of-health clinics and state and private sanatoriums: private physicians, however, might well employ this service for their patients. Further details can be secured by telephoning the Sheltered Workshop (Devonshire 8328).

TERMINAL CARE IN CANCER

A Study of Two Hundred Patients Attending Boston Clinics

RUTH ABRAMS,* GERTRUDE JAMESON,† MARY POEHLMAN,‡ AND SYLVIA SNYDER§

BOSTON

MEDICAL social workers who daily attempt to cope with the task of arranging for the terminal care of cancer patients have long been concerned with the fact that the combination of limited facilities for the care of chronic cases, hospital policies and human nature makes this an almost insurmountable problem. Because this situation became increasingly difficult, four medical social workers representing as many tumor clinics in Boston met to discuss the nature of the problem, to review the limitations of resources and to discover how they could derive mutual help. An analysis of the situation relative to the medical and nursing provisions in the community seemed timely. The social workers combining in this project represented the Beth Israel Hospital, the Boston Dispensary, the Massachusetts General Hospital and the Palmer Memorial Hospital, a division of the New England Deaconess Hospital. All these institutions are set up primarily for the treatment of acute illness with the exception of the last, which has, in addition, limited facilities for chronic cases.

It was decided to study an unselected sampling of 200 patients known to the tumor clinics of these hospitals who had died of cancer within one calendar year to determine the care received by them and the conditions at home during the period of terminal care. The period selected was an arbitrary one — from November 1, 1941, to October 31, 1942. Fifty cases from each of these clinics were analyzed in relation to age, sex, place of death, length of terminal-care period, living conditions, effect of family finances on plan of care, medical and nursing care provided and the question whether hospital care (general-hospital or chronic or both) would have been acceptable to a greater number if available.

"Terminal care" is an indefinite term used flexibly

by physicians, nurses and social workers. For the purposes of this study, it is taken to apply to that period beginning when the patient is failing and only sedation is being given.

For most patients, this period tends to divide itself naturally into two phases — early terminal and late terminal. During the early terminal phase, the patient may be semiambulatory and able to care for himself and to travel to a clinic or a physician's office for medical supervision. Although unable to work, to be economically self-maintaining or to assume responsibility for household tasks, he can go to the table for meals and has bathroom privileges so that he is not yet a burden to his family. The most obvious problems are environmental. If the patient is a housewife, she must be relieved of household responsibility. If the patient is the wage earner, there may be a need for securing financial assistance if the rest of the family cannot assume the burden of support. Transportation to the clinic may also have to be arranged. It seems natural to assume that there are also emotional reactions. Since the patient can to some extent carry on an active life, the family may not at this point have accepted the medical situation, and the emotional upheaval that may follow has not yet occurred. In the late terminal stage, as the patient's condition gradually becomes worse, requiring more and more attention, — that is, complete bed and nursing care, additional medical supervision or hospitalization, — the family is inevitably forced to the realization that nothing further can be done to halt the patient's decline.

Several elements are involved in providing adequate terminal care. These are the patient's medical and nursing needs, the family's acceptance of the medical situation and what it implies, the family's ability to care for the patient at home — both physically and emotionally — the patient's wishes referable to care at home or elsewhere and existing facilities that are available.

*Social worker, Tumor Clinic, Massachusetts General Hospital.

†Director of Social Service, New England Deaconess Hospital.

‡Social worker, Tumor Clinic, Boston Dispensary.

§Social worker, Tumor Clinic, Beth Israel Hospital.

Principles and Practice of Surgery. By W. Wayne Babcock, M.D., acting consultant, Philadelphia General Hospital. 4th, cloth, 1331 pp., with 1141 engravings and 8 colored plates. Philadelphia: Lea and Febiger, 1944. \$12.00.

Dr. Babcock's new text on surgery is the work of thirty-seven collaborators, all of whom, with one exception, are affiliated with Temple University. The work covers practically every method of surgical diagnosis and treatment.

Ourselves Unborn: An embryologist's essay on man. By George W. Corner, M.D. 8th, cloth, 188 pp., with 18 illustrations. New Haven: Yale University Press, 1944. \$3.00.

This small volume contains the Terry Lectures given at Yale University by Dr. Corner. The first lecture is entitled "The Embryo as Germ and as Archive"; the second, "Prenatal Fate and Forcoordination"; and the third, "The Generality and the Particularity of Man."

Contagious Diseases: A guide for parents. By W. W. Bauer, M.D., director, Bureau of Health Education, American Medical Association. Second edition. 12th, cloth, 188 pp. New York: Alfred A. Knopf, 1944. \$2.50.

The first edition of this popular book appeared in 1934, and this edition embodies the advances in the treatment and diagnosis of the contagious diseases that have taken place in the interim. The text has been thoroughly revised and rewritten and should be of help to parents confronted with this type of disease.

The Pathology of Internal Diseases. By William Boyd, M.D., LL.D., F.R.C.P. (Lond.), professor of pathology and bacteriology, University of Toronto. Fourth edition, thoroughly revised. 8th, cloth, 857 pp., with 366 illustrations and 8 colored plates. Philadelphia: Lea and Febiger, 1944. \$10.00.

This authoritative text has been thoroughly revised in the light of recent advances in pathology. Much new material has been added, and many sections have been rewritten, especially those covering the etiology of rheumatic fever, calcareous aortic stenosis, the time factor in coronary infarcts, the arterial lesions of hypertension, diffuse arteriolar sclerosis, healed infarcts of the lung, the geography of primary carcinoma of the liver, pyelonephritis, intracranial aneurysms and the pathogenesis of poliomyelitis. Twenty-two new figures and four new colored plates have been added to the text.

Fractures and Fracture Treatment in Practice. By Kurt Colsen, M.D., tutor to the Department of Surgery and registrar to the Surgical Firm, University of the Witwatersrand, Johannesburg. Second edition, revised. 8th, cloth, 154 pp., with 163 illustrations. Johannesburg: Witwatersrand University Press, 1944. 12 shillings, 6 pence (plus 4 pence postage).

This small manual has been written for students and practitioners, and the text has been revised in keeping with advances in the subject since the first edition was published in 1942.

Arthritis and Allied Conditions. By Bernard I. Comroe, M.D., associate in medicine, University of Pennsylvania, and senior ward physician and chief of the Arthritis Clinic, Hospital of the University of Pennsylvania. Third edition, enlarged and thoroughly revised. 8th, cloth, 1359 pp., with 329 illustrations. Philadelphia: Lea and Febiger, 1944. \$12.00.

This new edition of a standard work has been enlarged by the addition of thirteen new chapters and more than a hundred new photographs. The work has been thoroughly revised, and extensive changes have been made in the text to bring the subject matter up to date. New chapters have been added on penicillin, psychogenic factors in rheumatic diseases, rheumatic manifestations of tropical diseases, Dupuytren's contracture, effect of climate on arthritis, occupational therapy, and differential diagnosis of rheumatoid arthritis. The chapter on massage has been enlarged, twenty photographs having been added. The sections on orthopedic care, roentgen diagnosis and therapy, and physical therapy have been expanded. Rheumatoid arthritis and degenerative joint disease are discussed in detail. The

etiology and treatment of painful shoulder and bursitis, as well as painful feet and backache, are thoroughly covered. The book has been written for the general practitioner, and emphasis has been placed on treatment.

Manual of Clinical Mycology. By Norman F. Conant, Ph.D., assistant professor of bacteriology, Duke University School of Medicine, and mycologist, Duke Hospital; Donald S. Martin, M.D., associate professor of bacteriology and associate in medicine, Duke University School of Medicine; David T. Smith, M.D., professor of bacteriology and associate professor of medicine, Duke University School of Medicine; Roger D. Baker, M.D., associate professor of pathology, in charge of surgical pathology, Duke University School of Medicine; and Jasper L. Callaway, M.D., assistant professor of medicine, in charge of dermatology and syphilology, Duke University School of Medicine. Prepared under the auspices of the Division of Medical Sciences, National Research Council. 12th, cloth, 348 pp., with 148 illustrations. Philadelphia and London: W. B. Saunders Company, 1944. \$3.50.

During the past ten years the authors have had the opportunity of studying all types of mycoses. They believe that it is necessary to consider mycotic disease in the differential diagnosis of practically every obscure infection.

The Biological Basis of Individuality. By Leo Loeb, M.D. 8th, cloth, 711 pp. Springfield, Illinois: Charles C Thomas, 1945. \$10.50.

In this book the attempt has been made to distinguish between two types of individuality: the mosaic, which represents the sum of the particular organ and tissue characteristics, thus determining structure, metabolism and motor and psychical activities, and the type that may be designated as the essential individuality, which is characterized by the presence of a chemical factor. These types of individuality are analyzed regarding their evolution and their biologic and physical manifestations. The work is based on a series of investigations on the transplantation of normal tissues and of tumor tissues that the author and his collaborators have carried out in the course of forty-eight years.

The Art of Resuscitation. By Paluel J. Flagg, M.D., visiting anesthetist, Manhattan Eye and Ear Hospital, and consulting anesthetist, St. Vincent's, The Woman's, Sea View, Jamaica, Mount Vernon, Flushing, Mary Immaculate, St. Mary's and Nassau hospitals. 8th, cloth, 453 pp., with 176 illustrations. New York: Reinhold Publishing Corporation, 1944. \$5.00.

This monograph on asphyxia and resuscitation is based on the author's twenty-five years of intimate experience with unconscious patients. The work begins with a chapter on history, which is followed by one on the principles of resuscitation and by others on asphyxia as a generic and as a specific problem. A large part is devoted to the discussion of the field of asphyxia and resuscitation, especially in the armed forces, in industry and in public health. Part six is on the co-ordination of gas therapy and includes an interesting table on the signs of death. Part seven discusses the instruction of technicians, asphyxia neonatorum and judicial electrocution. A bibliography of ten pages is appended to the book.

NOTICES

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JUNE 21

FRIDAY, JUNE 22

*9.00-10.00 a.m. Medical clinic. Isolation Amphitheater, Children's Hospital.

10.50 a.m. What Not to Do in Dermatology. Dr. Edward L. Frieniere. (Postgraduate clinic in dermatology and syphilology) Amphitheater, Mallory Building, Boston City Hospital.

SATURDAY, JUNE 23

*10.00 a.m.-12.00 m. Medical staff rounds. Peter Bent Brigham Hospital.

(Notices continued on page xvii)

of change as each case progressed, attempting to maintain emotional security for the patients in the face of limited resources. In cancer, one of the values in the service of the social worker who has gained the confidence of the patient and his family at the time of diagnosis and initial treatment lies in the fact that they can turn to her at any time as needs develop. Because of this, it is often true that,

admission and holding of patients who are untreatable and in the terminal stage.

One hundred and twenty-five patients stated that they would have accepted placement in a chronic hospital if it had been located near home. During the period of this study the only resources of this type available for immediate admission were chronic hospitals so far distant from Boston that the families

or months of the terminal period; nor does it show where he would have chosen to be could his wishes have been carried out. In the early terminal stage, when the patients were still physically somewhat independent, they usually wished to remain in familiar surroundings where their friends and families were accustomed to see and visit them. In the late terminal stage, however, when they were in bed and almost entirely dependent, they often needed and welcomed a placement where constant nursing care under medical supervision could be provided. It will be seen from Table 2 that of the patients included in this study, 21 died in chronic hospitals, 49 in general hospitals, 39 in nursing homes and 91 at home. But in comparing this table with Table 3, showing the attitude of patients toward hospitalization, one notes that only 31 of the 91 who died at home had wished to remain there throughout the terminal period. According to the figures, 169 patients would have preferred care in a general hospital had one been available. It is well known that hospitals have to discourage or refuse both

and friends of patients could visit them only occasionally, with much cost in time and money. Of the 21 patients who died in these hospitals, 13 were without close ties with family or friends, and therefore felt no objection to entering a hospital at some distance from their place of residence. It was believed that the other 8 entered only because of necessity for care and contrary to their own choice. The 39 who died in nursing homes were in no case more than fifteen miles from their own homes, and usually much nearer. The social workers who knew these patients believe that they would have preferred the security of a nearby general or chronic hospital

but seemed satisfied with this type of placement, which in most cases was found to be adequate. All the nursing homes used for the placement of these patients were visited and approved by an agent of the Greater Boston Community Council.

PROBLEMS INVOLVED IN HOME CARE

Of the 91 patients who remained at home, all except 8 had supervision from a local private physician or a district physician of the domiciliary-care

In each of these clinics the decision regarding the point at which a plan for terminal care should be worked out with the patient or his family rests with the physician who refers the situation to the medical social worker, with recommendations relating to the type and amount of care needed. Correlating the social situation with the medical recommendation, the social worker attempts to work out with the patient and family a plan that will take into consideration the medical and nursing needs, the adequacy of the home environment and the wishes of the patient and family, as well as the facilities that are available. Since it is difficult to prognosticate in terms of life expectancy and amount of care, several plans may be necessary for the patient as the disease progresses, additional attention is needed or the family situation changes.

The necessity of planning for terminal care carries with it a sense of finality. Families, bewildered, often find it difficult to accept the situation. Even when they understand it, their emotional reactions frequently block their ability to move ahead, so that they resist the making of plans. The suggestion of care elsewhere, particularly in a chronic hospital, stirs up implications and anxieties that they are unprepared to accept. Thus, the first reaction is to keep the patient at home even though the physical strain of caring for him and the emotional strain of watching him fail may precipitate physical and emotional breakdowns in the relatives.

The patient, having been advised to discuss a plan of care with the social worker, usually knows only that he may be ill over a long period of time. Thus, he is not always aware of the implications, and many a patient, not knowing the prognosis, prefers care at home secure among loved ones. As he becomes worse, the security of a medical institution assumes paramount importance and the patient, knowing only that he is ill and needs care, often seeks admission to the hospital where he has previously received treatment. A sick person finds it difficult to accept any interpretation regarding hospital policy or differentiation of general and chronic hospitals. "Doctor, why are you telling me to go to another hospital [or "to a nursing home"] when I am sick and need care?" is a frequent question, and a patient groping and searching for relief of pain feels only that the hospital is withdrawing help.

The available facilities necessarily influence the family's attitude and decision in relation to terminal care. Hospitals for the care of patients with chronic illness have lagged far behind other medical services, and little progress has been made in improving them. Massachusetts is widely known for the excellence of its cancer program in its state-aided clinics for education, consultation, diagnosis and treatment. The Commonwealth appreciates that the problem of terminal care merits humanitarian consideration but at present makes no tangible provision for it.

Available chronic hospitals have such long waiting lists that many patients expire while awaiting admission. The city and state facilities are such that it is frequently impossible to admit patients for bed care, and location makes access for visiting by relatives difficult. At one time the superior facilities of Pondville Hospital were available for these patients, but at present the bed capacity has been reduced and is limited in effect to treatable patients. Although many may feel a sense of stigma attached to chronic hospitals and a sense of futility at the suggestion of admission to one, such hospitals are acceptable to more patients than have actually been admitted.

The problems identified with cancer in turn influence facilities that will be available for care of patients in the terminal stage. Among these are odors associated with some forms of malignancy, incontinence, hematuria, colostomies, frequent changes of dressings and the need for repeated sedation. The proprietors of nursing homes claim that these patients need far more nursing care than do others, both because of their physical condition and because of their extreme fear and anxiety.

In Greater Boston there are approximately two hundred and fifty nursing homes varying greatly in facilities, physical equipment and personnel. Of these, only a small proportion are equipped or are willing to care for extremely sick people. Rates vary from a minimum of \$18 to \$40 and upward weekly, to which must be added the costs of medication and essential medical supervision — rates that to the average family become prohibitive.

With the limitations of hospital resources and of nursing-home care, there is little left for the dying patient except to remain at home and to get along as well as he can. The daily visits of the district nurse hardly meet the need of the patient who is taking opiates by injection for relief of pain. Even in prewar days, it was not possible to secure immediately the services of a physician. Some domiciliary medical service is provided by the Boston Dispensary and Massachusetts Memorial Hospitals for those who cannot afford private medical care, but their volume of work makes frequent visiting impossible.

GENERAL CONSIDERATIONS

Of the 200 patients studied, 88 patients were males and 112 were females. The largest age group was that between fifty and sixty, with 61 patients. The youngest patient was seven and the oldest over eighty (Table 1).

The length of terminal care averaged fifteen weeks and ranged from one week to two years. Since the physicians did not feel justified in expressing themselves as to life expectancy, the social workers, given the responsibility of advising with the patients and their families concerning possible plans for care, had to foresee and consider the need

of change as each case progressed, attempting to maintain emotional security for the patients in the face of limited resources. In cancer, one of the values in the service of the social worker who has gained the confidence of the patient and his family at the time of diagnosis and initial treatment lies in the fact that they can turn to her at any time as needs develop. Because of this, it is often true that,

but seemed satisfied with this type of placement, which in most cases was found to be adequate. All the nursing homes used for the placement of these patients were visited and approved by an agent of the Greater Boston Community Council.

PROBLEMS INVOLVED IN HOME CARE

Of the 91 patients who remained at home, all except 8 had supervision from a local private physician or a district physician of the domiciliary-care

services supplied in Boston. These physicians visited only when called, and it was difficult for them to give continuous supervision or even frequent emergency relief. Of the 200 patients studied, 101 received visits at home from private physicians and 19 from physicians of the district services. In considering this proportion it should be borne in mind that whereas only 91 patients died at home, nearly all the total group lived at home during some portion of the terminal-care period.

It was known that 47 of these 91 patients received no other nursing care than that of an unskilled relative or friend. Actually, the care they did receive from their families, many of whom had had no previous experience or training in the care of the sick, evidenced great effort and devotion. Although visiting nurses knew 51 of the patients who remained at home, they attended only occasionally and never more than once a day. Of the trained attendants caring for 19 patients, only a few remained in the home for a twenty-four-hour or even a twelve-hour day. In most cases these nurses came for a limited number of hours daily, thereby leaving the greater part of the day for the family to care for the patient.

EFFECT ON FAMILY LIFE

The lack of continuous professional medical and nursing care for the patients who remained at home undoubtedly gave rise to some feeling of insecurity and hardship to both patient and family, but was often overbalanced by the satisfaction of maintaining the unbroken family group with the security of home and the devotion of family. It is thought, however, that in some cases the wearing down of reserves of physical and nervous strength and the undesirable psychologic effect on young or unstable members of the family should be carefully weighed with the desire of the patient and his kin that he remain at home. The demands of the sick person are often paramount, with resulting disruption of normal family life, causing problems among children or even older members of the family group.

THE LONE PATIENT

The makeup of the household of these patients was carefully studied before plans were made. One of the most frequently challenging jobs for the medical social worker was planning for the hopelessly sick patient who lived, and had lived for many years, alone. At the time of referral 40 patients, or 20 per cent of the series, were living alone. Many of these had become so accustomed to independence that they found it difficult to join any family group. Usually in considering placement for a patient of this type the worker offered a hospital or nursing home and did not suggest entering a family group. When these patients could not pay for nursing-home care, however, their only actual resource was a chronic hospital distant from such

friends and relatives as they possessed. To return the sick person to his own family from whom he had long been separated, or to the family of kin among whom he had never lived, forced him to give up all the independence he had been able to attain and of which he was usually proud. For the patient who was already living in a family group, the immediate problem of planning was not so great. The lone patient had to face almost immediately his needs for the later period of care, whereas the patient already within a family could remain with it long enough to allow considerable deliberation in planning, with the patient himself a participant in the decision concerning plans.

COST OF CARE

Financial status looms large as a determining factor in plans for care. One hundred and seven patients were aided either by fully or partly free care while in hospital or by public or private relief agencies, or both, in securing chronic hospital or nursing-home care. The remaining 93 patients were

able even during long-continued illness to maintain themselves or to receive aid from families that covered their expenses, including payment for hospital care at ward rates (Table 4).

One hundred and twenty-three patients suffered cessation of income or financial difficulty because of the illness itself (Table 5). Seventy-seven families had sufficient income to provide for the patient. To be sure, it must be borne in mind that the period

of this study covers a time when there was a definite upsurge in employment and consequently incomes were higher than in the previous decade. The time element is often so long in these cases, however,

that it seems remarkable to find that in so large a number of cases long illness had not completely reduced financial resources.

HOME CARE

The attitude of the family toward the problem of terminal care of the cancer patient (Table 6) was made the subject of direct inquiry. Here entered

small children or of the noisy social life of other adults. — accessibility of medical care, visits by a supervising physician and services of a visiting nurse were also considered. In each case the reiterated wishes of the patient and family were weighed against the apparent result in terms of human adjustment and relations. Table 7 shows the judgment of the four social workers in summary. indi-

TABLE 6. *Attitude of Families Toward Home Care.*

a number of factors. The close relation between patient and family was often the controlling element, sweeping away all other considerations. Lack of physical equipment or space sometimes forced a decision. Inability to provide for financial support in some cases became a decisive difficulty. Changes in the patient's need and in the family situation necessitated a change in plan. One hundred and fifty-three of the families were willing to give care in the early stage of the terminal periods, while the patient was still up and about and able to look out for himself. One hundred and five wished to continue to do this in the later stage, when the patient was helpless and required constant care. On the other hand, 40 thought best to have the patient placed outside the home even in the earlier period. In judging the suitability of the home the social

cating as unknown those cases in which the findings were insufficient for basing an opinion on them.

There were unsuitable homes in 62 cases (31 per cent) during the early terminal stage, and in 113 (57 per cent) during the late terminal period. This evidences the need of adequate and acceptable provision for cancer patients beyond that now available.

CONCLUSIONS

In summary, we believe that the individualization of each patient is of paramount importance. Close family ties, when these exist, should be encouraged by close co-operation between the relatives and the social worker in making plans. Community resources — that is, medical and nursing care, financial aid, housekeeping service and so forth —

TABLE 7. *Suitability of the Patient's Home for Care during the Early and Late Stages of Terminal Care.*

HOSPITAL	EARLY TERMINAL PERIOD			LATE TERMINAL PERIOD

worker took into consideration the size and equipment of the home itself, the kind and amount of service available to the patient, the relations within the group and the effect of the patient's illness on the family group, as well as his own feelings and desires. A room to himself—light, airy and equipped with a comfortable bed — and bathroom facilities were considered essential. Continuous and intelligent care, including preparation of meals, was needed within the home, with sufficient funds to buy both food and necessities for nursing care. A peaceful and serene atmosphere with reasonable quiet, — not too much difficulty in the restraint of

should be used to the fullest extent in making possible home care for at least part of the terminal period when this seems feasible. In each case the needs of the family should also be given consideration.

The following needs are submitted as basic to the carrying through of adequate terminal care for the cancer patient: competent medical supervision uninterrupted throughout the course; good nursing service to supplement the supervision of the physician; the services of a medical social worker continuously available for aid and consultation to the physician, patient and family; chronic-hospital facilities sufficient to meet the need of patients de-

siring hospital care, with location within easy reach of the patients — ideally such a hospital should be closely associated geographically with a hospital having a tumor clinic so as to have available the clinical and laboratory facilities and experience of such an institution.

To accomplish these things means the enlargement of present services and the creation of new chronic

hospital resources, with provision for such service and facilities in large part free or at low cost. It is hoped that such provision can soon be made. Every known resource for diagnosis and early treatment is already available. It is felt with increasing urgency that in this dread disease one should, with consistent excellence of care, see through to termination those patients who cannot be cured.

THE CARE OF THE PATIENT*

EGON E. KATTWINKEL, M.D.†

WEST NEWTON, MASSACHUSETTS

MY EXCUSE for presenting a nonscientific paper at this scientific meeting is that I believe that a periodic consideration of this important subject is good for all of us. Among the lectures in my student days that are high lighted, none stand out more sharply than the Peabody Lectures, which were titled "The Care of the Patient." Since everyday practice has demonstrated the great importance of this phase of medical practice, I have often wondered why medical schools allot so little time to its consideration. As I remember it, there were only two or three lectures each year on the subject. I suppose the faculty feels that the art of our profession is learned only through example and practice. Perhaps this is correct, although I sometimes question it when I consider the quality and quantity of the literature on the subject and the time that the leaders of the profession have spent on its consideration.

Medicine as it is practiced today is less conducive to the development of the art than it was in the days before the advent of scientific medicine. In our grandfathers' time the doctor's most potent weapon was his personality and his art. Without the specifics of today, he banked heavily on the self-limited character of the majority of illnesses; and through his art he maintained the patient's morale until Nature had effected the cure. He drove his horse and buggy leisurely from call to call, having time to reflect on the mysteries of man's complex psychic make-up. To keep up with medical knowledge required less time than it does today. He could spend more time with each patient, and he grew to know his patients intimately. He was father confessor as well as healer. Today, with chemotherapy, penicillin, shock treatment, liver extract, insulin and the host of other effective therapies, the disease itself has pushed its way to the center of the stage and the patient as a person tends too often to be neglected. The modern mode of travel requires the driver's complete attention, and reflection on his

patient's personal problems results, at least in a traffic ticket. With the advent of the war, the load on the doctor is immensely increased; his time is precious, and the finer intangible aspects of practice suffer. The medical man in the armed forces falls under the influence of regimentation, and routine procedure is the rule unless the medical officer is thoroughly imbued with the importance of his art. Strangely enough, never before has the community so urgently needed the thoughtful care of the true follower of Hippocrates — he who practices the spirit of the oath as well as its letter. Think a moment of the people who crowd your offices. How few of them need the specifics in your bag and how many of them need your understanding heart! The strain of war with its separations, worries and bewilderments increases many-fold the incidence of functional disorders. Chronic fatigue, functional indigestion, tension headache, neurocirculatory asthenia, the irritable colon and the many forms of depression, to mention only a few, are the disorders that consume more than half your working hours and interrupt your much-needed sleep. Although it is true that this curve of incidence is particularly high during these war years, it will not drop appreciably when peace returns, because other problems will add fuel to the fire, such as the readjustment of the serviceman to civilian life, the reassimilation of the wounded into the community, the ever-increasing pace of our civilization and, most important of all, the growing importance of the problems of geriatrics. It is inevitable that chemotherapy, penicillin and the advances in surgery should swell the ranks of the old-age group of patients, and at no time of life is the need for the practice of the art of medicine so great as in old age. Unfortunately, as senescence advances and the ability to varnish daily living with the veneer of self-control is weakened, man's underlying selfishness and pettiness rise to the surface and he becomes a burden to himself and those about him. The person who grows old gracefully is the exception, although this observation may in part be due to the fact that we, as physicians, are likelier to see that group who

*Presented to the Newton Hospital Staff on January 22, 1945.

†Visiting physician, Newton Hospital, and preceptor, Tufts College Medical School.

do a poor job of aging, since those responsible for them turn to us for help with the innumerable symptoms of their charges, the more fortunate group coming to our attention only during acute illnesses.

The growing importance of this whole problem is reflected in the current medical literature. New books are appearing on psychosomatic medicine and geriatrics urging men well established in practice to study the problem and develop a technic of handling it. Some have even proposed the development of a specialty of geriatrics, arguing that soon its importance will outweigh that of pediatrics. Be that as it may, the doctor to whom the practice of the art of his profession is as natural as breathing will find little trouble in solving these growing problems in his own practice.

I have been impressed in observing the students under my care, with a real deficiency in their knowledge of what constitutes the art of medicine. They are imbued with a hot devotion to the science of their profession, showing keen interest in the technic of diagnosis, with special emphasis on laboratory and other technical aids, but when questioned about the social history of the patient or the minute details of treatment on which the practice of the care of the patient so often depends, they answer in generalities that indicate a lack of an appreciation of the importance of such knowledge. Their feeling doubtless is that this is the province of the Social Service Department. They will find that when they leave the security of the walls of the hospital or of the Army they will have to be their own social service department or else be content with a meager practice — that is, if there is any degree of competition when they arrive at that golden day.

Unfortunately today, because of the shortage of physicians, the public is willing to put up with treatment minus the art as they put up with mediocre services at every turn. The doctor does not have to sell himself to his patients as he did — to be sure, usually unconsciously — in the past. It has been said that any doctor can build up a large practice if he possesses a good bedside manner, but that does not indicate how badly he practices it. This temporary upset in the balance of supply and demand removes one incentive toward the study and practice of the care of the patient, and the fact that most medical-school graduates are going into the armed forces removes another, at least in the minds of many. Too many fourth-year students believe erroneously that military medicine is cold and efficient and spurns any thought of the finer sensibilities with which the art of medicine is concerned. I have had occasion to talk to wounded men of the Marine Corps who have returned from the South Pacific, and their glowing tribute to the medical officers who treated them stressed the humaneness with which they were handled even above the technical skill which was used. As one of them

stated, "He was my best friend — and I mean friend, not doctor." The need for the art of medicine is universal.

One other obstacle is that it takes more time and energy to practice this kind of medicine. Osler has said the man most to be pitied is the forty-call-a-day man. It is well-nigh humanly impossible adequately to care for the patient on that schedule. Corners must be cut to get through the day, and the more difficult features of practice — those relating to the understanding of the patient as a person — suffer. Such a man easily sinks to the level of a pill dispenser or at best a mere diagnostician. Even the man with a less crowded day avoids the exacting demands of the care of his patients. The best of us are fundamentally lazy, as someone has said, and we try to avoid that which taxes our time and maximum ingenuity. It is easier to get in and get out of the sickroom quickly, dodging the endless questions, the answers to which constitute in part the adequate care of the patient. It is, however, true that there are some patients, especially those in the lonely, psychoneurotic group whose stereotyped questions waste the doctor's time, their solution adding nothing to the real care of the patient except as it acts as a pleasant interlude in the boring hours of the sickroom. It takes a real artist to handle such patients satisfactorily. Osler is said to have been a master in like situations. He would come breezing into the sickroom with a cheery greeting, size up the patient's real needs quickly, and then proceed to divert his or her attention from the unimportant complaints and grumblings by an apt anecdote and leave with specific instructions to the nurse or family, having wasted little time but having effectively instituted therapy necessary for the care of the patient. The long list of carefully written out questions were unanswered, but somehow the patient's mind was at rest and he was satisfied.

I need not argue the crying need of the patient's care, especially today, any further. It may, however, be worth while to consider briefly how the recent medical graduate can go about acquiring the nearly automatic technic that spells success in this care. I certainly cannot set myself up as an authority in this field. I am too young in practice, and the art grows slowly and too often never. I can only refer the neophyte to the literature and urge him to aim at the goal that the many masters in the art have set in the past.

In the first place, it is wise for him to be a student of man himself. This he may do by reading about, observing and talking with his fellow man. Provocative books such as Alexis Carrel's *Man the Unknown*, Fosdick's *On Being a Real Person* and Zinsser's *As I Remember Him* are helpful. An interest, limited as it may be, in his community life demonstrates how the men outside the profession think, talk and live. A close nonmedical friend or

two will serve as a stimulant to argument, especially in front of an open fire, and will help crystallize ideas previously shrouded in foggy generalities. A study of religion will help the neophyte to understand that vital force which is so important in many lives.

In the second place, he should acquaint himself with the literature of those men who have pondered the subject, notably William Osler, Francis W. Peabody, L. Eugene Emerson and Alexander Gibson. I know of no man of medicine who had a fuller, busier life than Osler, yet all his biographers agree that he never lost the human touch. His patient, as a person, always came first in importance before diagnosis, treatment and case discussion. At one time he was walking through the operating room of a Philadelphia hospital when an old man, a pauper, was about to have an ingrowing nail cut out. The old man was frightened nearly to death. When Osler grasped the situation he amazed the students by his rage when he said: "Don't you dare touch that old man. You can do him no good, and you know it. Take him back to the ward."

Osler was constantly reminding his students that the patient is not a piece of experimental laboratory apparatus. He once said: "The practice of medicine is an art, based on science. . . . It has not reached, perhaps never will, the dignity of a complete science with exact laws like astronomy and engineering." A letter written when he was only twenty-five to the father of a young Englishman dying of smallpox under his care in Canada is a masterful illustration of his understanding of human beings. The letter follows:

My dear Sir:

No doubt before this, the sorrowful intelligence of your son's death has reached you, and now when the first shock has perhaps to a slight extent passed away, some further particulars of his illness may be satisfactory. On the evening of Thursday the 22nd and on the following day I discovered unmistakable evidence of the nature of the disease. On Saturday in consultation with Dr. Howard, the leading practitioner of the city, his removal to the smallpox hospital was decided upon. I secured a private ward and took him there in the evening. Even at this date was seen the serious nature of the case and I sent for Mr. Wood at his request. At 10 p.m. I found him with your son, and we left him tolerably comfortable for the night. He was easier Sunday morning, but well aware of his dangerous state. He spoke to me of his home and his mother and asked me to read the 43d Chapter of Isaiah, which she had marked in his Bible. I spent the greater part of the evening talking and reading with him. Mr. Wood called in three or four times in the day and at 9:30 p.m. I found him there again. Mr. Norman had also been in just previously. He was still sensible and requested to see Dr. Howard again in consultation with Dr. Simpson, the attending physician in the smallpox hospital. After 11 o'clock he began to sink rapidly and asked me not to leave him. He did not speak much but turned round at intervals to see if I were still by him. About 12 o'clock I heard him muttering some prayers but could not catch distinctly what they were—"God the Father, Son and Spirit." Shortly after this he turned round and held out his hand, which I took, and he said quite plainly, "Oh, thanks!" These were the last words the poor fellow spoke. From 12:30 he was unconscious, and at 1:25 passed away without a groan or a struggle. As the son of a clergyman and knowing well what it is to be a "stranger in a strange

land," I performed the last office of Christian friendliness I could and read the commendatory prayers at his departure.

Such, my dear Sir, as briefly as I can give them are the facts relating to your son's death.

The little book, *Doctor and Patient*, by Francis W. Peabody,² director of the Thorndike Memorial Laboratory at the Boston City Hospital from 1921 to 1927, is filled with good advice on the subject we are discussing. The following quotation is a practical illustration taken from this book.

Suppose, for instance, you find conclusive evidence that his [the patient's] symptoms are due to organic disease: say, to a gastric ulcer. As soon as you face the problem of laying out his regimen you find that it is one thing to write an examination paper on the treatment of gastric ulcer and quite another thing to treat John Smith, who happens to have a gastric ulcer. You want to begin by giving him rest in bed and a special diet for eight weeks. Rest means both nervous and physical rest. Can he get it best at home or in the hospital? What are the conditions at home? If you keep him in the hospital, it is probably good for him to see certain people, and bad for him to see others. He has business problems that must be considered. What kind of compromise can you make on them? How about the financial implications of eight weeks in bed followed by a period of convalescence? Is it, on the whole, wiser to try a strict regimen for a shorter period, and, if he does not improve, take up the question of operation sooner than is in general advisable? These and many similar problems arise in the course of the treatment of almost every patient, and they have to be looked at, not from the abstract point of view of the treatment of the disease, but from the concrete point of view of the care of the individual.

Peabody stresses among other things the great lasting harm that can be done a patient by a careless snap diagnosis of a serious condition that later proves to be incorrect. This is especially true of the diagnosis of heart disease. To tell a man that he has heart disease and at the same time caution him "not to worry about it" is playing with dynamite. Every day the patient looks at the obituary pages and sees mention of men in the prime of life dying suddenly of coronary thrombosis. He cannot appreciate the fact that the prognosis in neurocirculatory asthenia or other functional cardiac disorder is quite different from that in coronary-artery disease. Heart disease is a black label to him. Twenty minutes of careful explanation with this man may mean the avoidance of years of invalidism, at least psychologic if not actual physical invalidism.

Not long ago a young patient of mine got up late, rushed through his breakfast, ran a mile for his train and, while riding into town, experienced palpitation, sweating, weakness and slight pain in the left elbow. When he arrived at work a physician was called who listened to his story, listened to his heart, told him that he had had a heart attack and sent him home by taxi. He had never seen the patient before. He failed to find out that he had had a similar attack ten years previously while playing tennis after a heavy meal, that he had not had the slightest suspicion of anginal symptoms since then, in spite of the fact that he was a strenuous tennis player, skier and bowler, and that he had lost

sleep for the last three weeks because his wife was in the hospital and the household duties had fallen on him. The physician did not even take the patient's blood pressure. If he suspected a coronary attack,—although the history was much more suggestive of paroxysmal tachycardia,—he should, if he had the care of his patient as his first consideration, have suggested further observation, reassurance and an electrocardiogram. When all the evidence had been collected a sane, intelligent talk would have saved years of worry and fear. Now, in spite of a negative electrocardiogram, excellent coronary reserve and a disappearance of all symptoms, it is likely that the words "heart attack" may haunt this patient for years to come. About a year ago the same physician treated an eighty-year-old patient of mine in an institution for the aged for an ulcer of the face for a month in spite of the development of a pearly border. He probably thought that she did not have long to live anyhow, but following x-ray treatment the lesion healed, and she may still have several years of living in comfort. In neither case did this physician consider the mental health and happiness of his patient.

Too much laboratory investigation and prolonged hospitalization are often not in the best interests of the patient. In the anxious patient with a functional disease, they make him suspect that the doctor is unable to locate the trouble and that it must therefore be serious and deep-seated. In the older patient, the laboratory investigations use up the patient's strength and deplete his pocketbook. At best they only satisfy the ultimate scientific curiosity of the doctor and seldom add information that improves the quality of treatment. The best interests of the patient are usually served by a rapid thorough workup, including only definitely indicated laboratory studies. For example, what is the need of a urea-clearance test, phenolsulfonephthalein test and even a nonprotein nitrogen determination if an eighty-year-old patient has a specific gravity in the urine of 1.020 without appreciable albumin or formed elements in the sediment?

There is also the danger of meddlesome medicine. Withholding from the old patient his few comforts such as tobacco, alcohol, coffee and certain items of diet just because this is theoretically sound from the point of view of the disease may at best add only a few weeks of unhappy life. Alfred Worcester³ has

emphasized this point in his excellent book, *The Care of the Aged, the Dying and the Dead*. We must also question carefully the heroic use of chemotherapy, penicillin and oxygen in trying to close the door to that friend of the aged Osler has spoken of, pneumonia.

Finally, the student who sincerely wants to perfect his technic in the care of the patient will find numerous examples exhibited by the older men in the profession. One of the great advantages of the old preceptor method of medical education was the close association of teacher and student. The latter acquired the fine art of medicine by example, a method of learning that is not readily available from the lecture platform and at bedside teaching rounds. The best teachers, however, exhibit it even in the largest clinics. As always in education, one learns that to which one's senses are attuned and open.

In general our ranks are made up too largely of men overbalanced at one end of the scale or the other. At one end are mostly the younger men stressing the science of medicine and bewildered by the details of the practical handling of the patient. At the other end are the busy older practitioners who in lieu of ready knowledge of the newer therapies and intricacies of diagnosis lean heavily on their knowledge of the patient as a person, giving comfort but missing the satisfactions that come with the thorough understanding of the disease process. The medical student's goal should be a proper balancing of these two cornerstones of medical practice. The relatively rare men who have achieved this goal are the envy of their brother physicians and form the backbone of the profession.

I have tried in this short paper to plead once more for the patient as an individual. For most of you such a plea is superfluous, but if a few of the younger graduates have been stirred into a renewed interest in this important subject, I shall not feel that your time or mine has been wasted. As Peabody² stated, "The secret of the care of the patient is in caring for the patient."

MEDICAL PROGRESS

SKIN TESTS IN BACTERIAL AND VIRAL DISEASES*

LEWIS W. KANE, M.D.†

BOSTON

IN RECENT years the clinician has employed the products of a variety of bacteria, viruses, protozoa and fungi as antigens in performing skin tests to demonstrate a previous infection with a given pathogenic agent. In numerous cases these tests have proved to be of great value in the differential diagnosis of many infectious diseases, and have been of inestimable aid in determining susceptibility to or immunity against a given infectious agent. In addition, a skin test has been employed to give valuable prognostic information as well as to guide serum therapy in pneumococcal pneumonia. It is the purpose of this paper to review critically certain dermal tests employed in bacterial and viral diseases and to define their usefulness to the clinician. No attempt will be made to discuss the lesser known skin tests, such as the Mallein reaction for glanders. The fundamental mechanism that governs skin reactions in general will be briefly reviewed as a background for the proper understanding of such tests and as a guide to their interpretation.

HISTORICAL BACKGROUND

Nearly one hundred and fifty years ago Jenner¹ clearly recorded that persons who had been vaccinated or who had undergone a smallpox infection reacted locally to the inoculation of cowpox with a more rapid reaction than did those who had no previous contact with the virus. This observation was disregarded until one hundred years later, when Koch^{2, 3} published his observations on the changed dermal sensitivity following tuberculous infections. The tuberculin test was a direct result of this study.

In 1907, von Pirquet⁴ reinvestigated the problem of vaccinal hypersensitivity and suggested that the term "allergy"—that is, altered reactivity—be used to express the changed reaction capacity of the body resulting from infection or contact with a foreign protein. On the basis of this study and a previous one on serum sickness, von Pirquet tried to explain certain clinical features of other infections on an allergic basis. It was an obvious step in the study of these infections to apply dead bacteria or their products to a scarified area of the skin by the same technic as was used for the vaccine virus. As a result, the von Pirquet technic for applying tuberculin was devised. This simple and safe cutaneous

test stimulated efforts to demonstrate allergy in other infectious diseases, as a result of which a number of valuable skin tests have been developed.

FUNDAMENTAL MECHANISMS GOVERNING SKIN REACTIONS

It became manifest from the start that there are two distinct types of dermal hypersensitivity. One type corresponds to protein anaphylaxis and can be produced by the injection of any protein, bacterial or otherwise. In this type, circulating antibodies can be demonstrated. The intradermal injection of the test substance results in its union with its specific antibody at the site of inoculation. Such an antigen-antibody combination may be irritating and lead to a histamine-like reaction. Approximately fifteen minutes after injection a wheal with a zone of erythema appears, which usually disappears in a few hours. In the interpretation of this type of reaction it is important to keep in mind that the antigen is a bland substance and produces dermal irritation only after union with its antibody.

The second type of hypersensitivity is a true tissue allergy in which no circulating antibodies can be demonstrated. This type of sensitivity can be established experimentally only as a result of infection or the injection of whole dead bacteria. The dermal reaction so produced is always of the delayed type and leads to a more profound injury of the tissues. There is no reaction for a number of hours following injection; then induration, pain and redness occur, reaching a maximum intensity only after twenty-four to forty-eight hours. In the more intense reactions a central area of necrosis may be present. The tuberculin test is the paradigm for this type of hypersensitivity.

Although the reactions obtained with the Schick and Dick tests are delayed in type, they are dependent on an entirely different mechanism from those due to tissue sensitivity. It should be clearly borne in mind that, unlike the other skin tests described in this review, the Schick and Dick reactions depend on the inherent toxic properties of the materials used for testing. Their injurious effects are exerted in persons who possess no specific neutralizing antitoxin. Hence, a positive Dick or Schick test indicates susceptibility in contrast to a positive reaction of the tuberculin type, which indicates previous infection with the pathogenic agent that may or may not have led to the emergence of resistance.

*From the Departments of Bacteriology and Immunology and of Hygiene, Harvard Medical School.

†Assistant in bacteriology and immunology and physician, Department of Hygiene, Harvard Medical School.

The hypersensitivity established in a number of diseases may last for years or even a lifetime. Consequently the demonstration of dermal allergy to a given bacterial or viral agent, although it signifies a previous contact with a given infectious agent, does not necessarily mean that this agent is responsible for the disease immediately under consideration.

SKIN TESTS EMPLOYING BACTERIA AND THEIR PRODUCTS AS ANTIGENS

Tuberculin Test

It has been amply demonstrated that the most satisfactory method for tuberculin testing is the intradermal route (Mantoux).⁵ The two tuberculin preparations now in use are O. T. (old tuberculin), introduced by Koch,^{2, 3} and P. P. D. (purified protein derivative), isolated by Seibert.^{6, 7} O. T. is a crude product that besides active skin-reacting principle also contains various other constituents of the tubercle bacillus. The only disadvantage of this product is the variation in the amount of skin-reacting substance in different preparations, depending on the culture medium used and the strain of tubercle bacillus employed. This objection has been overcome, however, by standardizing O. T. in tuberculous guinea pigs against a standard P. P. D. obtained from the National Institute of Health. The initial test dose of O. T. ordinarily used for intracutaneous testing contains 0.01 mg. of O. T. in a volume of 0.1 cc. (1:10,000).^{*} To avoid systemic reactions in persons suspected of having active tuberculosis, it is well to start with a dose of 0.001 mg. (1:100,000). If no reaction is produced with the initial dose, the concentration can be increased tenfold until 1.0 mg. has been injected. If this is negative, the succeeding dosage should be 5.0 mg. and 10 mg.[†] The usual procedure is to inject 0.01 mg. and to retest all negative reactors with 1.0 mg. With 1.0 mg. as the final dose a small proportion who fail to react may be called negative, although they might react to 10 mg. No case should be regarded as genuinely negative unless there has been a failure to react to 10 mg. of O. T.^{5, 8}

A positive reaction is one that shows edema and redness of varying degree after forty-eight hours. Positive reactions should be arbitrarily classified +, ++, +++ or ++++, depending on the extent of the edema. A reaction showing some redness with definite edema more than 5 mm. in diameter but not exceeding 10 mm. is recorded as a + reaction. A ++ reaction is characterized by an area of redness and edema measuring from 10 to 20 mm. in diameter. A +++ reaction is characterized by marked redness and edema exceeding 20 mm. in diameter. A ++++ reaction consists of

marked redness and edema and an area of necrosis. If there is no edema at the site of injection, even if slight redness is present, the reaction should be recorded as negative.

Since dilute solutions of O. T. and P. P. D. deteriorate on standing, only freshly prepared solutions should be used. If dilutions are stored at refrigerator temperature when not in actual use, deterioration is less rapid, but such solutions should not be used after storage for longer than three or four days.⁹

It became obvious from Zinsser's¹⁰ and Mueller's¹¹ work that the skin-reacting substance in tuberculin is associated with a protein or nucleoprotein fraction that can be separated from other serologically active compounds. Subsequently Seibert^{6, 7} succeeded in isolating from O. T. a proteose or polypeptide (P. P. D.) that is responsible for the dermal reaction given by O. T. As supplied commercially at present, the first test dose consists of 0.00002 mg., and the second dose, for use when the reaction to the first is negative, of 0.005 mg. In terms of O. T. the first test dose of P. P. D. is equivalent to 0.01 mg. of O. T. and the second is somewhat stronger than 1 mg. of O. T.¹² The second-strength skin reaction must be read carefully, since Long and Seibert⁹ and others¹³ have stressed the fact that non-specific reactions are frequently seen with this strength. The positive reactions are graded as described for O. T.

In 1933, Grozin¹⁴ made the observation that if a strip of adhesive plaster previously treated with tuberculin is applied to the unbroken skin, or if the skin is moistened with a drop of tuberculin and covered with adhesive, a susceptible person shows within twenty-four to forty-eight hours an inflammatory area of reaction limited to the surface covered by the adhesive plaster. He called this test the tuberculin patch test. Since then a number of variations have been used, the most usual one being filter paper impregnated with old tuberculin and held in close apposition to the skin with adhesive tape for forty-eight hours, at which time the tape is removed.^{15, 16} Readings are made forty-eight hours after the removal of the tape. If the reaction is positive, an area of inflammation studded with tiny papules and vesicles appears, limited to the part in contact with the tuberculin. The ease of this technic aroused immediate interest. In 1939, Vollmer and Goldberger¹⁶ showed a 100 per cent conformity between the tuberculin patch test and the Mantoux test using first strength P. P. D. or 0.01 to 1.0 mg. of O. T. In Smith, Faulkner and Cordi's¹⁷ study only 6 of 223 negative reactors to the patch test turned out to be positive by the Mantoux test after a comparatively strong dose of O. T. These authors conclude that their cases responded to the patch test in nearly the same degree as to 0.1 mg. of O. T. Hence, it appears that the patch test is a suitable screening test and would be highly efficient if followed when negative by an intradermal inoculation

^{*}In preparing dilutions of O. T., each cubic centimeter of undiluted O. T. is assumed to contain 1000 mg. of tuberculin. Thus, a 1:10,000 dilution of O. T. contains 0.01 mg. of O. T. in 0.1 cc.

[†]With these higher doses a control injection of the medium alone should be used to rule out nonspecific reactions.

with 1.0 to 10.0 mg. of O. T. or second strength P. P. D.

It has been amply demonstrated that a positive tuberculin skin test means past or present infection with the tubercle bacillus.⁵ The question arises concerning the frequency with which a negative test may occur in persons who have previously been infected. Lloyd and MacPherson¹⁸ reported that of 303 healthy London children who reacted to 1.0 mg. of O.T., 2 per cent became negative to that dose two years later. Nelson, Mitchell and Brown¹⁹ were able to find calcification by chest films in 43 per cent of 27 persons who were negative to the P. P. D. dose equivalent to 1.0 mg. of O. T. Dahlstrom²⁰ reported that 11.1 per cent of 2490 persons who were tuberculin positive to 1.0 mg. of O. T. or the equivalent P. P. D. became negative within five to fifteen years. Seventy per cent of those who became negative were originally weak reactors. Thus, it has been recently demonstrated that tuberculin sensitivity may be lost unless stimulated periodically by reinfection with the tubercle bacillus. Perhaps this fact is not yet clearly recognized by many clinicians.

The state of present knowledge does not permit a definite statement whether a positive tuberculin test is an asset or a liability. There have been a number of publications²¹⁻²⁵ that indicate that a positive test is a definite index of relative immunity. On the other hand, there have been reports in which the incidence of the development of tuberculosis has been higher in tuberculin-positive groups than in tuberculin-negative groups.²⁶⁻²⁸ Still other publications have failed to indicate that there is any difference in the incidence of pulmonary tuberculosis between negative and positive reactors.²⁹⁻³¹ At the Harvard Medical School in the last fifteen years the number of cases of tuberculosis have been almost evenly divided between positive and negative reactors.³²

The clinician is most interested in whether the symptoms presenting in a given case are the result of an acid-fast infection. In most cases it is only the negative result that is of diagnostic aid, since, except in the terminal stages of the disease, a genuinely and persistently negative reaction to 10 mg. of O. T., with rare exception, rules out progressive infection.^{5, 8, 33} Although dehydration, intercurrent infection, early stages of pleural and peritoneal effusion and the terminal stages of tuberculous infection are not infrequently accompanied by a temporary absence or depression of reactivity, sensitivity is not depressed to such a degree during uncomplicated tuberculosis that 10.0 mg. of O. T. fails to provoke a reaction.

Brucella Skin Test

The development of dermal sensitivity following brucellosis was first investigated in 1918 by Fleischner and Meyer.³⁴ Sufficient data have since been accu-

mulated to show that dermal sensitivity to *Brucella* antigens occurs regularly enough following brucellosis so that its demonstration can be used as a diagnostic procedure.³⁵⁻³⁹ It is apparently much more sensitive and is present in a much higher percentage of infected persons than are serum agglutinins. Huddleson⁴⁰ has shown that if the agglutination test alone had been used as a diagnostic procedure, it would have failed to detect 86.9 per cent of 845 cases of brucellosis that gave positive dermal reactions.

Two antigens are at present in wide use to elicit skin reactivity: a heat-killed suspension of *Brucella* organisms in saline solution, and brucellergen, a so-called "nucleoprotein" from *Brucella* organisms, developed by Huddleson and his colleagues.⁴⁰ Both these antigens appear to be effective in eliciting dermal sensitivity. The whole organism, however, is likelier to produce local sloughs and systemic reactions.^{41, 42} Since there is no evidence that the whole organism gives better results, brucellergen appears to be the antigen of choice.

The bulk of evidence indicates that a positive skin test means past contact with any one of the *Brucella* organisms. Gould and Huddleson⁴³ regard the intradermal test with brucellergen as an extremely reliable indicator of *Brucella* infection. They believe that if the test is negative, brucellosis can usually be ruled out. In only 1 out of 925 cases negative to the intradermal test were the agglutination and opsonic tests indicative of past infection. On the other hand, it has been shown by others that some persons proved by the isolation of the organisms to have brucellosis have had negative skin reactions.^{35, 44, 45} The incidence of a negative reaction in the presence of chronic disease has been reported as varying from 5.5⁴⁶ to 39 per cent.⁴⁷ Thus, whereas a positive test denotes previous contact with *Brucella* organisms, a negative test does not necessarily rule out previous infection.

Since the skin hypersensitivity lasts for many years, a positive test does not necessarily mean present active disease but may indicate a past contact with the organisms. The status of a patient with a positive skin test can be established only by determining the phagocytic activity of the leukocytes in the presence of *Brucella* organisms.⁴⁰

The skin test must not be performed before blood has been drawn for the agglutination or opsonocytaphagic determinations, because the introduction of the antigen may stimulate the production of opsonins and agglutinins. This stimulation has been observed with both brucellergen⁴⁸ and whole organisms.^{49, 50}

The brucellergen test is performed by injecting 0.1 cc. of a standardized solution intradermally on the volar surface of the forearm. The test is read at forty-eight hours, and the reaction is considered positive if, in addition to an area of redness, there is also edema or induration that measures at least

5 mm. in diameter. If whole organisms are used, the reaction should be observed on the fourth and seventh days.

Chancroid Skin Test (*Ito-Reenstierna Test*)

In 1913, Ito,⁵¹ using a vaccine prepared from a culture of *Haemophilus ducreyi*, was able to demonstrate the development of dermal allergy in chancroidal infection. The diagnostic value of this test was confirmed by Reenstierna,⁵² and it has come to be known as the Ito-Reenstierna test. For years a skin-test vaccine (Dmelcos vaccine) has been prepared commercially in France and used extensively in Europe and Canada; this preparation has never been available in this country owing to public-health regulations. Because of this and the difficulty American workers experienced in growing the etiologic agent, pioneer work in this country on the value of the intradermal test was done in 1935 by Cole and Levin⁵³ with pus obtained from unbroken buboes. These authors stressed the need for further investigation on the growth requirements of *H. ducreyi*. Within two years methods for growing the organism were published.^{54, 55} Vaccines prepared from these cultured organisms have subsequently been shown to be highly satisfactory for use as antigens in eliciting dermal hypersensitivity⁵⁶⁻⁵⁸ and are now commercially available.

It is generally accepted that the Ito-Reenstierna test is of definite aid in the differential diagnosis of the venereal bubo since the buboes of syphilis, gonorrhea, chancroid and lymphogranuloma inguinale and the pseudobubo of granuloma inguinale frequently simulate one another. In the experience of most investigators the test is highly reliable. Kornblith and his co-workers⁵⁹ have found the test to be positive in 95 per cent of 93 proved cases of chancroid. Cole and Levin⁵³ have demonstrated negative tests in lymphogranuloma inguinale, primary and secondary syphilis, gonorrhea and granuloma inguinale, the diseases likeliest to be confused with chancroid clinically.

There is some disagreement in the literature concerning when the skin test becomes positive following infection. Reports have varied from six to ten days⁶⁰ to five weeks.⁶¹ Greenblatt and Sanderson⁵⁸ have obtained positive reactions regularly from the twentieth day onward in experimentally induced infections. A positive test is uniformly obtained by the time the buboes appear.⁶²

Since dermal allergy may last for years, possibly a lifetime, a positive reaction commits one to the diagnosis of chancroid only when the Frei test, Wassermann test and dark-field examination as well as biopsies and smears for granuloma inguinale, are negative. It is difficult to reconcile the favorable reports in the literature with the statement in Circular Letter No. 74 from the Office of the Surgeon General⁶³ that the intradermal test is not recommended for the diagnosis of chancroid.

The test is performed by injecting 0.1 cc. of the vaccine intradermally into the volar surface of the forearm. The reaction is positive if an area of induration measuring at least 8 mm. and an area of erythema 14 mm. in diameter are present forty-eight hours after injection. Nonspecific reactions may appear in twenty-four hours, but they usually disappear within forty-eight hours. The local reaction may last for weeks.

Whooping Cough Skin Test

The use of the skin test to determine immunity or susceptibility to whooping cough must be considered as still in the experimental stage. A skin test should not be considered satisfactory unless the results correlate with the incidence of clinical and bacteriologically proved cases after subsequent exposure. As yet this has not been done in the case of the whooping cough skin test.

Haemophilus pertussis contains at least two antigens — a so-called "agglutinin" and a thermolabile toxin — that are capable of eliciting dermal reactions. In the past the skin test as a method for determining susceptibility was unsatisfactory because the preparations used contained both these antigens. By means of supersonic vibration, Florsdorf and his associates⁶⁴ have been able to separate the agglutinin from the toxic components. This material has been used in an endeavor to establish immunity or susceptibility by means of the response obtained on intradermal inoculation.⁶⁵⁻⁶⁷ The antigen is injected intradermally, and readings are made in half an hour and twenty-four hours. In immune persons two types of response have been obtained — an immediate wheal-like reaction and a delayed or tuberculin type of reaction. Some immune persons show both these reactions, whereas others show only one of them. Felton and Florsdorf⁶⁶ have shown that there is a close correlation between the agglutination titer of the blood serum (which is thought to be an index of immunity^{64, 68}) and the positive skin test. In only one case did they find the agglutinating titer high and the skin test negative.

Florsdorf, Felton, Bondi and McGuiness⁶⁷ have recently summarized their experience using the agglutinin as an antigen in performing the whooping cough skin test. Of 122 babies from six to fourteen months of age with no history of whooping cough, only 1 gave a false-positive test. Eleven per cent of those with a positive history and 8 per cent of the vaccinated group, however, were negative. It is possible that some of the children with positive histories were infected with *Bacillus parapertussis* and hence a positive skin reaction did not result.⁶⁴ Although the results obtained with the detoxified antigen are encouraging, more work will obviously have to be done before it can be accepted that a positive test means immunity.

As outlined above, there are two types of dermal allergy. One depends on the presence of circulating antibodies, whereas the other is a true tissue sensitivity. In the former type a response is obtained fifteen minutes after inoculation of the antigen and usually disappears in three hours, whereas in the latter the reaction is always of the delayed type. Since both types of reaction may be elicited in the whooping cough skin test, it seems probable that the material used may contain two antigens — one reacting with the circulating antibody and the other acting directly on the tissue cells.

In 1940, Streat et al⁶⁹ described a skin test with purified pertussis toxin, which he believed might be used to indicate susceptibility or immunity. An immune response is obtained only in those who have recovered from the disease or those immunized with the toxoid. It is interesting that a susceptible reaction is found in those who have been vaccinated with whole Phase I organisms. Silverthorne, Fraser and Brown⁷⁰ have recently repeated Streat's work, however, and have shown that the toxin does not distinguish between those who have had the disease and those who are presumably susceptible.

Tularemia Skin Test

The early work on the diagnostic skin test in tularemia was done using whole organisms killed with formaldehyde.⁷¹ The sensitivity that develops following tularemia is apparently of a very high degree, and a few patients have suffered alarming constitutional reactions following the use of this skin-test material.⁷¹ Because of these reactions, Foshay⁷² prepared a detoxified antigen by treating the organisms with nitrous acid. This antigen is apparently bland and does not produce constitutional reactions. The skin test with this material appears to be highly specific and is not positive in patients with brucellosis whose serums are able to agglutinate *Pasteurella tularensis*. The reaction becomes positive within the first week of the disease and is probably lifelong in duration. Since the agglutination test does not become positive until the second week of the disease, a positive skin test is of great value in the early diagnosis of tularemia. Friedewald and Hunt⁷³ have skin-tested 32 proved cases of tularemia with Foshay's antigen and found the dermal reaction positive in all. They have clearly shown that the test becomes positive within the first week of the disease. These same authors skin tested a large number of patients with numerous clinical conditions and found no false-positive reactions.

The skin test is performed by injecting 0.05 cc. of the antigen intracutaneously on the volar surface of the forearm. A positive test is a delayed tuberculin-like reaction consisting of erythema and induration. Nonspecific reactions appear early and usually fade rapidly after forty-eight hours, whereas a specific reaction generally persists for a week or

longer. Unlike the antigens used in the Brucella skin test, the antigen used in the diagnosis of tularemia does not stimulate to any marked degree the production of agglutinins.

To make a diagnosis of tularemia before the development of dermal hypersensitivity, Foshay has described a test^{74, 75} in which antitularense goat or horse serum is injected intradermally to detect circulating bacterial antigen such as might be present early in the disease. In all the dermal tests previously described in this paper, antigen is injected to detect circulating or fixed antibody. In this test antibody is injected to demonstrate antigen. Presumably this type of test should be positive early in the infection. Four one hundredths cubic centimeter of a 1:10 dilution of serum is injected intradermally, accompanied by the same volume of diluted normal serum as a control. In most cases positive reactions appear almost immediately and consist of a wheal and areola of erythema. This test has been reported as being positive as early as eight hours after the initial chill. Friedewald and Hunt⁷³ believe that if the antiserum test shows a definitely positive reaction and the control serum is negative, a diagnosis of tularemia can be made with reasonable certainty. In their experience, however, the controls were positive in a high percentage of cases, so that they were able to diagnose only a third of the cases by this method. The same authors⁷³ used convalescent serums from cases of tularemia and found that the reactions obtained in normal patients and those with tularemia were variable and unreliable. The usefulness of this test is obviously limited because of the positive skin reactions obtained with the control serum.

Francis Test

In 1929, Tillet and Francis⁷⁶ showed that specific capsular pneumococcal polysaccharides when injected intradermally into patients convalescent from pneumonia caused an immediate wheal and erythema that appeared in ten to twenty minutes and faded in one to two hours. The polysaccharide causing the reaction was found to be always homologous in type with the pneumococcus causing the pneumonia. The patient's capacity to react became manifest coincident with or shortly before recovery from the infection and was invariably associated with the presence of type-specific antibodies in the blood. In 1930, Francis and Tillet⁷⁷ extended their observation and reported that recovery from Type 1 pneumonia was associated with the development of a positive skin reaction to Type 1 polysaccharide. In every case in which the skin test became positive the patient recovered. In Finland and Sutcliffe's⁷⁸ experience, however, only half the Type 1 and two thirds of the Type 2 and 3 patients who recovered gave a positive reaction. In 1933, Francis⁷⁹ recommended a skin test with specific capsular poly-

saccharide of the pneumococcus as a guide to serum therapy. He believed that the skin test was a valuable aid to serum therapy and of definite prognostic aid. When the test was negative, he believed that further serum therapy was indicated. The value of this test as a guide to serum therapy has been repeatedly confirmed.⁸⁰⁻⁸²

The development of a positive Francis reaction is due to the local union of polysaccharide and its specific antibody in the skin. A relatively large amount of circulating antibody must be present to produce the dermal reaction.⁸² During the course of severe pneumonia the skin may lose its ability to react owing to the general toxemia, and this probably explains the negative reactions observed in patients who die of pneumonia despite the presence of appreciable amounts of circulating antibodies. In Wood's⁸² series of serum-treated cases, in every case in which a crisis occurred the Francis skin reaction became positive several hours before or during the fall of temperature. No patient who failed to develop a positive skin reaction survived the pneumonia. Wood believed that the test could also be employed as an aid in the early diagnosis of the complications of pneumonia. In every case in which fever persisted in the presence of a positive skin reaction, pleurisy with effusion, empyema, meningitis or endocarditis was subsequently demonstrated.

As in any skin test, there are false-positive reactions to the Francis test. MacLeod, Hoagland and Beeson⁸¹ have found 13 per cent false positives and Wood⁸² 9 per cent. Obviously, because of these false-positive reactions the Francis test cannot be used as an index of immunity unless the reaction is negative when it is first employed. When it is observed to change from negative to positive, recovery seems assured unless complications are present. A persistently negative reaction means a less favorable prognosis. It goes without saying that the etiologic organism must be typed so that the homologous polysaccharide can be employed.

Skin Tests for Influenza-Bacillus Infections

In 1939, Dingle and Fothergill⁸³ isolated a specific carbohydrate from the Type B influenza bacillus. Using this material as in the Francis test, Dingle and Seidman⁸⁴ were able to obtain a reversal of the test from negative to positive in 5 cases of influenza-bacillus meningitis treated with rabbit antiserum. The test failed to be reversed in cases treated with horse antiserum. This may be related to the fact that precipitins are less readily produced in horse serum than in rabbit serum. There were no false-positive reactors among the controls. Although this test is based on firm bacteriologic principles, much more work will have to be done before it can be recommended.

(To be concluded)

CASE 31251

PRESENTATION OF CASE

A fifty-six-year-old Greek woman was admitted to the hospital complaining of chills and fever and a mass in the left upper quadrant.

Three years before admission the patient entered another hospital because of a painful mass in the left upper quadrant and easy bruising of six months' duration. She had tired easily and had lost about 20 pounds in weight during the preceding year. She also complained of episodes of red urine and a bloody vaginal discharge. Physical examination at that time revealed a small wizened woman who showed evidence of considerable weight loss. There were petechiae on the palate, and a tourniquet test was positive. Several quite large purpuric areas were seen on the extremities, especially on the legs. The liver was felt by one observer two to three fingerbreadths below the right costal margin. The spleen extended to 10 cm. below the left costal margin. Hinton and Wassermann tests were negative. The urine was normal. The red-cell count was 3,500,000, with 10.5 gm. of hemoglobin and a hematocrit of 30 per cent; the white-cell count was 2100, with 55 per cent neutrophils, of which 10 per cent were band forms, and 42 per cent lymphocytes. The red cells showed mild anisocytosis, and the platelets were markedly reduced, numbering 59,000 per cubic millimeter. A gastric analysis showed no free acid in the fasting specimen and 17 units of total acid after histamine. The icteric index was normal. X-ray examination of the long bones was negative. During the twenty-three hospital days her temperature was 98.6°F., except for a rhythmic rise to about 100°F. every third day. She was given four x-ray treatments of 65 r each over the splenic area, with no change in the size of the spleen. Five days after x-ray treatment she was discharged unimproved.

The patient had taken quinine irregularly once or twice a week for about a year, with some relief. During the five months before admission to this hospital she experienced regular attacks of chills and fever, occurring every seventy-two hours between 6:00 and 7:00 p.m. A backache in the upper

lumbar region was present at all times of the day and had persisted since the onset of the present illness. For approximately two months before admission her appetite had been poor, and she had some exertional dyspnea and orthopnea and a slight cough.

The patient was born in Greece and had lived there for eighteen years. She came to the United States thirty-eight years previously and had worked in a cotton mill in Massachusetts. She was married at the age of twenty-six and had had two full-term babies, both delivered by cesarean section. One infant was stillborn, and the other died at fourteen days. Until the present illness she had been in good health. She remembered no infections or other diseases.

Physical examination revealed an emaciated, chronically ill-appearing woman in no distress but for occasional stabs of pain in the left upper quadrant and epigastrium, which were induced by moving about. The skin was warm and dry and had a slight yellow tinge. The peripheral lymph nodes were not remarkable. There were many varicose veins over the legs and thighs, and fairly prominent superficial veins over the lower chest and abdomen. There were no ecchymoses. There was slight pitting edema of the legs. The left pupil measured 2 mm. in diameter and was fixed and slightly irregular. The neck veins pulsated in the erect and supine positions. The lung fields were clear and hyperresonant. The left heart border was at the mid-clavicular line. A Grade 2 blowing systolic murmur was heard over the entire precordium and was loudest at the left sternal border in the fourth interspace. The spleen was firm, smooth and mobile; it extended into the left lower quadrant and a small distance across the midline at the level of the umbilicus. The liver edge was sharp and extended three fingerbreadths below the costal margin. There was no ascites. Vaginal and rectal examinations were negative. The tendon reflexes of the lower extremities were absent.

The temperature was 99.6°F., the pulse 90, and the respirations 20. The blood pressure was 140 systolic, 70 diastolic.

On admission the blood contained 3,200,000 red cells, with 7 gm. of hemoglobin and a hematocrit of 26 per cent. The white-cell count was 2400, with 61 per cent neutrophils and 35 per cent lymphocytes. A reticulocyte count was 1.2 per cent. The platelets were slightly reduced in number. The bleeding time, clotting time and clot retraction were normal. The urine was straw-colored, with a specific gravity of 1.018, and gave a +++ test for albumin; the sediment contained an occasional red cell and hyaline cast. A catheterized specimen showed no growth on culture. A stool was dark, formed and guaiac negative. The sedimentation rate and a van den Bergh test were normal. The serum nonprotein nitrogen was 36 mg. per 100 cc., and the protein

*On leave of absence.

5.58 gm., the albumin-globulin ratio being 1.71. The phosphorus was 4.5 mg. per 100 cc., and the alkaline phosphatase 2.9 Bodansky units. A Hinton test and a spinal fluid Wassermann test were negative. A cephalin flocculation test was +++ in forty-eight hours, and the prothrombin time was 21 seconds (normal, 18 to 20 seconds). A bromsulfalein test showed 30 per cent retention forty-five minutes after the injection of 5 mg. per kilogram. An electrocardiogram was normal. A phenolsulfonphthalein test showed 55 per cent excretion in two hours, and the urine concentrated readily to a specific gravity of 1.020. A lumbar puncture yielded normal findings.

X-ray examinations of the chest and abdomen showed the left diaphragm to be elevated, with the heart in a transverse position. The aorta was tortuous, with some calcification in the arch. A large mass extended down from the left upper quadrant to overlie the sacrum and the left iliac wing, displacing the colon downward and the stomach to the right. The left kidney outline was seen through the mass. A gastrointestinal series was negative. No esophageal varices were seen.

At 5:30 p.m. on the second hospital day the patient had a severe chill. At 7:00 p.m., the temperature rapidly rose to a peak of 106°F., and during the following six hours gradually returned to normal. The pulse and respiratory curves closely followed the temperature curve. Four similar episodes of chills and fever occurred during the following two weeks at regular seventy-two-hour intervals. Blood cultures taken during the chills and during the peak of the fever showed no growth, and blood smears taken at the same times showed no parasites. Because the spleen was firm and presumably fibrotic, a splenic puncture was deemed safe and was performed.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM DAMESHEK*: Chills, fever and a mass in the left upper quadrant in a Greek woman might conceivably mean malaria. So we immediately have a rather plausible diagnosis to start with. Of course there are other possibilities that I shall introduce as I go along.

There were petechiae on the palate, and a tourniquet test was positive. These findings usually indicate a platelet deficiency and remind me of what I like to call "the dental plate test." If you have a patient with thrombopenia, due to whatever cause, and if he happens to have dental plates, when the upper plate is taken out, you will find petechiae on the palate, due to the suction of the dental plate. It is a fairly good test. The chances are that this woman had a low platelet count.

The liver was felt two or three fingerbreadths below the right costal margin, and the spleen ex-

tended a handbreadth below the left costal margin. That signifies a rather sizable organ. So she had hepatosplenomegaly and purpura, probably thrombopenic in type.

The Hinton and Wassermann tests were negative. Apparently we do not have to be concerned about syphilis.

There were 3,500,000 red cells, with 10.5 gm. of hemoglobin. In other words, she had a reduction in hemoglobin slightly out of proportion to the reduction in red-cell count. To digress from the case for a moment, let me say a word about the color index. This is calculated readily by taking the percentage of hemoglobin and dividing by the first two figures of the red-cell count. If the hemoglobin is 50 per cent, and the red count 5,000,000, the index is 0.5. If one is dealing with grams of hemoglobin, as we now are, we multiply the figure for grams by 3 and divide by the first two figures of the red count. At the time of admission to the other hospital, it was $10.5 \times 3 \div 35$, or 0.9, which indicates some degree of hypochromia, or hypochromic anemia.

Whenever I see a Greek or Italian woman with hypochromic anemia I wonder about Mediterranean anemia of the target-oval-cell type, a mild form of Cooley's anemia. The mean corpuscular volume was $30 \times 10 \div 3.5$, or 86, which is either less than normal or approximately normal. There was a definite leukopenia, the white-cell count being only 2100, with 55 per cent polymorphonuclears. Although the lymphocytic proportion was increased, it was really only relatively increased. Thus, although they numbered 42 per cent of 2100, this is only 20 per cent of 4000 white cells. So she really had no absolute increase, in fact the lymphocytes were somewhat diminished. The granulocytes were 55 per cent of 2000, which is a definite granulocytopenia. The normal granulocyte proportion is 70 per cent of 7000 to 8000, and here it was 55 per cent of 2000, or only 1200 to 1300 in absolute numbers. So she had leukopenia, granulopenia and anemia. The platelets were reduced, numbering 59,000. She had then what I like to call "pancytopenia," a reduction in all the cellular elements in the blood, including the red cells, white cells, granulocytes and platelets.

Pancytopenia may be due to various conditions involving the marrow: aplasia, hyperplasia, leukemia and sarcomatous infiltration. Pancytopenia is also frequently associated with splenomegaly, the bone-marrow being either normal or hypercellular. There may be total pancytopenia, or anemia, leukopenia or thrombopenia may dominate the clinical picture. In this patient, the thrombocytopenia was most evident and the patient had extensive mucous membrane bleeding.

X-ray studies of the bones were negative which helps to exclude Mediterranean anemia, myeloid sclerosis, Gaucher's disease and sarcoma.

*Professor of clinical medicine, Tufts College Medical School.

"During the twenty-three hospital days the temperature was 98.6°F., except for a rhythmic rise to about 100°F. every third day." This I think is the leading theme in this case. It is repeated throughout the history. This one-two-three rhythm may be said to represent the ominous rumbling in a developing "symphonic" situation, which we shall find out more about as we read the history.

The fact that the spleen did not change in size after x-ray treatment helps to exclude lymphosarcoma of the spleen, Hodgkin's disease, leukemia and related conditions.

We come next to the second phase of this woman's illness. She had taken quinine irregularly once or twice a week for about a year after she left the hospital "with some relief." That statement may or may not be of diagnostic value.

The exertional dyspnea, orthopnea and cough might indicate a pulmonary infection or the beginning of heart failure at the age of fifty-six, with anemia and chronic illness.

We find that the patient was born in Greece and lived there for eighteen years. We are not sure whether she had an infectious disease when she was in Greece, and we do not know whether she came from the northern or southern part.

DR. BENJAMIN CASTLEMAN: Dr. Cotzias, can you enlighten us about that?

DR. GEORGE C. COTZIAS: She came from southern Greece.

DR. DAMESHEK: That may mean something, since malaria is more frequent in the southern section.

Anyone is apt to have pain with a large spleen from whatever cause, either infectious or otherwise. It is apt to become infarcted from time to time, and a perisplenitis often develops. Pain on motion is frequently present in these cases.

The varicose veins and the prominent veins over the chest and abdomen suggest a delay in portal circulation with some collateral circulation.

What significance the systolic murmur has, I cannot say. She might have had it before or she might have developed it recently. It might have had something to do with the anemia or arteriosclerosis, or both.

I suppose that albuminuria in a woman of fifty-six who has been ill and has some degree of arteriosclerosis of the kidneys is of no significance.

A catheter specimen of urine was cultured and yielded no growth. That is an important test for urinary infection and helps to rule out colon-bacillus infection.

The patient on entry to this hospital had a red-cell count of 3,200,000, with 7 gm. of hemoglobin. So multiplying the grams of hemoglobin by 3 and dividing by the first two figures of the red count, we get the figure 0.65, or a hypochromic, low color-index anemia, and $26 \times 10 \div 3.2$ gives a mean corpuscular volume that is diminished, a hypochromic, microcytic anemia. She had leukopenia, granulo-

cytopenia of an absolute variety, with no abnormal cells. There is no statement about monocytes. Since monocytes are frequently miscalled lymphocytes, perhaps there were monocytes included in the lymphocytic count. A monocytosis might be expected in malaria. The reticulocyte count was normal. She had lost the marked thrombocytopenia and the abnormal clot retraction that she had on admission to the hospital three years previously.

I suppose that the van den Bergh was a quantitative test for bilirubin and was within normal limits, indicating that she did not have jaundice, which helps to exclude the question of hemolytic disease. One always has to consider this possibility with an enlarged spleen, but if the bilirubin is normal one can almost always exclude it. The albumin-globulin ratio was essentially normal, showing no hyperglobulinemia and no reversal of the albumin-globulin ratio. This tends to rule out such conditions as multiple myeloma and Boeck's sarcoid. The bromsulfalein excretion was definitely delayed, indicating some degree of hepatic insufficiency.

"No esophageal varices were seen." That is a finding that helps to rule out cirrhosis, at least of a marked degree.

"Because the spleen was firm and presumably fibrotic a splenic puncture was performed." That apparently is the end of the story. We do not know whether the patient recovered after this procedure or whether she died.

In summary, this was a woman who came from Greece to this country a long time ago and had apparently been well since. Three years previously she went to a hospital, essentially for a hemorrhagic condition. At that time she showed an outstanding thrombocytopenia with the clinical evidence of purpura, so that we have to say that she had thrombocytopenic purpura. This condition may be idiopathic, or it may be due to many causes, such as leukemic or aplastic bone marrow or various types of splenic disease, which I like to call "hypersplenism." This may result in either leukopenia, thrombopenia or anemia, or in all three together. In some cases of hypersplenism, there is a marked degree of thrombocytopenic purpura. I therefore explain the first episode three years previously on the basis of an enlarged hyperactive spleen. We do not know the cause of the enlarged spleen at that time. It may have been due to infection, but she left the hospital and took quinine for a while, with perhaps some response.

Five months before admission to this hospital she had regularly recurring chills and fever every seventy-two hours. We also know that she had had it to some degree three years previously. The only disease that I know of that causes recurring fever and chills every seventy-two hours at exactly the same time of day for a period of many months is malaria of the quartan type. It is true that other conditions associated with splenomegaly cause

fever. One of the most frequent types that we have to contend with is that due to lymphoma, Hodgkin's disease and atypical leukemia. If this patient had had an irregular fever coming at various times or had had a relapsing fever of the Pel-Ebstein variety, we should have concluded that she had one of these conditions. Some cases of brucellosis, or undulant fever, have the same type of fever chart. But this woman did not have an irregular type of fever or relapsing fever. She had a regular one coming on at the same time of evening, between 6:00 and 7:00 p.m.

Infections other than malaria have to be considered, such as tuberculosis and subacute bacterial endocarditis. The heart murmur was systolic in type but the blood cultures were negative, and furthermore, subacute bacterial endocarditis does not give this type of fever. It is true that we have to consider atypical leukemia and myeloid metaplasia, but she had no myelocytes and no nucleated red cells. The outstanding feature of this case is certainly this rhythmic fever; in a Greek woman with a big spleen I do not believe that it can be anything but malaria.

Quartan malaria is the slowest of the malarial infections and is the one that takes longest to incubate. It may be present for a number of years and then vanish. It may isolate itself in the reticulo-endothelial system, notably the spleen. Splenic enlargement may occur, and the parasites may never be demonstrated in the blood. I do not know how the tests were done; probably with extreme care. I do not know whether they made thick smears or whether a sternal puncture was done. Dr. Castleman let me look at a blood smear, but it was entirely normal. It was not a thick preparation. If one has a case of suspected malaria in which the blood smears appear normal one of several things can be done. A sternal puncture, which is simpler than a splenic puncture, and without danger, or an adrenalin injection may be done. The latter is a favorite maneuver in the Latin-American countries and in France. Or one can do a splenic puncture. Whether the splenic puncture in this case showed malaria, I do not know. To my mind the present case was dominated by rhythmic fever, which makes malaria likely.

DR. CASTLEMAN: Dr. Richardson, have you any suggestions?

DR. WYMAN RICHARDSON: I never saw this patient, but I feel the same way about it that Dr. Dameshek does.

CLINICAL DIAGNOSIS

Quartan malaria.

DR. DAMESHEK'S DIAGNOSIS

Quartan malaria.

ANATOMICAL DIAGNOSIS

Quartan malaria.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The intern and resident staff and the visiting men all looked at the smears, thick and thin, and were unable to find any malarial parasites. The material that I received from the spleen was composed almost entirely of histiocytes. I looked carefully for parasites and was unable to find any. There were no hemosiderin granules, which one usually finds in a malarial spleen. Dr. Volweiler took the slides to the Department of Tropical Medicine at the Harvard Medical School, and Dr. Geiman kindly examined them. We shall hear from him now.

DR. Q. M. GEIMAN: Dr. Volweiler brought films of the splenic puncture to me for examination and told me the history of the case. The history immediately interested me greatly because of the number of cases of so-called "transfusion malaria" that have occurred at various hospitals in Boston. Blood films from the patients are brought to us for examination from time to time. Although we find positive films in these patients, the donors of the blood seldom give a history of recent clinical malaria and no malaria parasites are found.

Since this patient was born in Greece and was having periodic chills and fever every seventy-two hours, quartan malaria seemed to be the first possibility, at least in my experience; the patient could have obtained the infection a number of years previously. The films from the splenic puncture were examined, and parasites were not found at that time. I might say that the films were examined for ten minutes, which is in excess of the usual five minutes for the study of such films.

I asked Dr. Volweiler to make films, both thin and thick, at intervals during a period of several days with the hope that we might catch some of the parasites during their asexual cycle in the peripheral blood. These films were brought to me, and the thick film taken at 4:00 p.m. on February 6 yielded one parasite, which was an unmistakable half-grown schizont, with typical cytoplasm, chromatin and pigment. With that one parasite, I went back through the splenic film, examining it from one end to the other, and fortunately another parasite, a segmenter, was found that determined the exact species, *Plasmodium malariae*. The examination of additional blood films, made at intervals, produced a total of ten unmistakable and two doubtful parasites. That result of prolonged microscopical study gives you an idea of the scarcity of malaria parasites in this patient. It is outstanding that such a low concentration of parasites could be responsible for clinical malaria.

I thought that you might be interested in a case reported by Shute,* which emphasizes the same point. The case seen by Shute and this case demonstrate that the parasite of quartan malaria can persist in a patient for long periods of time and eventually give rise to a relapse of malaria. At the Children's Hospital, Boston, one of the donors of blood for a case of transfusion malaria had been in this country thirty-seven years without ever having clinical malaria. What the basis for this latency is we do not know, but new information is being accumulated which suggests that there are tissue stages of the parasite in the spleen or other reticulo-endothelial tissue that are the reservoir of organisms for this small dribble of parasites into the circulating blood and the origin of parasites that cause relapsing malaria.

DR. CASTLEMAN: I might add that the patient has received Atabrin and is now free from chills and fever.

CASE 31252

PRESENTATION OF CASE

A fifty-eight-year-old man was admitted to the hospital because of chills, fever and vomiting.

Twenty-two months before admission a pilonidal sinus, which during the previous twenty-five years had frequently opened and discharged pus, again began to drain. A few days later he noticed, while at work, that the right leg was becoming heavy and lifeless. By the end of the day the entire right leg was paralyzed without obvious sensory disturbance. He was admitted to a community hospital. Motor function and strength slowly returned, but the patient was unable to stand and he remained incontinent of urine and feces. He was then transferred to this hospital, where he remained for an additional seven weeks, during which time he learned to walk slowly with a cane and his bladder function improved so that he could retain his urine for about an hour. Infarction of the lower spinal cord was thought to be the likeliest diagnosis. During the entire hospital period, after the first four days, the temperature, pulse and respirations were normal. The urine gave a +++ test for albumin constantly, the specific gravity was 1.010 to 1.018 and the sediment almost always contained innumerable white cells. The red-cell count was 3,000,000, and the white-cell count 6000 to 8000. A month after discharge he began to notice slight swelling of the ankles in the evening, but examination of the heart was negative and he had no dyspnea, orthopnea, precordial pain or palpitation. His walking slowly improved, but he continued to have incontinence. Eighteen months after discharge he developed an ulcer on the sole of the left heel, which slowly be-

came larger and drained seropurulent fluid. About a month later, or approximately one month before this admission, he began to notice malaise and progressive weakness. The legs swelled more than usual, and the ulcer of the left heel became worse. On the day before admission he had several shaking chills, fever and drenching sweats. He vomited and for a brief period became quite dyspneic.

He had had pneumonia and empyema eighteen years before entry.

Physical examination revealed an obese, pale, febrile, perspiring man. He moved himself about in bed with little help from his legs, which were quite weak. He was surrounded by a strong uriferous odor. A deep penetrating ulcer on the left heel drained thin serous fluid. The tongue was coated and fiery red but not smooth. The neck was not stiff. Examination of the chest suggested emphysema, and moist crackling rales were heard in the right axillary line. The heart was enlarged to 10 cm. to the left of the midsternal line. The sounds were distant. There was an occasional, irregular beat. A soft, rumbling, apical murmur lasted throughout systole and early diastole. The aortic and pulmonic second sounds were equal. The liver extended 2 cm. below the right costal margin. There was no costovertebral-angle tenderness. There was minimal pitting edema of the left leg. Examination of the rectum revealed a loose anal sphincter. The terminal portion of the penis was macerated, swollen and chronically infected. The right leg was weaker than the left, and the tendon reflexes of the right knee and ankle were stronger than those on the left. There was a right Babinski. There was decreased pain and temperature response over the left leg, and diminished vibration sense of the right leg. These changes were seen on the trunk and shaded off to normal about two segments below the nipples. The remainder of the neurologic examination was negative.

The temperature was 99.0°F., the pulse 90, and the respirations 20. The blood pressure was 93 systolic, 50 diastolic.

The urine was cloudy, acid in reaction, with a specific gravity of 1.014, and gave a ++ test for albumin. Uncentrifuged urine contained an occasional red cell, 50 white cells, an occasional hyaline cast and many bacteria per high-power field. The blood showed a red-cell count of 3,000,000, with 9.5 gm. of hemoglobin, and a white-cell count of 23,000, with 92 per cent neutrophils, mostly band forms. The red cells and platelets appeared normal. The stool was normal and guaiac negative. The Hinton test was negative.

X-ray examinations of the chest on the first and third days showed no active disease in the lungs. The heart was prominent and rounded in the region of the left ventricle. An electrocardiogram showed a normal rhythm of 120, marked variation in the form of the P waves in the amplitude of the QRS

*Shute, P. G. Relapse of quartan fever after twelve and twenty-one years. *Lancet* 2:146, 1944.

complexes, PR intervals ranging from 0.16 to 0.23 second, slight left-axis deviation, upright T_1 and T_2 , low upright T waves in Leads 3 and CF_2 and upright T waves in Leads CF_4 and CF_6 . An occasional ventricular complex showed aberrant conduction. The serum nonprotein nitrogen was 42 mg. per 100 cc., the protein 4.2 gm., and the chloride 98 milliequiv. per liter. The fasting blood sugar was 111 mg. per 100 cc. Repeated blood cultures on the first and third hospital days showed a Type 13 pneumococcus.

Small doses of sulfathiazole were given on the first three days. On the third day intravenous penicillin was begun, and 84,000 to 270,000 units were given daily through the eleventh day. On the sixth day a heavy dose of sulfadiazine was begun and continued through the eighteenth day.

The temperature spiked irregularly once or twice daily as high as 103 to 106°F., not becoming normal or subnormal until the fourth day. The following three days showed a continued fever above 102°F. On the eighth day the temperature, pulse and respiration became normal. Blood cultures taken on the fifth day and after were negative. Because of the unexplained bacteremia associated with mental clouding a lumbar puncture was performed on the fifth day. The initial pressure was normal; the fluid was imperfectly transparent and contained 392 cells per cubic millimeter, almost all of which were polymorphonuclear cells. No bacteria were seen by smears, but the culture grew a beta-hemolytic streptococcus. There were no signs or symptoms of meningitis. Twenty-four thousand units of penicillin were instilled intrathecally. On the following day the spinal-fluid cell count had risen to 2750, with about 80 per cent polymorphonuclear cells. The culture was negative. Thirty to fifty thousand units of penicillin were injected intrathecally in two injections daily for the next five days, during which time there was a gradual reversion of the polymorphonuclear-lymphocyte ratio; the cells finally disappeared on the eleventh hospital day. The urine continued to show an occasional red cell and 5 to 50 white cells per high-power field. Despite eight whole-blood transfusions the red-cell count fell to 2,800,000. The white-cell count after the third day remained about 10,000, with approximately 75 per cent neutrophils.

On the nineteenth hospital day examination of the chest showed dullness in the region of the right lower lobe. Rales were heard over the right scapular region. The heart was enlarged, to a maximum of 11 cm. to the left of the midsternum. A systolic apical thrill was easily felt. The sounds were regular but of poor quality. A harsh Grade 4 systolic murmur was heard all over the lower precordial region, maximal between the apex and lower end of the sternum and best heard near the latter. A mid-diastolic sound was present at the apex. The liver was palpable 5 cm. below the right costal margin.

The tip of the spleen was firm and palpable 2 cm. below the left costal margin. There was slight pitting edema of the sacrum. An electrocardiogram taken at that time showed normal rhythm at 100, a PR interval of 0.23 second, slight left-axis deviation, a low upright T_1 , normal T_2 and T_3 , a low upright T wave in Lead CF_2 , a notched T wave in Lead CF_4 and a normal T wave in Lead CF_6 , with sagging ST segments in Lead CF_6 . An x-ray examination of the left os calcis showed some new-bone formation, with evidence of sequestration. The ulcer had a slight discharge at that time. An intravenous pyelogram was normal. The bladder appeared to be small and quite irregular in outline, especially at the roof, where there was a suggestion of a bilateral filling defect. A gastrointestinal series and barium enema were negative. The spleen appeared enlarged. A repeat x-ray film of the chest showed the heart to be enlarged without a characteristic configuration. There was apparently a considerable amount of fluid in the right pleural cavity, and a small amount in the left. The pulmonary markings were increased.

During the seventh and tenth weeks there were sudden chills followed by fever that spiked irregularly to 104°F. for periods of one to four days and then returned to normal. During these periods the blood cultures were negative. Shortly after the chill in the tenth week a periurethral abscess was found. This drained spontaneously, with remission of the fever. A suprapubic cystostomy was performed. Cultures of the abscess yielded colon bacilli and a nonhemolytic streptococcus. The non-protein nitrogen was 25 mg. per 100 cc., the phosphorus 3.7 mg., the alkaline phosphatase 6.3 units and the acid phosphatase 0.8 units. A Congo red test was negative. Cultures from the draining left heel showed an anaerobic *Staphylococcus albus*. Despite vigorous treatment with iron, liver, diet and transfusions, the anemia progressed, and by the eleventh week the red-cell count had fallen to 2,100,000.

During the twelfth week the suprapubic cystostomy wound failed to heal and reopened spontaneously. Shortly thereafter the temperature rose to 104°F.; the patient became comatose and expired two days later.

DIFFERENTIAL DIAGNOSIS

DR. REED HARWOOD: I should like to ask first what the urine cultures showed on the two admissions.

DR. BENJAMIN CASTLEMAN: *Staph. albus* on the first admission, and colon bacilli on the second.

DR. HARWOOD: The neurologic findings represent a typical example of Brown-Séquard syndrome, with the lesion on the right side in the region of the seventh dorsal segment. The patient had weakness and diminished vibration sense on the side of the lesion, and diminished pain and temperature sense

on the contralateral side, owing to the fact that the fibers carrying pain and temperature sense cross immediately in the cord and ascend in the ventral and lateral spinothalamic tracts of the other side. The fact that the neurologic lesion improved in the succeeding two years suggests that the diagnosis of infarct was the correct one.

The record states that hemolytic streptococci were recovered in one culture of the spinal fluid. Considering the large doses of penicillin and sulfadiazine that the patient had received and the fact that a Type 13 pneumococcus was found several times in the blood cultures, I am inclined to believe that the streptococcus in the spinal-fluid culture was a contaminant.

We must now consider the nature of this patient's heart disease. We are told that the heart was normal on the first admission. I think that we must accept this statement and thereby exclude congenital heart disease and old rheumatic valvular disease. There is no mention of arteriosclerosis or hypertension, so that heart disease due to either of these conditions seems unlikely. The electrocardiogram presents no diagnostic abnormality. The changing PR interval suggests some interference with conduction in the auriculoventricular bundle. Dr. White, would you care to comment on that?

DR. PAUL D. WHITE: With a rate of 120, the heart must have been quite irritable to have had so much variation in the P waves. I should think that you were quite right about the possible importance of the variation in auriculoventricular conduction. Whether that should be ascribed to myocardial involvement or to other factors, such as a digitalis effect, is difficult to say on this record alone, although it might have been due to either or to both. The electrocardiogram is certainly not typical of acute myocardial infarction. Had the patient had digitalis?

DR. CASTLEMAN: There is no mention of it.

DR. HARWOOD: The most striking feature of this case is the development of evidence of heart disease. On the first admission the heart was said to be normal. On the second admission, an apical systolic and an early diastolic murmur were noted. Later, in the final illness, the character of this murmur changed: it became much louder and was accompanied by a thrill, and its location appeared to be in the region of the tricuspid valve rather than at the apex. These changes are extremely suggestive of bacterial endocarditis. The character of the fever, the progressive anemia, the bacteremia and the enlarged spleen are all consistent with this diagnosis. The evidence of embolic phenomena is not too positive. Changes in the x-ray films of the chest and in the physical findings in the lungs can be construed as being due to emboli from the right side of the heart. The enlarged spleen and the cloudy spinal

fluid suggest septic emboli from the left side of the heart. But the diagnosis of bacterial endocarditis really rests on the remarkable change in the character of the heart murmurs. I am unable to explain the enlargement of the heart and the changes in the electrocardiogram. It may be that he had a toxic myocarditis; or there may have been multiple small abscesses in the myocardium.

The final question is, Did he have bacterial endocarditis two years before his death, or did he develop an acute endocarditis as a result of the debility resulting from his chronic urinary sepsis? In favor of the former diagnosis are, first, the otherwise unexplained infarct of the spinal cord and, second, the chronic anemia, which was present even at the time of his first admission. On the other hand I must admit that he remained remarkably well during the interim of eighteen months before the acute illness appeared. I should like to make a single diagnosis and so I shall say that he had a subacute bacterial endocarditis.

DR. CASTLEMAN: Dr. Ayer, have you anything to add?

DR. JAMES B. AYER: I saw this man only on the admission two years before his death. He presented evidence of a partial transverse lesion of the spinal cord, which, as you have heard, remained permanently as a Brown-Séquard palsy. The immediate question concerned the possibility of epidural abscess, but the evidence for this was lacking. My opinion was that he suffered from a myelitis, which occasionally occurs in the presence of infection elsewhere and may be due to emboli. There was, however, no evidence of infection in the spinal cord or its meninges.

DR. WHITE: I saw the patient early in February, three weeks before he died, because of the development of this striking murmur. There was a Grade 4 murmur with a thrill. Both murmur and thrill were maximal just to the left of the sternum and not at the apex and resembled Roger's murmur and thrill. But in our analysis we believed, or at least I did, that an acquired ventricular septal defect, because of its great rarity, was less likely than mitral-valve involvement with a torn cusp or chordae tendineae resulting from bacterial endocarditis, which had been helped temporarily by the specific chemotherapy. The third sound could be explained by the delayed auriculoventricular conduction with a long PR interval.

CLINICAL DIAGNOSIS

Subacute bacterial endocarditis, with probable rupture of mitral leaflet.

DR. HARWOOD'S DIAGNOSES

Subacute bacterial endocarditis (Type 13 pneumococcus).

Chronic cystitis and pyelonephritis.

ANATOMICAL DIAGNOSES

Acute bacterial endocarditis, posterior aspect of mitral valve, with perforation into right auricle (Type 13 pneumococcus).

Acute and chronic pyelonephritis, urethritis, prostatitis and cystitis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The heart was only slightly enlarged, weighing 400 gm. Just below the aortic valve, between the left posterior and the anterior

to have arisen on that side of the heart. There was no evidence of previous disease on any of the valves. Microscopically the vegetation was fairly acute. It was made up almost entirely of polymorphonuclear cells and organisms that on culture proved to be Type 13 pneumococci. He had, of course, infection in the kidneys, urethra, prostate and bladder.

Before discussing whether the bacterial endocarditis could have been connected with the cord symptoms of almost two years previously, Dr. Kubik will tell us what he found in the cord.

FIGURE 1. Photograph of the Heart Showing the Ulcerated Vegetation below the Aortic Valve.

cusps but not involving either cusp and actually on the posterior aspect and within the wall of the aortic leaflet of the mitral valve, was a large granular pinkish-red ulcerating vegetation (Fig. 1). This obvious bacterial endocarditis did not penetrate through the endocardium of the anterior surface of the mitral leaflet into the left auricle but faced the left ventricle. It did, however, perforate through at its right border into the right auricle just above the tricuspid valve (Fig. 2). It extended only a bit onto the tricuspid valve, and it did not appear

DR. CHARLES S. KUBIK. I saw this patient on his last admission and said at that time that, although infarction or any other type of vascular lesion of the cord was extremely rare, it was suggested in this case by the sudden onset of symptoms and the subsequent improvement. I suppose that vascular lesions of the cord are rare because the cord has a good collateral circulation.

At autopsy there was a localized focus of degeneration in the anterior part of the cord at about the sixth thoracic level. The histologic appearance of

this lesion was consistent with old infarction, but one probably cannot be altogether certain of the diagnosis. In any case, because of the time relations, it cannot be satisfactorily explained by the acute bacterial endocarditis.

defect, but the murmur was absolutely characteristic of the latter.

DR. CASTLEMAN: Do you think that the perforation in the right auricle, rather than into the ventricle as is usual in septal defect, might have had

FIGURE 2. Photograph of the Heart Showing the Perforation of the Right Auricle.

DR. WHITE: May I add a comment about the murmur. It was so characteristic of Roger's murmur that we should have stuck to our auscultatory diagnosis of a ventricular septal defect. Because of the rarity of an acquired septal defect in such a case I voted for mitral valve rupture rather than septal

something to do with the change in the murmur?

DR. WHITE: I believe that one should find the same type of murmur with a defect leading from ventricle to auricle that one would find in the case of a hole between the ventricles. The flow of blood is much the same.

PULP PRESERVATION

ONE of the many difficulties besetting a journal editor in these grueling days, although only one of them, is that brought about by the current paper shortage. This is largely due, as are so many of our internal problems, to the lack of manpower, but it has also other more acute angles, although some of these too are indirectly the result of labor difficulties. Thus since steel is a critical material with high priority rating, there exists a shortage of axheads and sawblades. Without axheads and without lumbermen to cut the wood for axhandles, a shortage in the latter becomes obvious, still further embarrassing pulp production. It seems hardly

necessary to mention shortages of farm help, so necessary to raise the beans on which lumbermen are reputedly fed.

Various methods have been employed to conserve our depleted supply of paper. The *Journal*, for instance, having been sharply curtailed in its annual paper allotment, has had to stretch that allotment by the use of a lighter weight paper, by reducing the number of pages, despite an unusually good supply of excellent material for publication and the demands of our advertisers for more space, and by limiting the allowable number of reprints.

Printers have had their purchases of paper cut to a prescribed percentage of normal consumption as of a given year, according to regulations issued and sent to each one in the form of a governmental pamphlet containing as a part of its message, we have been told, five printed lines on page 4, three lines on page 5, and nothing on pages 6, 7 and 8. (These may have been left blank for remarks!)

One of the most serious problems that these curtailments have raised, however, has been their contribution to the shortage of waste paper. The uses of waste paper have been graphically illustrated; it is going overseas on a variety of missions, — as wrapping for artillery shells, jeep fenders, small-arms ammunition, bazookas, machine-gun triggers and K rations, — but the supply is dwindling. There seemed for a time no solution to this problem, but it has been inspiringly met.

Government itself has gone into the production of waste paper. By using eight pages where four would have sufficed, by tripling its regulations and doubling the number of words in each, by requiring fifty-six signatures where six would have served and by specifying quintuplicate instead of triplicate copies of declarations, questionnaires and directives, the emergency has been met. The war can go on!

ETIOLOGY OF EXUDATIVE PHARYNGITIS

MOST, if not all, clinicians have the impression that acute pharyngitis and acute tonsillitis are always caused by hemolytic streptococci. This is particularly true with respect to the cases that are associated either with a purulent follicular exudate or

with a fine pseudomembranous exudate. In recent years, however, many physicians interested in infectious diseases and others working on the medical wards of general hospitals where bacteriologic studies are made routinely have been surprised to find that many, or even the majority, of the seemingly typical cases of pharyngitis and tonsillitis — excluding, of course, cases of scarlet fever and septic sore throat — failed to yield positive cultures of beta-hemolytic streptococci.

In the course of the studies that are being conducted by the Commission on Acute Respiratory Diseases at Fort Bragg, about 10 per cent of the patients admitted to the hospital for acute respiratory diseases were found to have exudate on the pharynx or tonsils. Some of those patients had both bacteriologic and clinical evidence of hemolytic streptococcus pharyngitis; others had positive throat cultures, but the clinical picture was not entirely characteristic; and still others had neither cultural nor characteristic clinical findings of hemolytic streptococcus infections. The members of the commission* therefore undertook a systematic clinical and laboratory study of the problem. They believed that, since beta-hemolytic streptococci are harbored in the throats of healthy persons as well as in those of patients suffering from colds and other respiratory infections, the diagnosis of streptococcal pharyngitis could be made with certainty only if a specific antibody response was demonstrated against that organism during convalescence. Thus, samples of serum obtained during the acute febrile stage of the illness and again during convalescence were tested for their antistreptolysin titer in each case.

The patients under investigation were routine admissions for acute respiratory symptoms who came to the hospital from selected organizations of that post. The criterion for admission was simply the finding of a temperature of 100°F. or higher when the men reported to the dispensary. Of 900 men admitted during the period of study, 116 were found to have exudate on the pharynx or tonsils and were selected for the study.

On the basis of the laboratory data the cases were classified into three groups. The first group com-

prised approximately 25 per cent of the cases and included those in which beta-hemolytic streptococci were obtained in the cultures and in which a significant rise in the titer of streptococcal antibodies developed during convalescence. The second group consisted of another 25 per cent of the patients; these men had positive cultures for hemolytic streptococci but did not develop antibodies during convalescence. The last group, which consisted of the remaining 50 per cent of the patients, had neither positive cultures for beta-hemolytic streptococci nor rises in titer of antistreptolysin. Definite differences were demonstrated between the cases with and those without antibodies regarding the mode and rapidity of onset, the total frequency of symptoms, the severity of the physical findings and the height of the white-cell count. Cases with beta-hemolytic streptococci in which antibodies did not develop were similar in their clinical characteristics to those in which streptococci were not found.

The members of the commission concluded that in approximately 25 per cent of the cases that were studied the exudate was caused by beta-hemolytic streptococci, whereas in the remaining 75 per cent the causative agent was unknown. Except for the presence of exudate, the latter did not appear to differ from the great majority of cases of undifferentiated respiratory disease.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The History of Miners' Diseases: A medical and social interpretation. By George Rosen, M.D. With an introduction by Henry E. Sigerist, M.D. 8°, cloth, 490 pp., with 18 illustrations and frontispiece. New York: Schuman's, 1943. \$8.50.

The object of this monograph is to present a comprehensive historical study of miners' diseases from prehistoric times to the end of the nineteenth century. It is not a history of the occupational diseases that are known to afflict miners at the present day but rather an attempt to trace the growth of knowledge concerning such diseases, as it has developed through the ages. The objective of the book is to bring together related material bearing on the existence and recognition of occupational sickness among miners at different times and in various places and to present them in an ordered, systematic manner. The work is divided into two parts: the first covering the period from the time of the neolithic miners to the end of the eighteenth century, and the second, the period from 1800 through 1900. The work is printed on good paper with a good type and is recommended for all historical collections.

On the basis of the laboratory data the cases were classified into three groups. The first group com-

prised approximately 25 per cent of the cases and included those in which beta-hemolytic streptococci were obtained in the cultures and in which a significant rise in the titer of streptococcal antibodies developed during convalescence. The second group consisted of another 25 per cent of the patients; these men had positive cultures for hemolytic streptococci but did not develop antibodies during convalescence. The last group, which consisted of the remaining 50 per cent of the patients, had neither positive cultures for beta-hemolytic streptococci nor rises in titer of antistreptolysin. Definite differences were demonstrated between the cases with and those without antibodies regarding the mode and rapidity of onset, the total frequency of symptoms, the severity of the physical findings and the height of the white-cell count. Cases with beta-hemolytic streptococci in which antibodies did not develop were similar in their clinical characteristics to those in which streptococci were not found.

The members of the commission concluded that in approximately 25 per cent of the cases that were studied the exudate was caused by beta-hemolytic streptococci, whereas in the remaining 75 per cent the causative agent was unknown. Except for the presence of exudate, the latter did not appear to differ from the great majority of cases of undifferentiated respiratory disease.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The History of Miners' Diseases: A medical and social interpretation. By George Rosen, M.D. With an introduction by Henry E. Sigerist, M.D. 8°, cloth, 490 pp., with 18 illustrations and frontispiece. New York: Schuman's, 1943. \$8.50.

The object of this monograph is to present a comprehensive historical study of miners' diseases from prehistoric times to the end of the nineteenth century. It is not a history of the occupational diseases that are known to afflict miners at the present day but rather an attempt to trace the growth of knowledge concerning such diseases, as it has developed through the ages. The objective of the book is to bring together related material bearing on the existence and recognition of occupational sickness among miners at different times and in various places and to present them in an ordered, systematic manner. The work is divided into two parts: the first covering the period from the time of the neolithic miners to the end of the eighteenth century, and the second, the period from 1800 through 1900. The work is printed on good paper with a good type and is recommended for all historical collections.

*Commission on Acute Respiratory Diseases. Endemic exudative pharyngitis and tonsillitis: etiologic and clinical characteristics. *J. A. M. A.* 125: 1163-1169, 1944.

Personality and the Behavior Disorders: A handbook based on experimental and clinical research. In two volumes. Edited by J. McV. Hunt, Ph.D., assistant professor of psychology, Brown University. 8°, cloth: Vol. 1, 618 pp., and Vol. 2, 624 pp. New York: The Ronald Press Company, 1944. \$10.00 for the set.

This collective treatise is the work of thirty-five experts who have reviewed the present knowledge of personality in the biologic, psychologic and psychiatric aspects of the subject. Extensive bibliographies have been appended to each article and complete indices of names and subjects have been appended to the text. The work should prove of value as a reference source for psychiatrists, psychologists and sociologists, and also should find a place in every medical and reference library.

Essays in Biology: In honor of Herbert M. Evans. Written by his friends. 4°, cloth, 686 pp., illustrated. Berkeley: University of California Press, 1943. \$10.00.

This memorial volume was presented to Dr. Evans on his sixtieth birthday by his colleagues, his students and other friends. Dr. Evans is professor of anatomy, Hertzstein Professor of Biology and director of the Institute of Experimental Biology in the University of California. He has devoted his life to the fundamental problems of anatomy, embryology, endocrinology and nutrition and the physiology of reproduction. He also has been interested in the history of science and medicine in all their aspects. In this volume there are forty-eight papers written by his friends on the various subjects with which he is concerned. At the beginning of the volume there is a complete bibliography of the writings of Dr. Evans.

The Jews and Medicine: Essays. In two volumes. By Harry Friedenwald, M.D., D.H.L. (hon.), D.Sc. (hon.). 8°, cloth: Vol. 1, 390 pp., with 25 illustrations and frontispiece, and Vol. 2, 427 pp., with 13 illustrations. Baltimore: The Johns Hopkins Press, 1944. \$3.75 (for each volume).

Dr. Friedenwald has been interested in the history of Jewish physicians and the contributions of Jews to medicine for almost half a century. During this period he has written many articles and essays of a biographical and historical character, which are brought together in these two volumes. Coincidentally with his interest in Jewish literature and medicine, Dr. Friedenwald has made a fine collection of manuscripts and early printed books in these fields. Dr. Henry E. Sigerist, in the preface, discusses the medical collectors of Baltimore, especially those connected with Johns Hopkins University School of Medicine and particularly Dr. Friedenwald and his collection of medical classics of the Jews.

A Text-Book of Pathology. Edited by E. T. Bell, M.D., professor of pathology, University of Minnesota, Minneapolis. Fifth edition, enlarged and thoroughly revised. 8°, cloth, 862 pp., with 448 illustrations and 4 colored plates. Philadelphia: Lea and Febiger, 1944. \$9.50.

The greater part of the text has been thoroughly revised and a large amount of new material has been added. Among the new topics discussed at length are shock, vitamin deficiencies, blast injuries, Boeck's sarcoid and several infectious diseases of interest in war medicine. The work is primarily a textbook for the medical student to use during his clinical training.

Medical Care of the Discharged Hospital Patient. By Frode Jensen, M.D., instructor in medicine, Syracuse University College of Medicine; H. G. Weiskotten, M.D., dean and professor of pathology, Syracuse University College of Medicine; and Margaret A. Thomas, M.A. (Oxon). 8°, cloth, 80 pp. New York: The Commonwealth Fund, 1944. \$1.00.

This is a report of a successful experiment in extending the range of a hospital service, thus improving the care of chronically ill patients and relieving congestion in the medical wards. The study was carried out in the University Hospital of the University of Syracuse College of Medicine. A special extra-mural resident was assigned to the task of familiarizing himself with the medical aspects of chronic cases and their relevant emotional, social and economic factors. He also investigated the facilities for home treatment and was authorized to continue the medical supervision of the patients in their homes

after discharge. It was found that, because of proper facilities for care in the home, many patients could be discharged earlier and rehospitalization was greatly reduced. Sufficient hospital facilities were released to permit the acceptance of several hundred patients. The information revealed by this experience re-emphasizes the fact that the hospital is the pivot around which should revolve the various services: hospital care, outpatient care and public-welfare programs. The provision of adequate home care for discharged medically needy patients is a step toward a more economical and beneficial use of the hospital in the care of the indigent. This small monograph should be of interest to all hospital administrators as well as to physicians having to do with chronic illness.

Applied Dietetics: The planning and teaching of normal and therapeutic diets. By Frances Stern, chief of Frances Stern Food Clinic, Boston Dispensary, assistant in medicine, Tufts College Medical School, special instructor in dietetics in social service and associate in nutrition, Simmons College, Boston. Second edition. 4°, cloth, 265 pp., with 57 tables. Baltimore: The Williams and Wilkins Company, 1943. \$4.00.

This is a revised edition of a book first printed in 1936. The work is based on the methods developed in the food clinic of the Boston Dispensary, the pioneer clinic of its kind, organized twenty-five years ago. It has been revised to include the information on nutrition developed during the seven years that have elapsed since the publication of the first edition. The section on the vitamins has been rewritten to conform to the latest chemical knowledge of these elements. The bulk of the information is presented in tabular form. There are fifty-seven co-ordinated tables to simplify the computation of the diet, and there are twenty pairs of full-page tables setting out in detail typical menus and diets. A normal diet is considered in relation to normal physiology, whereas the therapeutic diet is treated as a deviation from the normal, calling for an increase or decrease in the amount of a food constituent, or the omission or change in the consistence of foods as used in the normal diet.

Sulfonamide Therapy in Medical Practice. By Frederick C. Smith, M.D., M.Sc., lieutenant colonel, Medical Reserve Corps, Army of the United States. With a foreword by George M. Piersol, B.S., M.D., professor of medicine, Graduate School of Medicine, University of Pennsylvania. 8°, cloth, 368 pp., with illustrations, tables and charts. Philadelphia: F. A. Davis Company, 1944. \$5.00.

This new manual has been written to point out the possibilities of sulfonamides in treatment and to emphasize their limitation and their toxic properties. The first 94 pages discuss pharmacology and therapeutics, toxic reactions and tests. The remaining portion of the work is devoted to clinical indications for sulfonamide therapy and is arranged alphabetically by diseases. An appendix of 12 pages discusses penicillin. Current literature has been utilized and a number of illustrative cases have been included in the text. This timely manual should prove of interest to all physicians who may wish to refer to the use of sulfa drugs in various infections.

Medical Physics. Edited by Otto Glasser, Ph.D., head, Department of Biophysics, Cleveland Clinic Foundation, professor of biophysics, Frank E. Bunts Educational Institute, and consulting biophysicist, University Hospitals of Cleveland. 4°, paper, 1744 pp., illustrated. Chicago: The Year Book Publishers, Incorporated, 1944. \$18.00.

This outstanding encyclopedia, with signed contributions by over two hundred authorities in various fields of biology and medicine, should prove to be a valuable reference book for all libraries and for all physicians who are brought into contact with medical physics in any of its varying aspects, as well as radiologists and biologists. The articles are arranged alphabetically by subject, but there are classified tables of contents preceding the text that show at a glance all the articles in the various fields of medicine and physics. Many of the authors have attached good working bibliographies to their contributions. The book is well illustrated, printed in a good type on good paper, but is rather unwieldy to handle because of its size and weight. Comprehensive subject and name indices are appended to the text.

TREATMENT OF PNEUMOCOCCAL PNEUMONIA WITH PENICILLIN*

MANSON MEADS, M.D.,† H. WILLIAM HARRIS, M.D.,‡ AND MAXWELL FINLAND, M.D.§

WITH THE TECHNICAL ASSISTANCE OF CLARE WILCOX

BOSTON

ALTHOUGH the sulfonamide drugs are highly effective in the treatment of the pneumococcal pneumonias, serious problems sometimes arise in their administration. In patients with underlying cardiac or renal disease there may be considerable difficulty in maintaining proper fluid balance and in preventing urinary-tract complications while the drugs are being given in adequate doses. Some of the toxic effects of the sulfonamides may not only be dangerous in themselves but may make it necessary to discontinue this therapy before the infection is adequately controlled. Moreover, occasional cases apparently fail to respond to treatment with adequate doses, either because the organism is not susceptible or for other reasons.

Penicillin, on the other hand, seems to be free from many of these difficulties and at the same time is extremely effective against the pneumococcus. In-vitro tests have shown that pneumococci are highly susceptible to penicillin.¹⁻⁶ This has been confirmed in the treatment of experimental infections in mice^{7,8} and in chick embryos.⁹ Resistant strains from clinical cases have not been reported, although strains have been made resistant in vitro¹⁰ and by serial passage through mice treated with subeffective doses of the agent.¹¹ Both sulfonamide-sensitive and sulfonamide-resistant strains seem to be equally susceptible to the action of penicillin.^{12,13}

Tillett, Cambier and McCormack¹⁴ report excellent results in the treatment of 46 cases of lobar pneumonia with penicillin. These cases were mostly of pneumococcal etiology and were of average severity. Others^{15,16} reporting miscellaneous groups of infections treated with penicillin have included

small numbers of cases of pneumococcal pneumonia in which similar results were obtained.

It is the purpose of this paper to report the results of treatment with penicillin in a series of 54 rather severe cases of pneumococcal pneumonia. Penicillin was used alone in 37 of these cases, whereas in the remaining 17 cases it was given only after sulfonamide drugs had either failed to bring about a satisfactory response or produced untoward effects that made it undesirable to continue their use, although the patients were still acutely ill.

MATERIAL AND METHODS

Selection of Cases

All the patients had pneumococcal pneumonia and were admitted to one of the medical services of the Boston City Hospital from March through December, 1944. The 37 patients who were treated with penicillin alone (Group I) had not previously received sulfonamides for this illness. This was determined from the history and confirmed, when there was any doubt, by the failure to find any sulfonamide in the blood taken on admission. All these patients had pneumococci that were readily typed directly from the sputum by the Neufeld method at the time of entry. Sulfonamides or specific antisera were not used during the penicillin treatment in these cases.

The remaining 17 patients (Group II) had received sulfonamides, usually in full doses, before the penicillin was started, and the change to the latter was made for one or more of the following reasons. In most cases, the clinical condition became worse. In 1 such case the penicillin was begun after fourteen hours on sulfonamides, and in 10 others after more than thirty hours. In 2 cases, peripheral vascular collapse or congestive failure developed. In 7 cases, there was clinical evidence of a spread of the pulmonary lesion after thirty hours or more on sulfonamides. In 5 cases, positive blood cultures were obtained thirty-six hours or more after sulfonamides were started. In 1 case, there was persistence of

*From the First, Second and Fourth Medical Services and the Department of Medicine, Harvard Medical School.

†The penicillin used in this study was provided, in part, by the Office of Scientific Research and Development from supplies assigned by the Committee on Medical Research for clinical investigations recommended by the Committee on Chemotherapeutic and Other Agents of the National Research Council.

‡Research fellow in Medicine, Harvard Medical School and Thorndike Memorial Laboratory.

marked toxemia and leukopenia. In 2 cases, the patients were in extremis on entry after receiving undetermined amounts of sulfonamides. In 1 case, there were severe renal complications of sulfonamide therapy. Other factors that influenced the decision to change to penicillin included the advanced age of the patient, elevation of the blood nonprotein nitrogen and severe underlying disease or prolonged sulfonamide therapy without adequate improvement.

Some of the salient features of all the cases are summarized in Table 1. On the whole, they repre-

TABLE 1. Summary of Data.

*Other complicating conditions — Group I: bronchiectasis, 2 cases; sickle-cell anemia, 1 case; aplastic anemia, 1 case; empyema on admission, 2 cases. Group II: bronchiectasis, 1 case; moderately advanced pulmonary tuberculosis, 1 case; chronic pyelonephritis, 2 cases; arteriosclerotic heart disease, 4 cases (1 with angina and 1 with asthma).

sented severe cases by all the usual criteria. More than two thirds of the patients were over forty years old. Penicillin was started in most cases after the fourth day of the disease. The majority had two or more lobes involved and appeared clinically to be severely ill, with delirium, evidence of peripheral vascular collapse — cold clammy skin, cyanosis and low blood pressure — or congestive failure. More than half the patients had positive blood cultures. The pneumococci were predominantly of the lower or so-called "common" types, but there were 2 cases in each group in which a higher type of pneumococcus was grown from the blood. A few patients had either leukopenia or extremely high white-cell counts before penicillin treatment was started. Several patients had severe underlying diseases, and in 2 cases there were signs of fluid at the time of entry. Judging from these findings, the cases in Group II were somewhat severer than those in Group I.

Methods

At the time of admission, sputum was obtained for typing by the Neufeld technic and venous blood was obtained for cultures in broth and agar and, in many cases, for sulfonamide determinations. Some of the sputum was also cultured and the pneumococcus strains were isolated. Additional blood cultures were made at irregular intervals after penicillin was started. In the Group II cases, a culture and sulfonamide determination of the blood were made before the first dose of penicillin. Para-aminobenzoic acid was added to all mediums used for cultures in cases under sulfonamide therapy, and penicillinase* was added in most of the cultures made during penicillin treatment.

In most cases, the pneumococcus strains isolated from the sputum or blood were tested for sensitivity to penicillin by the method of Rammelkamp and Maxon.¹⁷ Concentrations of penicillin in the blood were determined by the method of Rammelkamp.¹⁸

Penicillin Administration and Dosage

On the whole, the dosage was individualized with respect to the amount and frequency of the injections and the total duration of treatment. The severity of the disease, the clinical response and the concentrations obtained in the blood were all taken into account. Difficulties were encountered in properly maintaining the constant intravenous injections, particularly in the types of case in which that method seemed most indicated. Intermittent intramuscular administration was the most feasible method and was therefore generally used.

Most of the patients classified as Grade 2 or 3 in severity were given from two to six injections of 15,000 units every two hours, and the same amount was given every three hours until there was definite clinical improvement and the temperature had remained below 100°F. for twelve hours. Additional doses of 10,000 units each were then given every three hours for another two or three days. In the severest cases (Grade 4), the same general scheme of dosage was used except that a single dose of 5000 or 10,000 units was given intravenously in some cases at the time of the first intramuscular injection and from six to twelve injections of 15,000 units were given at two-hour intervals, depending on the response of the patient during that time. In most patients with congestive failure or in those with a low urinary output from this or other causes, bacteriostatic levels were usually maintained for somewhat longer periods than in other patients after similar doses. In such cases the interval between doses could therefore be increased.

The average total dose and duration of treatment in each of the various groups of recovered cases are shown in Table 2. The dosages are considerably larger than those used by Tillett et al.¹⁴ but they

*Kindly supplied by Drs. H. J. White and R. O. Roblin, Jr., of the Stamford Laboratories, Stamford, Connecticut.

were not deemed excessive in view of the severity of these cases and the clinical response observed. In the present series, the average dose and duration

TABLE 2. *Average Total Dosage of Penicillin and Duration of Treatment in Recovered Cases.*

TYPE OF CASE	AVERAGE TOTAL DOSAGE OF PENICILLIN units	AVERAGE DURATION OF TREATMENT hr.
Group I	411,000	86
Group II	728,000	162
Severity:

Grade 4	735,000	148
All cases	507,000	107

of treatment were directly proportional to the severity of the disease.

Other Therapy

Supportive and symptomatic therapy, including proper hydration, the use of oxygen, digitalis, sedation and stimulants, was used as indicated. Inadequate attention to some of these details may have contributed to the failures in single cases. The need for a large fluid intake, which is so essential in sulfonamide-treated cases to avoid renal complications, was obviated with the use of penicillin. This was particularly helpful in some of the patients with congestive failure.

RESULTS

Effect on the Clinical Course

The effect on the clinical course may be judged from the duration of fever and of acute symptoms, such as delirium, prostration and dyspnea, after the penicillin was started. These results are summarized in Table 3. About half the patients were

*Two of these patients were still acutely ill but had no fever when penicillin was started.

†One of these patients (Case 33) did not become afebrile until after penicillin was stopped and a sulfonamide drug was given.

essentially afebrile and markedly improved symptomatically within twenty-four hours, and most of the remaining ones who had not previously been treated with sulfonamides were essentially recovered by the end of the second day. In 10 cases, the fever continued for one to four days after marked clinical

improvement had occurred. In 4 of the Group II cases, on the other hand, symptoms persisted for one to four days after the fever had subsided. In several cases, the persistence of fever and symptoms was associated with active delirium tremens or with the presence of complications. Examples of the clinical course in a few cases are illustrated in Figures 1-7, which show various types of response to penicillin.

Effect on Bacteremia

The results of blood cultures taken in 18 of the bacteremic cases before treatment and again within the first twenty-four hours after penicillin was started are shown in Table 4. In only 4 cases was a positive blood culture obtained after the penicillin treatment was begun, and in each case only a single dose of 15,000 units had been given two or three hours before the positive culture was obtained. In one of these patients (Case 39), the culture taken after the last dose of sulfonamide and before the first dose of penicillin showed no growth. In all 4 of these cases, the blood culture taken six to twenty hours later was negative. In the remaining 14 cases, all the blood cultures taken after penicillin was started showed no growth. These negative cultures were obtained as early as fifteen minutes after the initial dose of penicillin in 1 case, thirty minutes after the first dose in a second case, and two to four hours after treatment was started in five others.

In the 11 bacteremic cases that are not listed in this table, either the patient died before a second blood culture could be obtained or subsequent cultures were negative but were taken after the patient was already afebrile.

Complications

It is noteworthy that no purulent complications developed in either group of cases after penicillin treatment was started. There were 2 cases, however, in which empyema was already present before the penicillin was given. One of these patients died two hours after the first dose. The other also had an early purulent arthritis. He was given five intrapleural injections of 10,000 units each, but it was necessary to resort to surgical drainage for cure. The arthritis in this case responded to a single intra-articular injection of 10,000 units of penicillin. In 1 other patient (Case 51), a Type 4 pneumococcus was obtained from both sputum and ascitic fluid at the time of entry. This patient died with congestive failure after two days on penicillin.

Sterile pleural effusions developed in 2 cases of Group I. Partial atelectasis of the resolving lung occurred in 3 cases of Group I and in 2 of Group II. These complications were associated with persistence of a low-grade fever after the acute symptoms subsided.

Relapse of the pneumonia with the same type of pneumococcus but with involvement of another

lobe occurred in Case 3 (Fig. 1). This patient received only 100,000 units of penicillin in ten hours by constant intravenous injection, and the relapse occurred ten days later. A relapse with a pneumococcus of a different type occurred in Case 46. This patient was a seventy-one-year-old woman who was from the sputum. She responded with complete recovery to a second course of 660,000 units of penicillin. A third patient (Case 20), with underlying pyelonephritis, hypertensive heart disease and persistent azotemia, was successfully treated for a Type 18 pneumococcus pneumonia of the left lower

FIGURE 1. Course and Treatment in Case 3. In this case the administration of 100,000 units of penicillin by constant intravenous drip over a period of ten hours was followed by slow but steady improvement. The onset of symptoms of relapse occurred on the third day after the patient was discharged. Type 1 pneumococci were found in large numbers in the sputum during both attacks.

first treated for Type 3 pneumococcus pneumonia of the right upper lobe that had failed to respond to sulfadiazine. She improved rapidly after penicillin was started, and she had received a total of 370,000 lobe and again one month later for a Type 3 pneumococcus pneumonia of the right lower lobe. The pneumococcus was obtained each time from blood and sputum.

†Continuous intravenous administration.

units. Three days after this course was completed she again developed fever, respiratory symptoms, leukocytosis and signs of a diffuse bronchopneu- monia and a Type 24 pneumococcus was obtained Thrombophlebitis occurred in 2 cases. In neither of them was penicillin given by the intravenous route. In one of these patients the thrombophlebitis developed on the seventh day after a good clinical

response, but later the patient suddenly died following a femoral-vein ligation. In the other patient, sulfonamides had been used first; a posterior tibial thrombophlebitis developed four days after penicillin was started and subsided after six days.

One patient in Group I developed acute cardiac failure and pulmonary edema and died shortly after treatment was started. Auricular fibrillation occurred in 2 of the Group II cases. In one of them, it commenced twelve hours after penicillin therapy was begun and lasted for twenty-four hours; in the other, it began after twenty-four hours of penicillin therapy and lasted for four days. In both cases, restoration of normal sinus rhythm accompanied

course of 2,000,000 units given over a period of eleven days.

In Case 43, penicillin was started because of the development of anuria and uremia on sulfadiazine. A drug rash developed six days after the sulfonamide was discontinued and the penicillin was started. The blood-sulfadiazine level at that time was 10 mg. per 100 cubic centimeters, 4 mg. of which was in the free form.

Untoward Effects of Penicillin

Except for a mild burning sensation experienced by several patients at the site of some of the intramuscular injections, there were only two complica-

‡Continuous intravenous infusion.

improvement in the acute symptoms of the pneumonia.

Active delirium tremens developed in four cases; in each case during the second day of penicillin treatment. In one of the cases of Group I it lasted for four days, and in another it lasted for seven days. In the latter, improvement did not occur until after penicillin was stopped and a sulfonamide was given (Case 33). In one of the Group II cases the active delirium continued for two days; in the other it lasted for three days.

One patient developed hemolytic *Staphylococcus aureus* tonsillitis eight days after penicillin treatment was stopped. Another patient, who had first been treated with sulfonamides, developed an exacerbation of a chronic pyelonephritis with a positive blood culture for hemolytic *Staph. aureus* on the fourteenth hospital day, five days after penicillin treatment was stopped. He recovered after a second

tions that could be attributed to the penicillin. In one case, a left-sided sciatic neuritis developed one week after penicillin treatment was completed. This may possibly have resulted from local nerve injury or from fibrosis about the nerve at the site of penicillin injections. In a second case, a morbilliform rash appeared about the knees, elbows and ankles after 475,000 units of penicillin had been given. The rash persisted for thirty-six hours after all therapy other than penicillin was discontinued, but it could not subsequently be reproduced with a total of 90,000 units given over twelve hours.

Fatal Cases

Some of the significant findings in the 10 fatal cases are listed in Table 5. For the most part these cases were of extreme severity in patients who were either old or had severe underlying diseases. Almost all of them had multiple-lobe involvement and

bacteremia, and treatment was started late in the disease.

Two of the patients died several days after their pulmonary lesions had apparently cleared. One of them (Case 27) had been treated with penicillin alone and died suddenly after ligation of the femoral

These 7 patients were all essentially moribund when penicillin treatment was started.

Penicillin Sensitivity of the *Pneumococcus* Strains

Tests for sensitivity to penicillin were carried out on thirty-six strains of pneumococci isolated from

FIGURE 2. Course and Treatment in Case 8 (left) and Case 15 (right). These charts illustrate the rapid response to penicillin in cases of moderate severity.

vein for thrombophlebitis. Multiple abscesses were found in the lungs at autopsy, and cultures yielded a Friedländer's bacillus. The other patient (Case 43) died of sulfadiazine anuria and uremia after two days of penicillin treatment. A third patient (Case 51) had cirrhosis of the liver, congestive cardiac

as many cases. The results are summarized in Table 6. The minimum inhibiting concentration was 0.016 units or less per cubic centimeter for twenty-seven of the strains, and 0.032 units for the remaining nine strains. In several cases pneumococci of the same type isolated from the blood and sputum of the same patient were tested simultaneously and identical results were obtained with each. Blood levels corresponding to the minimum inhibiting

concentrations or higher were rarely maintained for more than two hours after an intramuscular injection of 15,000 units. There seemed to be no correlation, however, between the sensitivity of the strains and the clinical response.

COMMENT

The results obtained in this series of extremely severe cases of pneumococcal pneumonia indicate that penicillin is a highly effective therapeutic agent in this disease. The results in the Group II cases show, in addition, that penicillin is equally effective in cases that are relatively resistant to

sulfonamide drugs as judged from the clinical and bacteriologic response. Among the 17 cases of this group, 10 had positive blood cultures after treat-

cases had the same mortality. Among the 46 cases reported by Tillett, Cambier and McCormack¹⁴ there were only 5 deaths (6 per cent). The difference is readily accounted for by the much greater severity of the present cases. Many patients were essentially moribund when treatment was started; seven of them died a half to eight hours after the first dose, and the others had severe complications.

The clinical response to penicillin in the patients who recovered was quite similar to that which occurs under sulfonamide therapy. Fever and acute symptoms subside rapidly, usually within twenty-four to forty-eight hours. In general, the severe cases in which there is bacteremia and multiple-lobe involvement and those with various complications respond more slowly than do the milder and uncomplicated cases. Improvement in the general condition as well as in the subjective symptoms

FIGURE 4. Course and Treatment in Case 33. The patient had active delirium, tremors and persistent fever and respiratory symptoms during almost eight days of penicillin therapy. She improved rapidly after the penicillin was discontinued and a sulfonamide given. The physical and x-ray findings suggested the presence of interlobar pleural fluid and possibly cavitation in the lung, but the lungs cleared completely without special treatment.

ment with sulfonamides for varying periods up to six days. Only 3 of these patients died after penicillin therapy, one within four hours and the other

FIGURE 5. Course and Treatment in Case 38. In this patient the symptoms persisted, the pneumonia extended and bacteremia recurred after six days of treatment with sulfadiazine and three days after specific antiserum was given. The bacteremia cleared rapidly but symptomatic improvement occurred slowly after penicillin was given.

within two from causes other than the pulmonary infection.

There were 10 deaths in this series, a mortality of 19 per cent. Both the Group I and the Group II

FIGURE 6. Course and Treatment in Case 39. There was a recurrence of bacteremia, together with persistence of a marked leukopenia and extension of the pneumonia, after two days of sulfonamide therapy. A slow but steady improvement occurred under treatment with penicillin.

often preceded the drop in temperature, as is the case with sulfonamide therapy. The definite impression was gained that in the extremely severe cases this objective and symptomatic improvement was prompter with penicillin than in similar cases treated with sulfonamides. This may be related to the lag phase in the action of sulfonamides, which probably occurs in patients as well as in the test tube. Delays in the clinical response under penicillin therapy have usually been associated with other underlying diseases, with mixed infections or with purulent or other complications. In severe but otherwise uncomplicated cases a delay in response may result from inadequate dosage.

Penicillin obviously has a distinct advantage over sulfonamides in patients with cardiac, renal or hepatic disease, in whom there is often difficulty in maintaining a proper fluid balance. With peni-

cillin it is not necessary to give alkalies and large amounts of fluids, which may result in serious water retention in such cases. Moreover, there is some evidence that in patients having a relatively low urinary output, and particularly in those with azotemia, higher penicillin levels are more readily maintained than in those with normal cardiorenal function having a large fluid output.

The failure of purulent complications to develop after penicillin treatment was begun is of interest in view of the severity of these cases and the high incidence of bacteremia. This is probably related to the effect that penicillin has in reducing the invasiveness of the susceptible organisms, as indicated by the prompt clearing of the bacteremia

were not ex of the cases intramuscul four to fort mild cases probably r every two twenty-four smaller am three days. must be ju response to treatment e side is sugg both in thi now being during pen eliminated from the b mococci m after clinic

It is stil penicillin : pneumococ present exp lished effectiveness of both agents and the temporary limitation of supply of penicillin, the indications for penicillin may be stated tentatively as follows.

Penicillin is the treatment of choice and should be used from the start in the following cases: in patients who are extremely ill and in a shocklike state; in patients with severe cardiac, renal or hepatic damage, particularly if there is edema or azotemia; if there is severe leukopenia; and in patients who are known to be sensitive to sulfonamides and have rashes, fever or severe nausea and vomiting early in the course of treatment with these drugs.

A change to penicillin from sulfonamides is indicated in patients who have received adequate doses and attained adequate blood levels but have failed to respond with improvement in the symptoms and a significant drop in temperature and pulse rate after twenty-four hours or longer, particularly if there is spread of the pulmonary lesion, persistent bacteremia or an increase in the number of pneumococci in the sputum as seen in direct smears; this change is also indicated if leukopenia, delirium tremens, auricular fibrillation or pulmonary edema develops before the symptoms of pneumonia have cleared or if severe untoward reactions, such as acute hemolytic anemia, gross hematuria, oliguria, anuria, nitrogen retention and even drug rash, occur before the pulmonary infection has been controlled. Crystalluria or microscopic hematuria need not be considered a cause for stopping sulfonamides but is an indication for alkalies and for increasing the fluid intake. Penicillin may be used locally when infected pleural fluid or other accessible foci of infection develop, and oral sulfonamides may be continued in such cases.

FIGURE 7. Course and Treatment in Case 40.

This patient had a severe pneumonia with involvement of the entire right lung on admission. He had been treated with sulfadiazine at home for about six days and had an adequate blood level of the drug on entry to the hospital. There was a steady drop in temperature after penicillin treatment was started, and clinical improvement followed.

after penicillin was started. On the other hand, the failure of some established purulent complications to clear following parenteral penicillin therapy is probably due to the failure of the agent to penetrate the infected foci in adequate amounts. It is possible, however, that early and more intensive treatment might result in the clearing of some of these focal infections before they become well established, as is often the case with sulfonamide therapy. Local instillation of penicillin into purulent foci may bring about additional cures. It should be emphasized that early diagnosis and treatment are still extremely essential if success is to be attained in saving life and in preventing serious complications.

It is not possible, on the basis of the available data, to define the effective dosage of penicillin for cases of pneumonia. The amounts used in the present cases were considerably greater than those employed by Tillett. These results suggest that the larger amounts were probably necessary and

SUMMARY AND CONCLUSIONS

Penicillin was used in the treatment of 54 severe cases of typed pneumococcal pneumonia. Sulfonamides had previously failed to control the infection in 17 of these cases.

Bacteremia cleared rapidly, usually after the first dose of penicillin. Fever and acute symptoms subsided in most cases within twenty-four to forty-eight hours. Subjective improvement often preceded the drop in temperature.

There were 10 deaths. Seven of these were in moribund patients and occurred within a few hours after treatment was begun; the other 3 were associated with severe complicating conditions.

Purulent complications did not develop in any of these cases following penicillin therapy.

Penicillin was equally effective in the patients in whom it was used alone and in those who had previously failed to respond to sulfonamides.

Tentative indications for penicillin are given, and the dosage is discussed.

LISTERELLOSIS

MARTIN M. KAPLAN, V.M.D., M.P.H.*

WALTHAM, MASSACHUSETTS

LISTERELLOSIS is a sporadic, infectious disease occurring naturally in man¹⁻²² and in animals,²³ including cattle, sheep, goats, swine, foxes, chickens, rabbits, guinea pigs, gerbils and rats.²⁴ The disease is caused by *Listerella monocytogenes* (Bergey) and is characterized by symptoms principally referable to the central nervous system.

The causative organism, *List. monocytogenes*, was first submitted as a new species (*Bacterium monocytogenes*) in 1924 by Murray, Webb and Swann,²⁵ who isolated it from an epizootic affecting their laboratory rabbits and guinea pigs. In 1929, Nyfeldt²¹ recovered the organism from the blood stream of a seventeen-year-old boy⁶ with infectious mononucleosis, thereby being the first observer to prove definitely that *List. monocytogenes* is harbored by human beings. In 1918, Dumont and Cotoni² studied a diphtheroid organism isolated from the cerebrospinal fluid of a twenty-four-year-old soldier, which Paterson²⁶ over twenty years later identified as *List. monocytogenes*. It is highly probable that the diphtheroid organisms isolated from cases of meningitis in 1915 by Atkinson¹ and in 1919 by Dick³ were *Listerella*.

Epidemiology

Far too few cases are available for study to yield any clear-cut epidemiologic pattern of human listerellosis. Sufficient information is known, however, to avoid some blind pathways of exploration in an attempt to construct an epidemiologic fabric.

Including the probable cases,^{1, 3-5, 10} — that is those in which the isolated organisms were described as diphtheroids but appear to have been *Listerella*, — listerellosis in human beings has been reported in Australia, France, Denmark, Scotland, Norway, Uruguay, Argentina, England and the United States (Illinois, Iowa, New York, Connecticut, Massachusetts, North Carolina, Missouri and California) (Table 1). Areas other than those cited for human infection in which spontaneous listerellosis has been recognized in animals include Sweden, South Africa, New Zealand, Germany and Russia, as well as Indiana, New Jersey, Colorado, Oregon, Minnesota, Arkansas, Vermont and Virginia.²³ Thus, it is quite evident that *List. monocytogenes* is well dispersed throughout the world.

A noteworthy fact is that Paterson's study of fifty-four strains of *Listerella*²⁶ revealed no relation between the bacteriologic type and the zoologic host species (man and animals), nor did the types

*Associate professor of preventive medicine and public health, Middlesex University School of Veterinary Medicine (on leave of absence).

TABLE 1. Data of 36 Human Cases of *Listerellosis*.

*In Baldrige's cases the diagnosis of listerellosis is doubtful.

appear to be associated with a particular geographic origin.

To date, the number of human cases from which *List. monocytogenes* has been isolated and identified is 23. Adding the probable cases, the total becomes 36. Of these 36 cases, 15 (42 per cent) terminated fatally. Computing the fatality after subtracting 14 cases diagnosed as infectious mononucleosis (for reasons given below), the mortality of human listerellosis in its typical meningeal form approximates 68 per cent. This latter figure would be higher (79 per cent) if the recent cases treated with sulfonamides were excluded.

The natural habitat of the organism is not known. The part played by animals as a reservoir of infection for human beings is questionable. Their role appears to be unimportant, but any opinion on this score should be given reservedly until there accrue more data on human infection. It is noteworthy, however, that in areas in which listerellosis is enzootic (the United States, — Illinois, New York and Iowa, — England, Germany and New Zealand), very few cases of human infection have been reported. Indeed, in only a single case of human infection has there been recorded the remotest possibility of exposure (to a pet rabbit ill with so-called "snuffles" that was not further examined").

Other than probable transplacental infection occurring in the newborn,⁷ the portal of entry of the organism in human beings is obscure. Julianelle²⁷ thinks that ingestion and penetration through the gastrointestinal tract are likely because of the successful infection of white mice by means of contaminated drinking water, whereas inoculation of a culture intranasally into highly susceptible rabbits failed to cause infection. In domestic animals, experimental production of listerellosis to simulate a spontaneous infection is difficult regardless of the method of infection utilized. The nasal route appears to be the likeliest pathway in natural infection of animals^{28, 29} but further work is needed to resolve this question.

Except for a convalescent carrier,⁸ the isolation of *List. monocytogenes* has been accomplished only in actively diseased animals and man. The few attempts to discover healthy carriers in man have met with failure.⁷ These few negative findings by no means eliminate the possibility of latent, indiscernible infection that flares into active disease under propitious conditions. The latter explanation, for example, can be applied to those cases of infection of the newborn that have occurred in human beings,⁷ cows^{30, 31} and sheep,³² in which the parent was apparently unaffected by the organism. Predisposing causes that are capable of producing a general lowering of resistance have been reported in several human cases,^{1, 3, 5, 7, 13, 16} and these are believed to exert an appreciable influence in producing the disease in animals.

All age groups and both sexes have been affected with listerellosis. The occurrence of the disease in the newborn,⁷ one of these patients being a three-week premature infant, is particularly interesting because of the incrimination of *Listerella* as a cause of abortion in cattle³⁰⁻³³ and sheep.³²

The isolation of *List. monocytogenes* from the blood or cerebrospinal fluid in 9 cases of infectious mononucleosis (Table 1) merits separate consideration. Three other isolated strains mentioned by Paterson²⁶ are not considered in this paper because of insufficient data. Murray, Webb and Swann²⁵ first noted the typical mononuclear response in the blood of rabbits affected with listerellosis. It was to be expected, therefore, that the blood picture seen in human beings with infectious mononucleosis would be ascribed to the same cause.^{6, 15} The available evidence, however, controverts this assumption. A filterable virus associated with infectious mononucleosis has been shown by van den Berghe, Liessens and Kovacs^{34, 35} and Nettleship.³⁵ Julianelle, Bierbaum and Moore³⁷ were unable to confirm these findings. Paterson²⁶ studied the antigenic structure of fifty-four strains of *Listerella* isolated from a variety of animals and from human beings. Ten of these strains were isolated from patients with infectious mononucleosis, and they comprised a distinct group (Group 3) in his classification of four groups. Serologic evidence against an etiologic relation between *Listerella* and infectious mononucleosis has been demonstrated by Kolmer,³³ Julianelle²⁷ and Janeway and Dammin.³⁹ Furthermore, the benignity of the cases of infectious mononucleosis from which *List. monocytogenes* was isolated, in contrast to the high mortality that occurred in the typical meningeal form of listerellosis, supports the likelihood that the organism was acting in the capacity of an adventitious invader. The possibility of a mutual relation between the discovered filterable virus and *List. monocytogenes* in the pathogenesis of infectious mononucleosis should be kept in mind. In this respect, the well-known virus-bacteria combination in the production of swine influenza may be pointed out as an established fact.

The sporadicity of human listerellosis indicates a low degree of communicability. A study of the case histories, however, reveals some possibly significant facts. Burn⁷ reported 2 infants born the same day in the visiting obstetric service of a hospital. The infant delivered early in the morning died the next day of listerellosis. The second infant, apparently delivered later on the same day, suddenly became ill eight days later and died of listerellosis within six days. Atkinson's⁴ 5 cases in children all occurred within a period of thirteen days. Until further information is available concerning interhuman communicability of listerellosis, it is unwise to ascribe the cited cases to pure coincidence.

Thus, the usual communicable-disease precautions should be applied to listerellosis. There is little question of the communicability of the disease in animals.

Symptoms and Signs

Because of the protean symptomatology of infectious mononucleosis and the likelihood that a *Listerella* is merely a fortuitous invader in the disease, only the meningeal form of listerellosis will be considered.

The usual clinical picture seen in all ages is that of a septicemia with severe meningoencephalitic involvement. In children and adults the following observations have been made: sudden or gradual illness with fever, vomiting, headache, lethargy, stupor, irrationality, loss of reflexes, convulsions, rigidity of the neck, strabismus, ptosis, diplopia and bilateral mastoiditis. In fatal cases, death usually occurred within a week. Many patients who recovered had a prolonged convalescent period. In 1 case, affecting a nurse,^{8, 22} ten weeks after the inception of symptoms a speech defect, impaired memory, emotional instability, difficulty in self-feeding, slight nodding of the head and a sprawling gait were present. *List. monocytogenes* was recoverable in the cerebrospinal fluid for over four months. In the newborn, signs were apparent at birth or two to eight days later.⁷ Refusal of food, diarrhea, cyanosis, drowsiness and clonic convulsions were noted. The 3 cases reported ended fatally within six days.

Laboratory Findings

The cerebrospinal fluid has shown the most consistent changes. Increased pressure, a positive Pandy reaction, an increased number of leukocytes (predominantly lymphocytes), intracellular and extracellular *Listerella* organisms in stained smears and recovery of the organism in pure culture have been recorded.^{1-3, 5, 8, 10, 12, 13, 16, 18, 19}

A moderate leukocytosis has been the one common hematologic observation in the few blood examinations performed. The interpretation of the differential count has been confused because of changes attributable to infectious mononucleosis when the latter disease has accompanied the isolation of *List. monocytogenes* from the blood. In cases in which listerellosis alone was present, neutrocytosis was originally found.^{7, 9, 12-14, 19}

Post-Mortem Findings

The post-mortem findings included suppurative leptomeningitis and ependymitis, purulent otitis media, focal necrosis and patchy fatty degeneration of the liver, a swollen and congested spleen, focal necrosis of the adrenal glands, atelectasis, focal pneumonia and bronchiolitis.^{1, 7, 9, 13}

Treatment

Before the advent of the sulfonamides, symptomatic treatment had been relied on with little success. Three patients with the meningeal form of listerellosis were treated with sulfanilamide,¹⁷ sulfapyridine¹⁹ and Prontosil, respectively.⁴⁰ Recovery ensued in all 3 cases.

Experimentally, Webb²⁰ achieved favorable results with sulfanilamide and sulfapyridine in mouse listerellosis. His best results were obtained with a therapeutic combination of sulfapyridine and specific antilisterella rabbit serum. Savino⁴¹ infected white rats with *List. monocytogenes* and noted a protective action with sulfapyridine. Porter and Hale¹⁷ reported that both sulfanilamide and sulfapyridine were therapeutically effective in mice experimentally infected with listerellosis. In-vitro tests showed penicillin to be ineffective against *List. monocytogenes*.⁴²

SUMMARY

There have been reported in the literature 23 definitely diagnosed and 13 probable cases of human listerellosis. In its typical meningeal form, this disease showed a mortality of approximately 79 per cent, excluding 3 cases treated with sulfonamides.

Ecologic, age and sex factors appear to be of little significance in the incidence of this disease.

The natural habitat and portal of entry of *Listerella monocytogenes* — other than transplacental infection in the newborn — are unknown. The nasal and gastrointestinal tracts appear as the likeliest routes of penetration.

The status of a healthy or latent carrier of *List. monocytogenes* has not been proved in man or animals. The facts that infection of the newborn can occur with no effect on the parent, that a *Listerella* bacteremia may be present in cases of infectious mononucleosis and that certain predisposing factors apparently produce active infection, however, suggest that latent carriers play a significant role in the pathogenesis of listerellosis.

At present there is little evidence to incriminate animals as direct transmitting agents of *List. monocytogenes* to human beings. The widespread prevalence of listerellosis in animals, however, establishes them as possible reservoirs of infection for man.

The significance of *List. monocytogenes* in cases of infectious mononucleosis is discussed. It is believed that the organism acts as a contingent invader in infectious mononucleosis rather than as an incitant of the disease. The possibility of a mutual virus-bacteria relation in infectious mononucleosis is pointed out.

Circumstantial evidence is cited supporting the possibility of interhuman communicability in active cases of listerellosis, thus making advisable the practice of communicable-disease precautions whenever this disease is encountered.

Clinically and at autopsy, listerellosis is characterized by a meningoencephalitic syndrome. The most usual spinal-fluid changes were increased pressure, globulin and leukocytes. A moderate neutrocytosis occurred early in the disease.

Treatment with Prontosil, sulfanilamide and sulfapyridine appears to have been successful.

MEDICAL PROGRESS

SKIN TESTS IN BACTERIAL AND VIRAL DISEASES* (Concluded)

LEWIS W. KANE, M.D.†

BOSTON

SKIN TESTS EMPLOYING BACTERIAL TOXINS

Schick Test

In 1908, Schick⁸⁵ showed that the toxin of the diphtheria bacillus is capable of eliciting dermal reactions in certain persons. His subsequent publications^{86, 87} announced that this test could be used as an index of immunity or susceptibility to diphtheria. His experiments indicated that a negative intracutaneous reaction usually means a high enough level of antitoxin to protect against the disease. The test dose of toxin was originally defined by Schick on an empirical basis as 1/50 of a guinea-pig M. L. D. (minimal lethal dose). This level was selected by him because he thought that persons who failed to react to this dose possessed sufficient antitoxin to protect them against all but the so-called "septic type" of diphtheria. In subsequent years when cases of diphtheria were reported in Schick-negative reactors there was some question whether the Schick test dose of 1/50 M. L. D. should not be increased. This problem was considered in 1931 by the Biological Standardization Commission of the League of Nations, and the 1/50 M. L. D. recommended by Schick was adopted by the commission as representing the optimal test dose. It was further recommended that Schick toxin be standardized by determining its combining power as well as its toxicity. The reason for this recommendation is that filtrates of diphtheria cultures contain varying quantities of substances that although unable to elicit the dermal reaction can combine with antitoxin. Hence, toxin standardized by means of toxicity alone varies in its ability to elicit dermal reactions, depending on the extent to which antibody has been eliminated locally by these nontoxic substances. The validity of these recommendations has been questioned by Taylor and Moloney,⁸⁸ who were unable to find that the combining power of Schick toxin had any significance for human beings with respect to the level of antitoxin detected. Furthermore, they recommended a dose of toxin containing three times the level usually employed (1/50 M. L. D.). Thus the question of the proper toxin level to be used in the Schick test is still an open one.

In 1913, Schick⁸⁶ noted that occasionally false-positive dermal reactions may occur. These reactions appeared a little earlier than the true re-

actions, reached their maximum intensity sooner and faded more quickly. Bessau and Schwenke⁸⁹ found that, when the toxin is destroyed by heat, false-positive reactions still occur. As a result of this observation, a control injection of heated toxin was introduced into the Schick test. It soon became apparent that this so-called "pseudoreaction" was due to hypersensitivity to the protein of the diphtheria bacillus. The reaction is highly specific and indicates some previous contact with the diphtheria bacillus. It is usually absent in infants and becomes more frequent as age advances. Further experience with the Schick control showed that immunizing injections often gave rise to unpleasant reactions in those exhibiting pseudoreactions. Thus the control not only came to serve as an indicator of false-positive reactions, but also indicated those subjects who might react severely to immunizing injections.

Moloney and Fraser⁹⁰ have advised employing a 1/20 dilution of diphtheria toxoid as a substitute for the heated-toxin control in the Schick test. They believe that this material is a better control, as well as an efficient indicator of those persons who will give severe reactions when immunized with toxoid. These reactions usually consist of chills, fever, general malaise, nausea and vomiting. This test has been frequently referred to as the Moloney test. Although it is of unquestioned value in determining when subjects are hypersensitive to bacterial protein, — and hence should be immunized cautiously with toxoid, — it is not a true control because the toxoid may contain one hundred times as much bacterial protein as does the Schick toxin. As a consequence of the higher bacterial protein content more persons react to the Moloney control than to the Schick control, thus making the Schick test more difficult to interpret.

The Moloney test, however, should be done on all Schick-positive subjects over the age of five who are to be immunized with toxoid.⁹¹ The 1:20 dilution of toxoid originally proposed by Moloney and Fraser was found to be too strong, and as a result a dilution of 1/100 is most generally used at present. The test is performed by injecting 0.1 cc. of a 1:100 dilution of toxoid into the volar surface of the forearm. Readings are made in twenty-four and forty-eight hours. Significant reactions consist of an area of erythema greater than 1 cm. in diameter. Bunch and his co-workers⁹² have recommended a scheme of immunization that is dependent on the degree of sensitivity to bacterial protein as demonstrated by the Moloney test.

The Schick test is performed by injecting 0.1 cc. of Schick toxin intradermally in the volar surface of the right forearm. This is controlled by injecting the same volume of heated toxin in the same manner in the left arm. Readings should be made at the end of two and of four days and are interpreted as follows:

Positive reaction. An area of erythema and infiltration measuring at least 10 mm. in diameter appears in twenty-four to thirty-six hours on the right arm and reaches its greatest intensity in four or five days. There should be no reaction on the left (control) arm. This response indicates susceptibility to diphtheria.

Positive-combined reaction. Reactions measuring at least 10 mm. are present on both arms in two days. The control reaction, however, fades by the fourth day, the time when the true reaction reaches its height. This response indicates susceptibility to diphtheria and sensitivity to diphtheria-bacillus protein.

Pseudoreaction. Reactions occur on both arms and run a similar course, reaching a peak on the second or third day and fading by the fourth. Persons showing this response are hypersensitive to diphtheria-bacillus protein but presumably immune to diphtheria.

Negative reaction. No reaction occurs, or one less than 10 mm. in one or both arms. This indicates that the subject has little or no sensitivity to diphtheria-bacillus protein and is probably immune to diphtheria.

A few reports have appeared in the literature describing cases of acute anaphylactic shock following the application of the Schick test. In 1936, Parish⁹³ described 14 cases of this character. Two of these patients were known to be sensitive to Witte peptone, an agent added to the toxin in order to stabilize it.

Following the acceptance of the Schick test dose as 1/50 M. L. D., a large number of experiments have indicated that this amount of toxin does not produce a dermal reaction on intracutaneous injection into human beings if the blood serum contains more than 1/30 unit of antitoxin per cubic centimeter. This value had for many years been generally regarded as representing the so-called "Schick level" of immunity. During the last few years, however, a number of reports have appeared indicating that this level is more accurately described by a considerably smaller amount of antitoxin. Glenny and Waddington⁹⁴ found that the Schick-negative level in guinea pigs corresponds to 1/250 unit of antitoxin per cubic centimeter of serum. Others⁹⁵ have shown that the level in man lies between 1/500 to 1/250 unit per cubic centimeter. Although Phair⁹⁶ accepts 1/100 unit of antitoxin as the threshold level, he found that 9.3 per cent cases of the Schick-positive group that he tested had sufficient antitoxin so that the test should have been negative. In addition, 7.5 per cent of the negative reactors had a level of antitoxin that should have rendered them positive. These conflicting results indicate that with the methods for measuring antitoxin now available, there is no precise Schick level of antitoxin that can be determined above which a person will be protected and below which he will be susceptible.

The failure to find a critical level of antitoxin as measured by the Schick test has cast some doubt as to its value as an index of susceptibility or immunity. Obviously only by long-continued observation of the behavior of groups of positive and negative Schick reactors can the value of this test be established. Although there are exceptions, the bulk of evidence that has accumulated since Schick's original publication in 1908 indicates that a negative Schick reaction means resistance against all *ordinary* risks of infection. This evidence is based on the following observations: there is almost no diphtheria in nurses who are Schick negative despite repeated exposures; there is an extremely low incidence of the disease in Schick-negative reactors in the population at large; virulent organisms can exist in the throats of Schick-negative reactors without producing the disease; and the results of challenge experiments add more evidence. Guthrie, Marshall and Moss⁹⁷ inoculated Schick-positive and Schick-negative persons with virulent diphtheria organisms and observed the disease in the former only. O'Brien, Okell and Parish⁹⁸ had occasion to observe an inadvertent experiment in which ten to twenty presumably lethal doses of toxin for man were injected intradermally into a known Schick-negative reactor; no symptoms occurred.

It must be kept in mind that immunity in diphtheria, as in any infectious disease, is only relative. Not only does the level of immunity fluctuate, but it may be broken down by massive infection. Despite this, the number of cases occurring in Schick-negative reactors is relatively few. O'Brien, Okell and Parish⁹⁸ followed 20,000 Schick-negative subjects for six years and were able to trace 18 cases of diphtheria, 17 of which were mild. Neale⁹⁹ reported 2 cases in Schick-negative persons, and Bauer¹⁰⁰ reported 21 cases occurring out of a total of 96,252 immunized and Schick-negative persons. Meersseman, Friess and Renard¹⁰¹ noted a 1 per cent incidence of diphtheria in a Schick-negative group numbering several thousand. Robinson and Marshall¹⁰² have observed 12 cases in which the Schick test was negative immediately prior to the onset of the disease. Underwood¹⁰³ reviewed the literature of diphtheria occurring in Schick-negative persons up to 1935 and reported 20 additional cases (1 per cent) occurring in 2761 known Schick negative reactors. In 19 of these cases the so-called "gravis" strain was isolated — an organism that is usually found in the severest cases. This suggests that the Schick test may not be an effective index of immunity against the gravis strain of organism. Many of the above reported cases were severe, showing that the disease is not always mild in Schick-negative cases. Parish and Okell¹⁰⁴ have shown that 1.1 per cent of 533 children who were originally Schick negative relapsed to a positive state within one to seven years, and 5 per cent of 440 vaccinated children relapsed during the same period. Since

SKIN TESTS EMPLOYING BACTERIAL TOXINS

Schick Test

In 1908, Schick⁸⁵ showed that the toxin of the diphtheria bacillus is capable of eliciting dermal reactions in certain persons. His subsequent publications^{86, 87} announced that this test could be used as an index of immunity or susceptibility to diphtheria. His experiments indicated that a negative intracutaneous reaction usually means a high enough level of antitoxin to protect against the disease. The test dose of toxin was originally defined by Schick on an empirical basis as 1/50 of a guinea-pig M. L. D. (minimal lethal dose). This level was selected by him because he thought that persons who failed to react to this dose possessed sufficient antitoxin to protect them against all but the so-called "septic type" of diphtheria. In subsequent years when cases of diphtheria were reported in Schick-negative reactors there was some question whether the Schick test dose of 1/50 M. L. D. should not be increased. This problem was considered in 1931 by the Biological Standardization Commission of the League of Nations, and the 1/50 M. L. D. recommended by Schick was adopted by the commission as representing the optimal test dose. It was further recommended that Schick toxin be standardized by determining its combining power as well as its toxicity. The reason for this recommendation is that filtrates of diphtheria cultures contain varying quantities of substances that although unable to elicit the dermal reaction can combine with antitoxin. Hence, toxin standardized by means of toxicity alone varies in its ability to elicit dermal reactions, depending on the extent to which antibody has been eliminated locally by these nontoxic substances. The validity of these recommendations has been questioned by Taylor and Moloney,⁸⁸ who were unable to find that the combining power of Schick toxin had any significance for human beings with respect to the level of antitoxin detected. Furthermore, they recommended a dose of toxin containing three times the level usually employed (1/50 M. L. D.). Thus the question of the proper toxin level to be used in the Schick test is still an open one.

In 1913, Schick⁸⁶ noted that occasionally false-positive dermal reactions may occur. These reactions appeared a little earlier than the true re-

actions, reached their maximum intensity sooner and faded more quickly. Bessau and Schwenke⁸⁹ found that, when the toxin is destroyed by heat, false-positive reactions still occur. As a result of this observation, a control injection of heated toxin was introduced into the Schick test. It soon became apparent that this so-called "pseudoreaction" was due to hypersensitivity to the protein of the diphtheria bacillus. The reaction is highly specific and indicates some previous contact with the diphtheria bacillus. It is usually absent in infants and becomes more frequent as age advances. Further experience with the Schick control showed that immunizing injections often gave rise to unpleasant reactions in those exhibiting pseudoreactions. Thus the control not only came to serve as an indicator of false-positive reactions, but also indicated those subjects who might react severely to immunizing injections.

Moloney and Fraser⁹⁰ have advised employing a 1/20 dilution of diphtheria toxoid as a substitute for the heated-toxin control in the Schick test. They believe that this material is a better control, as well as an efficient indicator of those persons who will give severe reactions when immunized with toxoid. These reactions usually consist of chills, fever, general malaise, nausea and vomiting. This test has been frequently referred to as the Moloney test. Although it is of unquestioned value in determining when subjects are hypersensitive to bacterial protein, — and hence should be immunized cautiously with toxoid, — it is not a true control because the toxoid may contain one hundred times as much bacterial protein as does the Schick toxin. As a consequence of the higher bacterial protein content more persons react to the Moloney control than to the Schick control, thus making the Schick test more difficult to interpret.

The Moloney test, however, should be done on all Schick-positive subjects over the age of five who are to be immunized with toxoid.⁹¹ The 1:20 dilution of toxoid originally proposed by Moloney and Fraser was found to be too strong, and as a result a dilution of 1/100 is most generally used at present. The test is performed by injecting 0.1 cc. of a 1:100 dilution of toxoid into the volar surface of the forearm. Readings are made in twenty-four and forty-eight hours. Significant reactions consist of an area of erythema greater than 1 cm. in diameter. Bunch and his co-workers⁹² have recommended a scheme of immunization that is dependent on the degree of sensitivity to bacterial protein as demonstrated by the Moloney test.

These conflicting results indicate that with the methods for measuring antitoxin now available, there is no precise Schick level of antitoxin that can be determined above which a person will be protected and below which he will be susceptible.

The failure to find a critical level of antitoxin as measured by the Schick test has cast some doubt as to its value as an index of susceptibility or immunity. Obviously only by long-continued observation of the behavior of groups of positive and negative Schick reactors can the value of this test be established. Although there are exceptions, the bulk of evidence that has accumulated since Schick's original publication in 1908 indicates that a negative Schick reaction means resistance against all ordinary risks of infection. This evidence is based on the following observations: there is almost no diphtheria in nurses who are Schick negative despite repeated exposures; there is an extremely low incidence of the disease in Schick-negative reactors in the population at large; virulent organisms can exist in the throats of Schick-negative reactors without producing the disease; and the results of challenge experiments add more evidence. Guthrie, Marshall and Moss⁹⁷ inoculated Schick-positive and Schick-negative persons with virulent diphtheria organisms and observed the disease in the former only. O'Brien, Okell and Parish⁹⁸ had occasion to observe an inadvertent experiment in which ten to twenty presumably lethal doses of toxin for man were injected intradermally into a known Schick-negative reactor; no symptoms occurred.

It must be kept in mind that immunity in diphtheria, as in any infectious disease, is only relative. Not only does the level of immunity fluctuate, but it may be broken down by massive infection. Despite this, the number of cases occurring in Schick-negative reactors is relatively few. O'Brien, Okell and Parish⁹⁸ followed 20,000 Schick-negative subjects for six years and were able to trace 18 cases of diphtheria, 17 of which were mild. Neale⁹⁹ reported 2 cases in Schick-negative persons, and Bauer¹⁰⁰ reported 21 cases occurring out of a total of 96,252 immunized and Schick-negative persons. Meersseman, Friess and Renard¹⁰¹ noted a 1 per cent incidence of diphtheria in a Schick-negative group numbering several thousand. Robinson and Marshall¹⁰² have observed 12 cases in which the Schick test was negative immediately prior to the onset of the disease. Underwood¹⁰³ reviewed the literature of diphtheria occurring in Schick-negative persons up to 1935 and reported 20 additional cases (1 per cent) occurring in 2761 known Schick negative reactors. In 19 of these cases the so-called "gravis" strain was isolated — an organism that is usually found in the severest cases. This suggests that the Schick test may not be an effective index of immunity against the gravis strain of organism. Many of the above reported cases were severe, showing that the disease is not always mild in Schick-negative cases. Parish and Okell¹⁰⁴ have shown that 1.1 per cent of 533 children who were originally Schick negative relapsed to a positive state within one to seven years, and 5 per cent of 440 vaccinated children relapsed during the same period. Since

several of the reported cases of diphtheria in Schick-negative reactors were not retested at close intervals, it is possible that the subjects had become Schick positive prior to the onset of the disease.

In summary, it may be stated that although there are reported failures, a negative Schick test usually means sufficient degree of immunity to protect against diphtheria. It is well known that there are persons who, having had an adequate primary stimulus but having lost with the lapse of time most of their demonstrable antitoxin, nevertheless react after exposure with the production of antitoxin rapidly enough to protect against the disease. This is seen in a number of persons who become Schick negative after the injection of the minute amount of toxin used in the Schick test. This of course is likeliest to occur in adults who have had repeated subclinical exposures. It is believed at present that a positive Schick test in adults does not necessarily mean susceptibility, whereas it is a much closer index of susceptibility in children.

Dick Test

In 1924, the Dicks¹⁰⁶ injected 0.1 cc. of a 1:1000 solution of beta-hemolytic streptococcus toxic filtrate intradermally into a number of persons and found that those with no past history of scarlet fever gave an inflammatory response more frequently than did those with positive histories. They also found that this filtrate could be neutralized by convalescent scarlet-fever serum. On this basis they suggested that the skin test could be used as an index of immunity or susceptibility to scarlet fever.^{*106} They later reported 20,856 subjects who were Dick negative and went through repeated exposures to scarlet fever without contracting the disease.¹⁰⁷ Despite these rather impressive figures, not infrequent reports have appeared in the literature from time to time describing scarlet fever in Dick-negative reactors.¹⁰⁸⁻¹¹¹ Since the Dick test measures only antitoxic immunity, a cause of the apparent failure of the Dick test may be that there is more than one antigenic strain of erythrogenic toxin.¹¹²⁻¹¹⁴ Theoretically, infection with a streptococcus producing an erythrogenic toxin different from that used in the Dick test could produce a rash in Dick-negative reactors. Another possible source of false-negative reactions is the use of toxin of inferior potency because of the difficulty in standardizing the erythrogenic toxin. Despite the reported failures, it is generally believed that the Dick test is reliable enough to be used as an index of immunity to the rash of scarlet fever. There is no convincing evidence that Dick-negative reactors are less susceptible to streptococcal infections than Dick-positive ones.

Schwentker, Janney and Gordon¹¹⁰ have recently reported their careful study of a scarlet-fever and

tonsillitis epidemic in Rumania that was caused by a Type 10 hemolytic streptococcus. They have clearly shown that although a negative Dick test usually indicates immunity to scarlet fever, a positive reaction does not necessarily mean susceptibility. Thus, in the group who became asymptomatic carriers of the type of streptococcus responsible for the then current scarlet-fever epidemic, there were equal numbers of Dick-positive and Dick-negative reactors. It therefore appears that whether the organism survives in the throat does not depend on the level of antitoxin present. Whether illness does develop apparently depends on the presence or absence of antibacterial immunity. The subsequent clinical character of the infection, however, is determined by the level of antitoxic immunity. Thus, Schwentker and his co-workers¹¹⁰ have found that 90 per cent of their patients with tonsillitis were Dick negative, whereas 32 of the 34 persons who developed scarlet fever had positive reactions.

It is now recognized that the toxic component of the streptococcus is responsible for the enanthem, exanthem and constitutional reactions found in scarlet fever, characterized by vomiting, generalized lymphadenopathy, arthralgia and albuminuria. Although precise information is lacking, there is no incontrovertible evidence that persons with a negative Dick test are less likely than others to develop septic complications following streptococcal infections. To establish this point definitely it would be necessary to observe an epidemic of scarlet fever and tonsillitis caused by the same type of streptococcus. Although this was done by Schwentker and his co-workers,¹¹⁰ they gave no clinical description of their cases. Stebbins, Ingraham and Reed¹¹⁵ found that complications following a milk-borne epidemic of streptococcal pharyngitis (and hence presumably caused by the same type) were as frequent in those with a rash as in those without one. Hobson¹¹⁶ concluded that complications were even more frequent when a rash was absent.

The Dick test should probably always be controlled with heat-inactivated toxin, since pseudo-reactions occur as they do with the Schick test. But the Dick-test material dispensed commercially contains no control material, since it is thought that if broth filtrates of high toxin content are used the protein elements will be sufficiently diluted in the final test material to eliminate the false reactions. It is believed that the pseudoreactions are due to streptococcal protein and are unrelated to the toxin. Unlike the true Dick reaction and like the pseudo-Schick reaction, it is more frequent with advancing age and is found oftener in communities where scarlet fever is or has recently been epidemic.

The Dick test is performed by injecting 0.1 cc. of toxin intradermally into the volar surface of the forearm. The reaction is read in twenty-four hours. An area of erythema measuring at least 1 cm. is

*The reverse of this test is the Schultz-Charlton phenomenon, in which the intradermal injection of immune serum blanches the rash of scarlet fever.

considered a positive reaction. The skin-test dose has been established by the Scarlet Fever Committee as representing the least amount of toxin to which all susceptible persons react positively. This has been determined by skin-testing a large number of children of different ages.

SKIN TESTS EMPLOYING ANTIGENS OF VIRAL ORIGIN

Despite the fact that the change in dermal sensitivity following infection was first demonstrated with a virus (vaccinia), it has only been in recent years that skin reactions with antigens of viral origin have been employed. Lymphogranuloma inguinale is the only viral disease in which a skin test is now widely employed as a diagnostic aid. Recently, investigators have shown that a dermal reaction may be elicited in persons convalescent from mumps. This test has proved of great aid in determining susceptibility or immunity to mumps. Beveridge and Burnet¹¹⁷ and Kane¹¹⁸ have independently shown that dermal allergy can be elicited in persons convalescent from influenza. Whether this reaction can be used to determine susceptibility has not been established. With improved methods for growing viruses in high titer, there is reason to believe that skin reactions will be employed with increasing frequency in viral diseases.

Frei Test

Frei's¹¹⁹ introduction of his test in 1925 made possible the exact diagnosis of lymphogranuloma inguinale and demonstrated that a number of conditions previously considered to be unrelated were diverse manifestations of infection with the virus of lymphogranuloma inguinale. As antigen, Frei used heat-inactivated pus obtained from the unruptured buboes of a patient with lymphogranuloma inguinale. Because of the difficulty in obtaining sufficient material and the possibility that other infectious agents are included, as well as the variation in antigen content, the use of pus from human buboes had major limitations that precluded its widespread use.

Following the demonstration that the virus of lymphogranuloma inguinale can be grown on intracerebral inoculation in mice, Wassen¹²⁰ introduced the mouse-brain antigen as a substitute for human pus in the performance of the Frei test. Further experience with this material showed that because of the nonspecific reactions obtained, mouse brain was unsuitable for skin testing.¹²⁰⁻¹²² When Rake and his co-workers¹²³ grew the virus of lymphogranuloma inguinale in high titer in the yolk sac of the developing chick embryo, the problem of securing a cheap and ready source of virus was solved. Grace and his co-workers¹²⁴ showed that this material gave satisfactory and specific dermal reactions in patients infected with the virus of lymphogranuloma inguinale. Further experience has shown the yolk-sac antigen

to be reliable and to be superior to mouse brain in eliciting the dermal response in infected persons.^{125, 126} There is some evidence, however, that it may give more false-positive reactions and is less sensitive than human pus.¹²⁷⁻¹²⁹ The former product is now available commercially under the name of Lymphogranum.

Extensive surveys have shown the Frei test to be positive in a high percentage (90 to 95 per cent) of persons known to have been infected with the virus of lymphogranuloma inguinale.¹³⁰⁻¹³³ In any group of persons picked at random, however, a number with no history or physical signs of the disease react positively to the antigen.^{126, 134} This has been explained on the basis of a latent or veiled infection. Although it is true that accidental laboratory infections in those working with the virus have been acquired via the respiratory tract and the skin of the hand,¹³⁵ and that such cases may go unrecognized, there is no evidence that this route of infection occurs in the naturally acquired disease. The question therefore arises whether the positive reactions in persons with no history or physical signs of the disease indicate unrecognized infections or are false-positive reactions. Recently attention has been called to the fact that there is a close antigenic relation between the viruses of lymphogranuloma inguinale, psittacosis, meningopneumonitis, trachoma, inclusion blenorhea, and the atypical pneumonia virus of Eaton.¹³⁶⁻¹³⁸ Positive Frei reactions have been obtained in cases of atypical pneumonia due to Eaton's virus.¹³⁷ Favour¹³⁹ observed a positive reaction in 1 of 4 cases of ornithosis that he tested. In this case the question of a previous infection with the virus of lymphogranuloma inguinale was eliminated on the basis of the history and physical examination. Although it is true that the incidence of positive Frei reactions is higher in persons exposed to venereal disease who give no history or physical signs of lymphogranuloma inguinale, to establish definitely the specificity of the Frei test the frequency of the occurrence of positive reactions in persons infected with the above viruses should be determined. Until this is done, there is reason to question some of the positive reactions obtained in persons who have had no history or physical signs of infection with the virus of lymphogranuloma inguinale.

There is a great deal of variation in the literature concerning when the Frei test becomes positive following infection. Reports have varied from one week to six months.¹⁴⁰⁻¹⁴³ Wassen¹⁴⁰ experimentally infected a number of volunteers and found that the Frei test became positive as early as the sixth day following the appearance of the lesions. Harrop, Rake and Shaffer¹³⁵ noted positive reaction as early as five to nine days following the symptoms in accidental laboratory infections. Reversal of the Frei test has been observed in persons who were intensively treated with chemotherapy early in the disease.

Since a positive Frei test persists for years, possibly for life, a positive reaction does not necessarily mean that a given disease under consideration is due to infection with the virus of lymphogranuloma inguinale. Also, a negative reaction does not necessarily mean that it can be ruled out, since unmistakable cases have been reported with negative reactions to potent antigens.¹⁴⁴ In these cases diagnosis may be established by using the so-called "inverted Frei test." In this test pus from the infected patient injected into persons known to be Frei positive induces a positive dermal reaction.

The Frei test is performed by injecting 0.1 cc. of the antigen intradermally in the forearm. A control injection, consisting of the same volume of uninfected chick-embryo material, is performed in the other arm. A positive reaction consists in the presence of an area of infiltration or a nodule measuring

fection, 50 per cent gave positive reactions. That these were not false-positive reactions is shown by the fact that 96 per cent of this group had mumps complement-fixing antibodies. This supports the suspicion based on epidemiologic grounds that inapparent mumps infection is not infrequent. I have observed 1 such case in a laboratory worker who was constantly exposed to mumps virus. She was known to have had no mumps complement-fixing antibodies and was skin-test negative, and hence was considered to be susceptible. Two months after she began working with the virus she complained of general malaise and ill-defined sensations in the left parotid gland. No salivary-gland involvement was discernible at any time. Shortly thereafter she developed complement-fixing antibodies and became skin-test positive.

Since mumps was observed only twice in several

TABLE 1. *Data on Skin Tests Employing Antigens of Bacterial and Viral Origin.*

TEST	MATERIAL EMPLOYED	TIME READ	SIZE OF POSITIVE REACTIONS	INTERPRETATION OF POSITIVE REACTIONS
Tuberculin	P. P. D. or O. T.	48 hr.	Edema and erythema greater than 5 mm.	Previous infection
Brucellergen	Brucellergen	48 hr.	Edema and erythema greater than 5 mm.	Previous infection

Pertussis	Detoxified agglutinin	15 min. and 24 hr.	Wheal in 30 min. or induration and erythema greater than 10 mm. in 24 hr.	Questionable immunity
Tularemia	Detoxified antigen	48 hr.	Edema and erythema greater than 10 mm.	Previous infection
Francis	Specific pneumococcus carbohydrate	15 min.	Wheal and erythema	Excess circulating antibody
Influenza-bacillus infection	Specific influenza-bacillus carbohydrate	15 min.	Wheal and erythema	Excess circulating antibody
Schick	Diphtheria toxin	48 and 96 hr.*	Edema and erythema greater than 10 mm.*	Susceptibility
Dick	Erythrogenic streptococcus toxin	24 hr.	Erythema greater than 10 mm.	Susceptibility to erythrogenic toxin
Frei	Inactivated lymphogranuloma-inguinale virus	48 hr.	Induration at least 5 or 6 mm.	Previous infection
Enders	Inactivated mumps virus	24 and 48 hr.	Erythema greater than 10 mm.	Immunity

*There is a great deal of variation in the literature as to what should be considered a minimal positive reaction. There is also variation as to when the test should be read.

at least 5 or 6 mm. in diameter that is present at the end of forty-eight or seventy-two hours. The control reaction should not measure more than 3 mm. If the test is negative at the end of seventy-two hours, it is necessary to examine the area at intervals of several days, since a delayed reaction occasionally occurs.

Enders Test

Using as antigen a heat-inactivated suspension of the parotid gland of a monkey infected with the virus of mumps, Enders, Cohen and Kane¹⁴⁵ were able to demonstrate the development of dermal hypersensitivity in persons convalescent from mumps. In a systematic survey of almost 300 students at the Harvard Medical School a dermal reaction consisting of an area of erythema measuring at least 10 by 10 mm. was obtained in 96 per cent of those students who had a definite past history of mumps.¹⁴⁶ Of those who denied any previous in-

fection, 50 per cent gave positive reactions. That these were not false-positive reactions is shown by the fact that 96 per cent of this group had mumps complement-fixing antibodies. This supports the suspicion based on epidemiologic grounds that inapparent mumps infection is not infrequent. I have observed 1 such case in a laboratory worker who was constantly exposed to mumps virus. She was known to have had no mumps complement-fixing antibodies and was skin-test negative, and hence was considered to be susceptible. Two months after she began working with the virus she complained of general malaise and ill-defined sensations in the left parotid gland. No salivary-gland involvement was discernible at any time. Shortly thereafter she developed complement-fixing antibodies and became skin-test positive.

Since mumps was observed only twice in several hundred persons who had a definitely positive skin test (an area of erythema greater than 10 by 10 mm. in twenty-four hours), it is clear that an inapparent infection will produce as solid an immunity as an overt attack. Accordingly, the demonstration of a positive dermal reaction with rare exception means immunity. In the last three years over 1500 skin tests have been performed without unpleasant local or general reactions of any description. Sixty-eight cases of mumps have been recorded in this group. In 57 of these there was either no dermal reaction or its area measured less than 2 by 2 mm. in diameter. In 8 cases areas were observed that ranged between 2 by 2 mm. and 10 by 10 mm. In only 3 cases was the area greater than 10 by 10 mm. If one accepts an area of erythema of 10 by 10 mm. or less as indicating susceptibility, then 95 per cent of those who eventually developed mumps were susceptible as determined by the intradermal test. Of several hundred persons who were found to have

reactions greater than 10 by 10 mm. in twenty-four hours, only 3 developed mumps*. It is therefore believed that a reaction greater than 10 by 10 mm. with rare exception means immunity against the mumps virus. The intradermal test is of no value as an aid in diagnosis, since the interval when a positive reaction is first observed may vary from several days to three months after the onset of the disease. Once hypersensitivity is established, it apparently persists for life.

Within the last few months the virus of mumps has been grown in the yolk sac of the developing egg embryo. This virus has been reported as giving reliable dermal reactions in immune persons¹⁴⁷. Should this prove to be so, a cheap and ready source of virus for skin testing should shortly be available.

* * *

The pertinent data on the practical application of the tests discussed in this review are summarized in Table 1.

*False-negative tests have been observed in about 2 per cent of the persons considered to be immune on the basis of positive complement-fixation tests

CASE 31261

PRESENTATION OF CASE

A thirteen-month-old boy was admitted to the hospital because of the sudden appearance of a mass on the right side of the neck.

The child had been well until five weeks before admission, when he awakened one morning crying more than usual. The mother sensed that something was wrong, but the temperature was normal. At 11:00 a.m. the temperature had risen to 104°F. and the child was rushed to a hospital. A diagnosis of early pneumonia was made. He was given sulfadiazine, and the temperature returned to normal in two days. On the third hospital day an orange-sized mass suddenly appeared on the right side of the neck. This was aspirated, and the neck again appeared normal. X-ray examination demonstrated a mass in the upper mediastinum pressing on the trachea. There was no discharge from the site of aspiration, and no return of the swelling in the neck. On the seventeenth hospital day the child was discharged to his home, asymptomatic. Approximately two weeks later, with no recurrence of complaints, he was admitted to this hospital for further study.

The child had been delivered at term with no difficulty and without forceps. The birth weight was 7½ pounds. He was breast fed for only one week and thereafter, until eleven months of age, was maintained on an evaporated milk Dextrimaltose formula, adequately supplemented with vitamins. At one year he weighed 25 pounds. One week before the onset of the present illness he had one injection of diphtheria-tetanus toxoid.

Physical examination revealed a well nourished boy who was well developed for his age. He had a lusty cry and no apparent respiratory difficulty. He weighed 25½ pounds and measured 75 cm. in length. The skin was normal. The pupils were normal and reacted to light. Four incisors above and below, and a right lower premolar were present. There was abnormally profuse drooling of saliva from the mouth. The right side of the neck just above the clavicle was fuller than the left. A blunt, soft, smooth, oval, nontender mass about 4 cm. in diameter lay anterior to and appeared to merge with the right sternocleidomastoid muscle. This mass

was thought not to move with swallowing. It presented no bruit or pulsation. The lungs were clear except for a few fine crepitant rales over the right upper lobe. The heart had normal position, size, rate, rhythm and sounds. The abdomen and extremities were normal.

The temperature, pulse and respirations were normal. The blood pressure was 105 systolic, 80 diastolic.

Examination of the blood showed a red-cell count of 4,200,000, with 12.2 gm. of hemoglobin, and a white-cell count of 13,600, with 70 per cent neutrophils, 28 per cent lymphocytes and 2 per cent monocytes. The urine was normal.

An x-ray examination of the chest showed a homogeneously dense mass in the right upper posterior chest that measured approximately 4 by 4 cm. in diameter (Fig. 1). It displaced the trachea to the right and anteriorly. There was no definite evidence of collapse of the upper lobe. The vertebral bodies and ribs showed no evidence of erosion. The heart shadow appeared to be normal. A barium swallow during fluoroscopy showed the esophagus to be displaced to the left by the mass both above and below the manubrium. Whether the esophagus was displaced backward or forward could not be determined.

The temperature, pulse and respirations and the appearance of the neck remained unchanged. The blood was grouped and crossmatched, and on the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. NATHAN B. TALBOT: One may introduce the discussion of this case by commenting that, with the information at hand, it is not going to be possible to make anything more than a tentative diagnosis. Had we been given information concerning the nature of the fluid aspirated from the mass in the neck, it might have been easier to make a reasonably accurate diagnosis. Had the fluid removed when the child was seen first been replaced by some radio-opaque material, such as iodide solution, valuable information concerning the size, connections and geography of the mass might have been obtained. Transillumination of the cervical mass at that time might have been helpful, for it should have distinguished between blood and clear fluid. It would also have been of interest to know whether the cervical mass was reduced by gentle pressure and whether such a procedure prompted a change in the size of the thoracic mass. In other words it may be possible to make a fairly accurate pre-operative diagnosis in such cases as this if advantage is taken of relatively simple procedures. Despite the paucity of information, certain possible diagnoses may be considered.

It seems probable that the mass in the neck was cystic, that the mass in the thorax was part of the same structure and that the mass was present prior

*On leave of absence.

to the episode of pneumonia, which perhaps through some mechanism induced a sudden increase in its size and hence called attention to its presence. It appears from the history that this lesion had not interfered seriously with the development of the child, since the measurements recorded are normal for an infant of his chronologic age. There was little to suggest that the process was inflammatory, since the temperature and pulse were not strikingly abnormal, and there was only a slight leukocytosis. Incidentally, no tuberculin test is recorded.

It is in this age group that congenital malformations frequently make themselves known. Of the cystic swellings of congenital origin that present in

DR. SCHULZ: At least some of it lies posteriorly and displaces the trachea anteriorly as well as to the left, and one may assume that it arises outside the lung rather than in it.

DR. TALBOT: Can you see continuity of the mass in the chest with that of the neck?

DR. SCHULZ: It is difficult to be sure about the mass in the neck; there is no demarcation between the visible mass and any mass that may be present in the neck, for it is the same density as the normal soft-tissue structures of the neck.

DR. TALBOT: There are no sharp outlines and no shadows suggestive of teeth, bone or anything of that sort?

FIGURE 1. Roentgenogram of Chest.

the anterior cervical triangle, branchial-cleft cysts and thyroglossal-duct cysts may be mentioned. Had the swelling presented in the posterior cervical triangle these could have been almost automatically ruled out. Although they cannot be completely discarded in the present case, I believe that they are unlikely diagnoses because of the fact that the cervical mass probably extended into or took origin in the posterior mediastinum. Incidentally, the mass did not move on palpation, which rules further against a thyroglossal duct.

May we look at the x-ray films?

DR. MILFORD D. SCHULZ: Here you see this rather sharply outlined mass in the right upper chest displacing the trachea anteriorly and to the left.

DR. TALBOT: Can we say it is a posterior mediastinal mass?

DR. SCHULZ: No.

DR. TALBOT: If we assume that there was a posterior mediastinal mass, not apparently of pulmonary origin or at least not seriously impairing upper or lower respiratory function, we can discard the possibility of lung cyst. We are left with certain other possibilities.

The first of these is cystic hygroma, which is a cystic overgrowth of lymph channels due to a developmental disarrangement of the tissues. It often originates in the neck and may extend upward toward the ears or jaw or downward into the chest.¹ This diagnosis cannot be ruled out.

Secondly, one might consider the presence of a teratoma of mediastinal origin. These usually have a dense wall and occasionally show areas of calcification, although I gather they are less likely to

do so in this region than in other parts of the body.

The mass might have represented cystic degeneration of a variety of mediastinal tumors. It is said, however, that in such a lesion there is often some remaining solid and hence palpable tissue, which gives a clue to the diagnosis. No solid tissue was described in the present case.

Next the possibility arises that the mass was an arteriovenous aneurysm. The only finding in favor of this diagnosis is the blood pressure, which was slightly to moderately elevated. On the other hand the heart was of normal size, which rules quite strongly against this diagnosis. It also seems most unlikely that blood was aspirated from the mass, since no mention of such a potentially important fact was made. A deeply seated hemangioma would also yield blood on aspiration.

There remains one other interesting possibility, an esophageal duplication or mediastinal cyst of enteric origin.² These may be silent for a period of time but are usually recognized during infancy. Cough, dyspnea, cyanosis and recurrent or chronic pneumonia are the usual presenting complaints and when present are due to pulmonary compression. Dysphagia and regurgitation of feedings occur when there is impingement on the esophageal lumen. In this connection it is of interest that the child was said to drool abnormally. Although this seems an extraordinary remark when applied to an infant of this age, it may have been inserted to provide us with a clue or — and such would not be unique in these meetings — as a sort of red herring. Incidentally, pain such as this patient apparently had at the onset of the illness may be caused by distention of the walls with suddenly increased intracystic pressure. In such cystic structures, infection such as this patient had may in some manner lead to obstruction of the normal lymph channels, with consequent rapid enlargement. Finally, the x-ray findings are characteristic of a posterior mediastinal tumor or cyst. Fluoroscopy, as in this patient, shows no fistulous connection. Although they occasionally erode the vertebrae, there was no evidence of that here.

In conclusion it is fair to say that the most important point in such a case as this is that surgical exploration should be carried out for the purposes both of an accurate diagnosis and of potentially corrective procedures. I should place mediastinal cyst of enteric origin as my first choice, and cystic hygroma as my second.

DR. BENJAMIN CASTLEMAN: Dr. Sweet, you operated on this child. Will you describe your findings?

DR. RICHARD H. SWEET: This was an amazing tumor in many ways. My preoperative diagnosis was a cyst of enteric origin, the so-called "reduplication" that Dr. Ladd talks about. I know enough about mediastinal tumors to appreciate that one can rarely make an accurate diagnosis ahead of time.

The fluid aspirated from the cyst within the neck was reputed to have been clear. That information obviously was not in the case history as presented.

The tumor was filled with cystic loculations, which contained watery fluid. It was an enormous tumor, considering the size of the child. Anatomically it covered a large surface, and in freeing it we disclosed a great many structures. The operation was a lesson in anatomy. It extended to the azygos vein and right main bronchus. Posteriorly it was necessary to denude the first and second ribs, the actual rib periosteum being removed with the tumor. It was an adherent tumor, and in taking it out we exposed and divided the first intercostal nerve and the highest intercostal artery, which are rarely seen. When we dissected the tumor medially we found that, although it was not an invasive tumor, it at least had surrounded all the structures and had grown around the innominate vein and innominate artery. In order to get the subclavian artery and other structures away from it I had to incise the tumor and peel it off one side one way and the other side another way. In doing that I exposed the right vagus nerve and the right recurrent laryngeal nerve and the cords of the brachial plexus as they crossed over the first rib. It was also adherent to the esophagus, and there was a portion of it that extended to the left behind the heart and great vessels, which I did not get. There was a portion within the neck, which I could not possibly remove because it had grown around all the structures there and I could not dissect beyond the confines of the superior portion of the chest.

CLINICAL DIAGNOSIS

Mediastinal cyst of enteric origin.

DR. TALBOT'S DIAGNOSIS

Mediastinal cyst of enteric origin.

ANATOMICAL DIAGNOSIS

Hygroma colli cysticum.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Dr. Sweet has outlined extremely well the gross penetrating character of the tumor. Microscopically this same feature was evident. The tumor was composed of multilocular cystic spaces of varying sizes, all of which were lined with flattened endothelial cells, namely, the structure of lymph vessels. It was then a true cystic hygroma, which is a form of lymphangioma and apparently arises from lymphatic rests, derived from the jugular lymph sac. Scattered in between some of the cystic spaces were many large nerves and blood vessels, which were apparently being surrounded and engulfed. This appearance is in keeping with Goetsch's³ exhaustive study of these hygromas. He showed that they grow and propagate by the sprouting from the cyst walls of endothelial-lined membranes that

continue to secrete and form more cystic spaces, and so on. As it continues to grow, it engulfs muscles, nerves and blood vessels, which accounts for the operative findings in this particular case. In Goetsch's series of 12 cases most of the tumors were in the neck and had not invaded the mediastinum. He also made the statement that the prognosis is poor in those cases in which the tumor goes down in the mediastinum. One case in his series responded well to x-ray treatment, so that perhaps it would be worth while to give the patient postoperative x-ray treatment.

DR. SWEET: It was obvious to me when I had exposed the tumor and had begun the dissection that it was one that could not be totally removed.

DR. TALBOT: What was the postoperative course?

DR. SWEET: The patient made an excellent recovery and went home. The only evidence of the operation, except for the scar, is that he has a Horner's syndrome.

DR. CASTLEMAN: But you expected that after the operation.

DR. SWEET: Yes; I wrote it in my operative note that I had interrupted the sympathetic chain, the intercostal artery and the first intercostal nerve.

DR. SCHULZ: When giving x-ray treatment it should be borne in mind that one might destroy the epiphyseal growth in a child of this age.

DR. CASTLEMAN: Has the child any symptoms of a mediastinal tumor?

DR. SWEET: No.

CASE 31262

PRESENTATION OF CASE

A seventy-two-year-old man was brought to the hospital because of hematemesis, tarry stools and a loss of consciousness.

About fifteen years before entry the patient began to suffer financial reverses and developed abdominal symptoms, which were attributed to a peptic ulcer. Ten years before admission he was treated at another hospital for a bleeding ulcer. He followed the prescribed diet sporadically and acquired such poor eating habits that four years later he was again admitted because of quite marked skin and other systemic changes consistent with severe nutritional deficiency. He responded well to an improved dietary regime but continued with periodic and vague epigastric symptoms, which included mild distress and a feeling of marked gaseous distention after meals. Four years before admission he passed

tarry stools for two weeks. He was treated at home with bedrest and a bland diet. From then until the time of admission to this hospital he had continued on a fairly well supervised, bland diet. Three and a half years before entry a gastrointestinal series showed a constant deformity at the base of the duodenal cap near the pyloric sphincter, with an ulcer at this point measuring 6 mm. in its greatest diameter. Another gastrointestinal series a month later showed some decrease in the size of the ulcer. A year later, or two years before admission, another gastrointestinal series showed a small 1-mm. ulcer niche, which was probably on the lesser curvature side at the pylorus. There was some deformity of the duodenal cap. Three days before admission he vomited a cupful of coffee-grounds fluid and began to have loose tarry stools, with increased epigastric pains. On the day of entry he fainted shortly after complaining of pain in his left leg. On regaining consciousness he complained of weakness and cold perspiration. Six years before admission he began having pain in the arms radiating to the shoulders. These pains came on when he walked in a cold wind or at the onset of any exertion. When severe this pain was promptly relieved by nitroglycerin. At that time the blood pressure was 158 systolic, 100 diastolic. Four years before admission he complained of substernal oppression on exertion, with less pain in the arms and shoulders. The blood pressure was 145 systolic, 85 diastolic. During the four years before admission, the substernal pains varied in frequency and severity. They were worse in cold, damp or extremely hot weather. Nitroglycerin for severe pains and barbiturate sedation continually afforded considerable relief. A long blowing systolic apical murmur was unchanged during the six years before entry. The heart size was consistently thought to be on the upper limit of normal by percussion and auscultation. The pulse was 75 to 80 and regular, and the blood pressure was quite constant at about 140 systolic, 80 diastolic. An electrocardiogram three months before admission showed a normal rhythm with a rate of 85, sagging ST₁ and ST₂, inverted T₁, diphasic T₂, low upright T₃, wide slurred QRS complexes measuring 0.14 to 0.16 second, occasional ventricular premature beats, deep S₂, small R in Leads CF₂ through CF₄, notched or bifid upright QRS in Lead CF₅, upright T waves in Leads CF₂ through CF₄ and inverted T waves in Lead CF₅.

Physical examination revealed a well developed, fairly well nourished man. The chest was moderately emphysematous. The skin was pale, cold and clammy. He was stuporous but was able to obey commands. There was a sagging but not a complete paralysis of the left face, and no apparent paralysis of the extremities. The lungs were clear. No heart sounds could be heard. The heart was not enlarged to percussion. The abdomen was soft, slightly tympanitic but not markedly distended; peristalsis

was diminished. The liver and spleen could not be felt.

The temperature was normal, the pulse not obtainable, and the respirations were 25. The blood pressure was not obtainable.

Examination of the blood showed a red-cell count of 1,960,000. After two whole-blood transfusions the red-cell count was 3,600,000, and the white-cell count 10,700, with 66 per cent neutrophils. A glove specimen of stool was tarry and gave a +++ guaiac test. Blood drawn after the transfusions showed a serum nonprotein nitrogen of 94 mg. per 100 cc., a fasting blood sugar of 137 mg. and a protein of 6.4 gm.

During the first twenty-four hours the blood pressure was periodically obtainable and rose on one occasion to 85 systolic, 50 diastolic. After the first twenty-four hours, despite whole-blood transfusions, the blood pressure was only rarely obtainable, reaching 100 systolic, 65 diastolic, on one occasion. The pulse was extremely weak when obtainable and remained between 80 and 100. During the first twenty-four hours he complained of epigastric and low substernal pain. He had no bowel movements and did not vomit. A Levine tube afforded relief from gaseous distention and abdominal discomfort. It brought up a small amount of blood in about 500 cc. of thin gastric contents. The urine gave + to ++ tests for albumin; the sediment showed an occasional red and white cell and a few hyaline casts.

Early on the second day the patient was digitalized with Cedilanid. An electrocardiogram a few hours later showed normal rhythm, at a rate of 120, a PR interval of 0.22 second, inverted T₁, upright T₂ and T₃, with slurred QRS complexes that measured 0.12 second, small R and deep S waves in Leads CF₁ through CF₄, and upright wide QRS in Lead CF₅ with inverted T waves. The blood pressure and pulse were again not obtainable near the end of the second day. The lungs were filled with rales, and the liver was enlarged.

The patient became cyanotic and comatose and expired quietly approximately forty-eight hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. DAVID HURWITZ: We are dealing with an elderly man whose history points to both severe gastrointestinal and cardiovascular disease. He had had ulcer symptoms for fifteen years and gastrointestinal bleeding off and on for ten years. X-ray confirmation of the ulcer was obtained three and a half years before entry, and subsequent x-ray examination showed evidence of healing. The last gastrointestinal series, two years before admission, demonstrated the presence of an ulcer that seems to have been in a somewhat different location than the one originally described. Are these films available?

DR. MILFORD D. SCHULZ: This 5-mm. fleck probably represents the ulcer crater that was described; it appears to be in the base of a severely deformed duodenal bulb, but it is difficult to be certain where the pylorus is. On the examination a month later the crater is slightly smaller. On the last examination a quite small ulcer is seen that occupies a position comparable to that previously described.

DR. HURWITZ: For the final two years there is no record of further gastrointestinal bleeding or distress until three days before entry, when he vomited blood and passed tarry stools. I think that the evidence for a bleeding peptic ulcer is excellent. The long duration of the recurrent hemorrhages and the x-ray evidence make ulcer by far the best possibility. The duration, x-ray findings and apparent freedom of significant symptoms for two years are certainly against neoplasm. There is also nothing pointing to bleeding esophageal varices.

In addition to the ulcer symptoms he had a six-year history of exertional substernal pain relieved by nitroglycerin. I think that we may call this angina without much question. "Pain in the arms radiating to the shoulders" is unusual, but later the symptoms became more typical. The blood pressure was not remarkable for his age. The electrocardiogram showed definite evidence of myocardial disease. From the description, I take it that he had left bundle-branch block. From the history and electrocardiogram, then, we can say that he had coronary heart disease.

On admission, he appears to have been in shock. His face showed "a sagging but not a complete paralysis of the left face." It is difficult to ascribe much significance to this in such an acutely ill patient. There is no further mention of pain in the leg. I assume that it did not recur. Apparently he remained in shock until death, in spite of transfusions.

The positive laboratory findings are, first, a severe anemia, which was improved by transfusions, and, secondly, an elevated nonprotein nitrogen. The latter is a frequent finding in cases of severe bleeding into the gastrointestinal tract. It occurs within twenty-four hours of the bleeding and, when markedly elevated, is considered to be a poor prognostic sign. Whether the elevation of the nonprotein nitrogen is due solely to absorption of blood from the intestinal tract or to the effects of acute blood loss, dehydration, shock and poor renal function is not clear. Perhaps a combination of all these factors is present. A blood sugar level of 137 mg. per 100 cc is ordinarily suggestive of diabetes but is not particularly significant in an elderly patient in shock who possibly was given some intravenous glucose with his transfusions during the preceding night. The urinary findings are consistent with what one would expect in a patient in shock. The electrocardiogram after Cedilanid shows a prolonged PR and a prolonged QRS, although the latter was

shorter than it was before entry. These findings are indicative of coronary disease, without pointing toward an acute process.

Severe hemorrhage from an ulcer that has eroded a sclerotic vessel can produce the major clinical picture alone. No added condition is necessary. It is interesting, however, to speculate on what effect, if any, the severe hemorrhage had on his coronary heart disease. It is known that severe blood loss may further increase coronary insufficiency and may result in irreversible myocardial changes, which, if of sufficient duration, may result in myocardial infarction. Is there any evidence of this having occurred here? He did have substernal pain after entry, but it was low and associated with epigastric pain that occurred before his collapse and was probably due to the ulcer. The final electrocardiogram did not give any evidence of an acute process, although it was taken early and the patient was in shock. It is quite possible that he had a fresh infarction on the basis of pre-existing coronary disease and shock, but I cannot make the diagnosis on the available data.

It is difficult to evaluate the history of pain in the left leg before entry. Leg pain followed shortly by collapse and subsequent substernal and epigastric pain suggests a dissecting aneurysm. The lack of antecedent hypertension, the absence of severe chest or back pain and the short duration of the leg pain, however, are against this diagnosis. Usually in this condition the blood pressure remains high after dissection takes place, and a few cases present the picture of collapse without pain. On the whole, it is not likely that the patient had a dissecting aneurysm, and I prefer to leave the leg pain unexplained.

In summary, then, I should say this patient had severe gastrointestinal bleeding from a duodenal ulcer, which had probably eroded a sclerotic vessel. This alone can explain practically the whole picture. In addition, this patient had had clinical evidence of coronary heart disease for some time before the onset of the hemorrhage. The shock might have been responsible for a fresh myocardial infarction, but we have no clinical evidence for it.

DR. BENJAMIN CASTLEMAN: Dr. Williams, have you anything to add?

DR. CONGER WILLIAMS: Bundle-branch block often obscures changes in the electrocardiogram that have been produced by myocardial infarction. This is especially true in left bundle-branch block complicated by anterior myocardial infarction, because both conditions result in the loss of R waves over the precordium in Leads 1 to 4. Sometimes the diagnosis can be made by observing serial changes in the T waves. In this case the electrocardiogram does not help in making the diagnosis beyond indicating likely damage to the coronary circulation, which could have been chronic.

DR. CHESTER M. JONES: A high nonprotein nitrogen level is always interesting when associated with hemorrhage. It is important, however, not to lay too much stress on it. It was believed for some time that a high nonprotein nitrogen associated with hemorrhage, as Dr. Hurwitz has pointed out, is a bad prognostic sign. It actually does not work out that way. We have seen them even higher than this and the patients do well.

CLINICAL DIAGNOSES

Duodenal ulcer, bleeding.
Coronary heart disease.
Coronary thrombosis, recent?

DR. HURWITZ'S DIAGNOSES

Duodenal ulcer, with erosion of sclerotic vessel and hemorrhage.
Coronary heart disease, possibly with recent myocardial infarction.

ANATOMICAL DIAGNOSES

Peptic ulcer, bleeding.
Coronary thrombosis, recent and old.
Myocardial infarction, early and old.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy findings were almost exactly as Dr. Hurwitz predicted. This man had a peptic ulcer that bled before he came into the hospital. There was evidence that the bleeding had stopped while he was in the hospital, because we found no blood in the stomach. There was, however, old blood throughout the intestinal tract. The ulcer involved the pylorus.

The heart weighed 500 gm. and showed severe sclerosis of the coronary arteries, such as one sees in patients with angina. There was an old occlusion of the right coronary artery, which must have occurred years previously, with resultant scarring of the posterior wall of the left ventricle. In addition there was a terminal acute coronary thrombosis in the left descending artery and an associated acute anterior myocardial infarction. The myocardium showed acute degeneration of the fibers with polymorphonuclear infiltration, the picture that one sees in the early stages of myocardial infarction.

DR. JONES: Was there arteriosclerosis of the arteries in the leg, which caused the pain?

DR. CASTLEMAN: He had generalized arteriosclerosis. There were no thrombi in the leg veins and no evidence of pulmonary infarction.

There was also an extensive terminal bronchopneumonia, which must have occurred during the last day or two. The final blow was the coronary thrombosis.

PROPHYLAXIS AND TREATMENT OF GAS GANGRENE

THERE was a great deal of optimism in the earlier part of the war about the relatively small number of cases of gas gangrene encountered in the various theaters where the British and American troops were operating. It was assumed that the widespread use of sulfonamide drugs locally and systemically was responsible for the low morbidity from this disease. Experimental studies on the use of these drugs in the prevention of infection in animals also served to strengthen this belief. As the fighting moved into European countries, however, cases of gas-gangrene wound infection have become of increasing importance.¹ The problem has been re-

viewed by the Medical Research Council in England,² and has been brought up to date more recently in a supplement of the *Army Medical Department Bulletin* issued by the British War Office.³ Most of the significant clinical features of this condition are brought out in the latter publication, including some that are not widely appreciated. Recommendations are also given for the use of sulfonamides, penicillin and antitoxins, both for prophylaxis and for the treatment of established infections. These recommendations are based on recent experiences. A few excerpts from this bulletin and a résumé of the recommendations for treatment should be of interest to American readers.

Gas gangrene (clostridial myositis) may be defined as an infection of muscle with anaerobic bacteria of the genus *Clostridium* (particularly, *Cl. welchii*; *Cl. oedematiens* and *Cl. septicum*), whose common habitat is in soil and in the intestines of many animals. These organisms produce powerful toxins which, by their necrotizing action, favor the local spread of infection and by their wider dissemination in the body rapidly produce a profound and shock-like toxemia. The mere finding of anaerobic bacteria in a wound of muscle is of little significance; in warfare over cultivated ground almost every wound will be so contaminated. In contrast to simple contamination, anaerobic infection of muscle is a true myositis, always acute and usually diffuse. Sometimes only a single muscle is involved, but as a rule whole muscle-groups are affected. The disease is extraordinarily acute, and can rapidly spread through an entire limb. It is this fulminating course that makes gas gangrene so dangerous, and renders its early and accurate diagnosis of such extreme importance.

The essential features in its prevention and treatment are the elimination of the bacteria by excision of the infected tissues and by chemotherapeutic drugs, and the neutralization of the toxins by the administration of antitoxins. The disease has a very high death-rate unless it is promptly diagnosed and properly treated. . . .

Gas gangrene can follow quite trivial injuries, but is most likely to develop where the wound is associated with the following features: interference to the main blood-supply of a limb; extensive laceration of muscle, particularly of the thigh, buttock and shoulder; compound fractures of the long bones, especially [those] of the lower limb; foreign bodies, clothing or dirt carried deeply into the tissues; prolonged application of a tourniquet, or tight packing; application of a tight plaster or even a tight dressing to an inadequately excised wound; delay in surgical treatment.

In the prophylaxis of gas gangrene it is recommended that the following measures be taken as soon as possible after infliction of the wound: one ampule containing 22,500 units of polyvalent gas-gangrene antitoxin should be immediately injected intravenously or intramuscularly, preferably by the

former route, together with the usual dose of tetanus antitoxin* (if there is a delay of more than twenty-four hours, 45,000 units—two ampules—should be given); sulfonamide drugs should be administered both locally and systemically (the British also include a 1 per cent suspension of finely powdered proflavine in sulfathiazole for local use, but the efficacy of all local chemotherapy has been questioned by American surgeons); adequate wound excision should be provided (this is the most valuable prophylactic measure and should *never* be unnecessarily delayed).

In the treatment of established gas gangrene, surgical measures are combined with antitoxin and drugs, speed being essential to the saving of life. Preoperatively it is recommended that 67,500 units (three ampules) of polyvalent gas-gangrene antitoxin, or 112,500 units (five ampules) if toxemia is severe, be injected, preceded or accompanied by sulfathiazole (sulfadiazine would probably be preferred in this country). The soluble form of the latter may be given subcutaneously in salt solution or intravenously either in saline or in distilled water (it is important not to give sodium salts of sulfonamide drugs in the same apparatus used for blood transfusion since clots may form). Transfusions of whole blood are advised unless particularly contraindicated. Pentothal, followed by nitrous oxide and oxygen (40 to 50 per cent), is recommended for anesthesia. Anoxia should be guarded against during the inhalation anesthesia.

Removal of the infection by complete excision of the affected tissues is essential. Amputation is by no means a routine necessity, though frequently inevitable because of vascular damage. Where only one muscle or one group of muscles is involved, that muscle or muscle-group should be extirpated from origin to insertion. An ample exposure is necessary, and great care must be taken not to damage the blood supply to adjacent muscles. . . .

If radical surgery is impossible, either because of the site of the infection or the condition of the patient, the muscle-sheaths and muscles should be freely incised to relieve tension, and intensive therapy with antitoxin and drugs pursued. Where a limb is involved, it is frequently of advantage to apply a tourniquet proximal to the upper limits of infection in order to establish a "physiologic amputation."

For local chemotherapy it is recommended that the wound should be washed out if necessary with a 0.1

per cent solution of proflavine and then frosted with a sulfonamide.

Penicillin therapy is also recommended. The initial dose (30,000 units) is given intramuscularly on the operating table or earlier. This is followed either by a slow intravenous drip at the rate of 5000 or 6000 units per hour for twenty-four to forty-eight hours or by the injection of 15,000 units every three hours. Larger doses, up to 25,000 units every two hours, are probably preferable.

It is best to give blood transfusions and glucose-saline infusions by drip during the following twenty-four to forty-eight hours. Antitoxin administration is continued so long as signs of toxemia remain. A dose up to 60,000 units, repeated every four to six hours, may be given by intravenous injection in a small volume. The reduction in the pulse rate is taken as evidence of diminishing toxemia. Sulfonamide therapy is continued by parenteral route so long as necessary and orally thereafter, adequate amounts of alkali being given and the fluids being adjusted to avoid renal complications.

It is of interest that Dowdy, Sewell and Vincent,⁴ on the basis of extensive studies on gas-gangrene infection in experimental animals, have also come to the conclusion that all these measures should be used.

With respect to sulfonamide treatment, interest has recently centered about the German preparation known as Marfanil. This compound is 4-aminomethyl-benzene sulfonamide and is of particular interest because its action is said not to be inhibited by *p*-aminobenzoic acid, serum or pus. Although the compound has been known in this country for at least three years, it did not receive much attention until it was found by the British among German supplies captured in North Africa.^{5, 6} Marfanil is highly soluble and, in preliminary clinical trials, appears to be somewhat more effective than the earlier preparations for local use in the prevention and treatment of anaerobic wound infections. These findings have not been widely confirmed, nor is the toxicity of the compound well understood. When given by mouth it apparently is no more effective than sulfanilamide. Further studies of this compound and related ones would be of interest, but since the use of penicillin is now occupy-

*The British Medical Corps still recommends the routine prophylactic use of tetanus antitoxin in spite of the fact that many British soldiers have been immunized with tetanus toxoid.

ing the attention of most workers, the clinical trial of these chemicals outside Germany will undoubtedly be delayed.

That considerable difference of opinion exists concerning the prevention and treatment of gas gangrene is evidenced by a recent directive issued by the War Department.⁷ This bulletin does not recommend the prophylactic use of gas-gangrene antitoxin and questions its therapeutic value, except the employment of trivalent serum, containing *Cl. oedematiens* antitoxin, in cases of the "wet" type of infection. Furthermore, although the administration of sulfonamides and penicillin is advised, it is stated that any form of chemotherapy probably does little more than to prevent the spread of infection. Chief reliance is placed on proper surgical management.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

COX — Oscar F. Cox, M.D., of Brookline, died June 3. He was in his fifty-eighth year.

Dr. Cox received his degree from Tufts College Medical School in 1914. During World War I he served with the Army overseas. He was a member of the staff of Massachusetts Memorial Hospitals and the Boston Dispensary. He was chief of the Genitourinary Clinic at Boston Dispensary, director of the Division of Genitoinfectious Diseases at Massachusetts Memorial Hospitals, chairman of the Advisory Committee on Venereal-Disease Control of the Massachusetts Department of Public Health, director of the Massachusetts Society for Social Hygiene, secretary of the American Neisserian Medical Society and a member of the Subcommittee on Venereal Diseases of the National Research Council. He was clinical professor of urology at Tufts College Medical School and associate professor of medicine at Boston University School of Medicine. He was a fellow of the American Medical Association.

His widow, his mother, a son and a daughter survive.

WHELAN — Charles Whelan, M.D., of North Cohasset, died May 29. He was in his sixty-ninth year.

Dr. Whelan received his degree from Tufts College Medical School in 1905. He was among the first sixteen of its graduates to enlist in the medical corps during World War I, and organized the x-ray department at the debarkation hospital in New York where 38,000 casualties were treated. He had been chief radiologist at the Quincy City Hospital for several years and was consultant in roentgenology at the Carney Hospital and New England Hospital for Women and Children. He was a member of the American Board of Radiology, the New England Roentgen Ray Society and the Radiological Society of North America and a fellow of the American Medical Association.

His widow and two daughters survive.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

SMITH — Henry O. Smith, M.D., a lifelong practitioner in Hudson, died suddenly on May 14, 1945, just after he had completed a visit at a patient's home in Londonderry. He was born in Hudson on December 18, 1864, graduated from Dartmouth College in 1886 and received his medical degree from Bellevue Hospital Medical College in 1887. He started practice in Hudson in 1888 and for the past fifty-seven years had continued the practice of medicine there.

Dr. Smith was a member of the county and state medical societies, having served as speaker of the House of Delegates of the New Hampshire Medical Society in 1925-1926, as president of the state society in 1929-1930 and as a member of the Board of Trustees from 1933 to 1942, when he was elected trustee emeritus.

He was presented the Gold Medal of the state society for fifty years' membership at the meeting in 1938, and that same year he was honored at a testimonial dinner by his townspeople, who presented him with a suitably engraved watch "in appreciation of fifty years of faithful service."

Dr. Smith was a member of the Hudson Baptist Church, Hudson Grange, New Hampshire Historical Society and New England Historical Genealogical Society.

A number of years ago he wrote the history of the Baptist Church of Hudson, and in 1927 he compiled and published *The Early Story of Hudson, New Hampshire*. He served as chairman of the committee to formulate plans for the observance of the one hundred and fiftieth anniversary of the New Hampshire Medical Society. Along with this work, he edited, amended and brought up to 1941 *The Story of the New Hampshire Medical Society*, which originally had been written, including the facts up to 1854, by Dr. L. Bartlett How. This was printed and distributed to the members of the state society.

Dr. Smith is survived by one son, Dr. Deering G. Smith, of Nashua, two grandchildren and one sister.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

NEW TYPE STANDARD DEATH CERTIFICATES

Under the General Laws, Chapter 46, Section 10, a physician or officer furnishing a death certificate shall insert a recital and specify the war, if the deceased is a veteran.

Secretary of State Frederic W. Cook has directed that there be printed on the reverse side of the Standard Death Certificate the following:

Date of entering military service
Date of discharge
Rank, rating
Organization, outfit and service number

Dr. Vlado A. Getting, commissioner of the Massachusetts Department of Public Health, has called to the attention of the boards of health of the Commonwealth that the Standard Death Certificate is not complete until the data called for, as to the veteran, is recorded thereon.

PENICILLIN FOR TREATMENT OF GONORRHEA

Penicillin is now available without cost to all physicians of the Commonwealth for the treatment of gonorrhea.

Physicians are requested to submit a report of the case of gonorrhea on the form supplied by the Massachusetts Department of Public Health for that purpose. A supply of these forms will be sent on request.

Two bottles of penicillin, each containing 100,000 Oxford units, may be requested for each case. Directions for administration of the penicillin are enclosed with each bottle.

Points of distribution outside of the Metropolitan Boston Area are located at the State Co-operating Venereal Disease Clinics. Otherwise the penicillin request should be made to the Antitoxin and Vaccine Laboratory, 375 South Street, Jamaica Plain. Requests should be submitted to the nearest point of distribution.

For further information call the Division of Venereal Diseases, Department of Public Health, State House, Boston (CAPitol 4600).

MISCELLANY

NEW DEAN AT DARTMOUTH MEDICAL SCHOOL

Dr. Ernest M. Hopkins, president of Dartmouth College, recently announced the appointment of Dr. Rolf C. Syvertsen as dean of the Dartmouth Medical School, effective with the start of the new academic year on July 1. Dr. Syvertsen succeeds Dr. John P. Bowler, who, although he has resigned his administrative post, will continue on the medical faculty as professor of surgery.

Dr. Syvertsen, a graduate of Dartmouth in the class of 1918, will remain on the faculty as professor of anatomy. He was named assistant dean of the medical school last June, after filling the position of secretary for twenty years. He joined the medical school faculty in 1923, after serving as assistant in biology and zoology in the college for two years. He obtained his M.D. degree from Rush Medical College in 1936 and has held his professorship in anatomy since 1938.

NEED FOR RED CROSS HOSPITAL WORKERS

Recognition of the outstanding contribution social workers are making in healing the emotional wounds of war has resulted in an unprecedented demand for their services.

The American Red Cross needs 750 trained social workers at once for supervisory, administrative and staff positions in military hospitals, largely in the United States. The wounded and disabled returned to this country for further treatment need the skilled help of trained and experienced social workers. New and higher salary schedules, ranging from \$170 to \$350 monthly, depending on education, experience and job assignment, have been adopted by the Red Cross. Quarters are provided, and if not available at the hospital, an additional allowance is made. Free uniforms are also issued.

In addition, 1650 untrained and partially trained workers are needed by the Red Cross to serve in the area of social case work under professional guidance. Salaries range from \$140 to \$200 monthly. The hospital program also calls for 600 recreation workers at monthly salaries of \$150 to \$325.

The project for which these 3000 hospital workers are being recruited will continue for many years. Despite this, however, employment will be offered by the Red Cross to any qualified worker willing to serve a minimum of one year. Applications should be filed at the nearest of the Red Cross area offices, which are as follows: North Atlantic Area, 300 Fourth Avenue, New York 10, New York; Eastern Area, 615 North St. Asaph Street, Alexandria, Virginia; Southeastern Area, 230 Spring Street, N. W., Atlantic 3, Georgia; Midwest Area, 1709 Washington Avenue, St. Louis 3, Missouri; and Pacific Area, Civic Auditorium, Larkin and Grove streets, San Francisco 1, California.

NOTES

At its meeting on May 18, the New England Roentgen Ray Society paid honor to its distinguished member, Dr. George W. Holmes, pioneer radiologist and teacher, by establishing an annual lecture to be known as the George W. Holmes Annual Lecture.

Dr. Wesley Bourne of McGill University, Montreal, Canada, will deliver the first of the annual series of Osler Lectures of the University of Vermont College of Medicine at the Fleming Museum, Burlington, Vermont, July 5 and 6, at 8 p.m., and July 7, at 10 a.m. His subject will be "Anesthesia: Some contemplations."

CORRESPONDENCE

DEPRIVATION OF LICENSES

To the Editor: At a meeting of the Board of Registration in Medicine held June 6, the Board took the following actions:

To revoke the license of Dr. Julius Shubert, 45 McLean Street, Boston, to practice medicine for not less than three years because of gross misconduct in the practice of his profession as shown by collusion.

To suspend the license of Dr. Pasquale E. Massa, 232 Hanover Street, Boston, to practice medicine for a period of one year because of gross misconduct in the practice of his profession as shown by violation of the narcotic law and conspiracy to violate this law.

H. QUIMBY GALLUPE, M.D., *Secretary*
Board of Registration in Medicine

State House
Boston

RESTORATION OF LICENSE

To the Editor: At a meeting of the Board of Registration in Medicine held June 6, the Board voted to restore the license to practice medicine in this Commonwealth of Dr. Ralph K. Coleman, 25 Fessenden Road, Arlington (formerly of Lowell).

H. QUIMBY GALLUPE, M.D., *Secretary*
Board of Registration in Medicine

State House
Boston

THE FLINT FAMILY

To the Editor: In a letter published in the May 3 issue of the *Journal*, I made the suggestion that the Austin Flint referred to in the anecdote by the Reverend George Allen might have been a connection or even an ancestor of the two famous Austin Flints of New York City.

I have since learned that the latter is true and that Austin Flint, of Leicester, was the grandfather of the younger Austin Flint of New York City. The line is as follows:

Dr. Edward Flint, of Shrewsbury

↓
Dr. Austin Flint, of Leicester (1760-1850)

↓
Dr. Joseph H. Flint, of Leicester (1786-1846)

↓
Dr. Austin Flint, of New York (1812-1886)

↓
Dr. Austin Flint, of New York (1836-1915)

There were at least eight physicians in this family, and several of them lived to be ninety years of age, including Edward Flint, of Leicester, also a son of Austin Flint of Leicester.

Shrewsbury, Massachusetts

A. E. P. Rockwell, M.D.

GIFTS OF MEDICAL BOOKS AND JOURNALS URGENTLY NEEDED FOR CZECHOSLOVAKIA

To the Editor: The Czechoslovak medical libraries and laboratories have been plundered by the Germans, and their research material wantonly destroyed. For the past six years no knowledge of the remarkable progress of American medicine has reached Czechoslovakia to benefit its people. Therefore a complete library of recent American medical literature is needed at the Charles University in Prague, as well as other universities and institutions. All publications since 1938 will be particularly welcome.

Any person or organization wishing to contribute is asked to communicate with the Secretary, American Friends of Czechoslovakia, 355 Boylston Street, Boston 16, or with the Masaryk Institute, 8 West 40th Street, New York City 18, which as a depository for Charles University in Prague receives and files donated publications.

MRS. J. PHILIP LANE, Secretary
American Friends of Czechoslovakia

353 Boylston Street
Boston 16

BOOK REVIEWS

The Religious and Philosophical Aspects of Van Helmont's Science and Medicine. By Walter Pagel. 4°, paper, 44 pp. Baltimore: The Johns Hopkins Press, 1944. \$1.00. (Supplements to the Bulletin of the History of Medicine. Editor: Henry E. Sigerist, M.D.)

This book, written by an experienced historian of medicine, makes a valuable contribution to the further understanding of that great medical figure Johannes Baptista van Helmont, the *per ignem Philosophus*. Students of medicine must come to this book prepared for a hard intellectual feast, for it is not easy reading; they will, however, be repaid for their effort.

The research activities of van Helmont show a close interdependence of religious belief, philosophical outlook and scientific achievement. Modern students would do well to pry themselves free occasionally from the present-day sharp cleavage between science and religion to read of the works of a scientist who lived in an atmosphere where religious conviction constituted a strong incentive to scientific work, where only the God-fearing believed they could attain the art of prolonging life and where religious pragmatism was the driving force to medicine as the ultimate aim of science, all of which brings to mind the names of Pasteur, Charles Bell and Darwin. The author succeeds in showing why van Helmont, who introduced the concept of "gas," who designed scientific instruments, who used the balance in scientific quantitative experiments, who discovered acid as the principle of digestion in the stomach and laid the foundations for biochemistry and pathology, could deprecate sheer reasoning (*Ratio*) as a means for the investigation of life.

The book is provocative and should be in all medical libraries.

The Gastro-Intestinal Tract: A handbook of roentgen diagnosis. By Fred J. Hodges, M.D. 8°, cloth, 320 pp., with 130 plates. Chicago: The Year Book Publishers, Incorporated, 1944. \$5.50.

This is one of a series of books on roentgen diagnosis. It is short but represents a careful summary of the present knowledge of the gastrointestinal tract as determined by roentgenologic methods. The descriptive text shown on the left-hand pages is conveniently placed opposite excellent reproductions on the right. The text is brief, but within it is a large amount of useful information. There is a short but well-chosen bibliography at the close of each chapter. It should be of value to the student and also to the practitioner.

Fertility in Women: Causes, diagnosis and treatment of impaired fertility. By Samuel L. Sieglar, M.D. With a foreword by Robert L. Dickinson, M.D. 8°, cloth, 450 pp., with 194 illustrations. Philadelphia: J. B. Lippincott Company, 1944. \$4.50.

This book is divided into eleven chapters. The first deals with the incidence of barrenness and the

evaluating and investigating fertility. The history subject matter of the third chapter, which also discusses causes of sterility, acquired and inherent, and points the way to the detailed investigation of the subject. The physical examination comprises the fourth chapter, which brings special details in examination. In this chapter the illustrations are profuse, well chosen and well done. The physiology of the female sex cycle, taken up in the fifth chapter, presents an extensive review of the literature, together with the author's own views. The illustrations here, several in number together with numerous charts, make of the subject a reference work. In chapter six the cervical and vaginal secretions in relation to spermatozoa are discussed. In chapter seven methods of determining tubal patency and tubal occlusion are discussed and illustrated. The contention is made regardless of all the fallacies and objections to tubal ligation and hysterosalpingography, there is no doubting the efficacy of both procedures from the diagnostic and therapeutic standpoints in sterility and fertility; chapter eight treatment is elaborated. It deals with endocrine factor, genital hygiene, control of venereal diseases, premarital advice and examination, medical advice on fertility control, general treatment and specific treatment. The chapter presents a rather complete review of the treatment of ovarian imbalance — endocrine, irradiation and surgery. The treatment of faulty reception of the spermatozoa, many modalities, is reviewed in the tenth chapter, and artificial insemination is discussed. The author's views on the subject are sound and conservative, he being of the opinion that only a small percentage of the patients who apply for so radical a procedure. The concluding chapter deals with abortion in all its phases.

This well illustrated book presents an extensive bibliography, which in itself is a valuable contribution to the study. It should serve not only as a textbook to the student of fertility but also as an important work of reference.

NOTICES

ANNOUNCEMENT

Dr. Joseph Igersheimer announces the removal of his office from 636 Beacon Street to 483 Beacon Street, Boston.

MEDICOLEGAL CONFERENCE AND SEMINAR

During the first week in October the departments of medicine of the medical schools of Harvard, Tufts and Boston University, in association with the Massachusetts Medical Legal Society, will present a six-day program of lectures, conferences and demonstrations having to do with the investigation of deaths in the interests of public safety. Attendance during five of the six days of the course will be limited to fifteen persons who have registered in advance. On one day (October 3) the program will be open to any physician, police official or senior medical student who may wish to attend. Further information may be obtained from the secretary of the Massachusetts Medico-Legal Society, 55 Shattuck Street, Boston 15.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JULY 5

FRIDAY, JULY 6
*9.00-10.00 a.m. Medical clinic. Isolation Amphitheater, Child Hospital.
10.50 a.m. Postgraduate clinic in dermatology and syphilis. Amphitheater, Mallory Building. Boston City Hospital.

MONDAY, JULY 9
*12.00 m.-1.00 p.m. Clinicopathological conference. Peter I. Brigham Hospital.

TUESDAY, JULY 10
*9.00-10.00 a.m. Medical clinic. Infants' Hospital.
*12.15-1.15 p.m. Clinicoroentgenological conference. Peter I. Brigham Hospital.

WEDNESDAY, JULY 11
*12.00 m. Clinicopathological conference. Children's Hospital.

*Open to the medical profession.

SEPTEMBER 17. American Public Health Association. Page 752, in issue of November 30.
OCTOBER 1-6. Medicolegal Conference and Seminar. Notice elsewhere.
